In the adult individual, the normal micturition reflex is mediated by a spinobulbospinal pathway, which passes through relay centers in the brain (Figure 1). In infants, the central pathways seem to be organized as on-off switching circuits, but after the age of four to six years, voiding is initiated voluntarily by the cerebral cortex [de Groat et al., 1999]. Studies in humans and animals have identified areas in the brainstem and diencephalon that are specifically implicated in micturition control, including Barrington’s nucleus or the pontine micturition center (PMC) in the dorsomedial pontine tegmentum [Griffiths, 2004., Fowler et al., 2008]. These structures directly excite bladder motoneurons and indirectly inhibit urethral sphincter motoneurons via inhibitory interneurons in the medial sacral cord. The periaqueudctal grey (PAG) receives bladder filling information, and the pre-optic area of the hypothalamus is probably involved in the initiation of micturition. According to PET-scan and functional imaging studies in humans, these supraspinal regions are active during micturition [Griffiths, 2004; Blok et al., 1998; Nour et al., 2000; Athwal et al., 2001; Griffiths et al., 2007; Hruz et al., 2008; Mehnert et al., 2008; Tadic et al., 2008].

III. PERIPHERAL NERVOUS CONTROL

Bladder emptying and urine storage involve a complex pattern of efferent and afferent signalling in parasympathetic, sympathetic, somatic, and sensory nerves (Figures 2-4). These nerves are parts of reflex pathways, which either keep the bladder in a relaxed state, enabling urine storage at low intravesical pressure, or which initiate micturition by relaxing the outflow region and contracting the bladder smooth muscle. Contraction of the detrusor smooth muscle and relaxation of the outflow region result from activation of parasympathetic neurones located in the sacral parasympathetic nucleus (SPN) in the spinal cord at the level of S2-S4 [de Groat et al., 1993]. The postganglionic neurones in the pelvic nerve mediate the excitatory input to the human detrusor smooth muscle by releasing acetylcholine (ACh) acting on muscarinic receptors. However, an atropine-resistant component has been demonstrated, particularly in functionally and morphologically altered human bladder tissue (see below). The pelvic nerve also conveys parasympathetic fibres to the outflow region and the urethra. These fibres exert an inhibitory effect and thereby relax the outflow region. This is mediated partly by release of nitric oxide [Andersson and Persson, 1993], although other transmitters might be involved [Bridgewater and Brading, 1993; Hashimoto et al., 1993; Werkström et al., 1995].

Most of the sympathetic innervation of the bladder and urethra originates from the intermediolateral nuclei in the thoraco-lumbar region (T10-L2) of the spinal cord. The axons travel either through the inferior mesenteric ganglia and the hypogastric nerve, or pass through the paravertebral chain and enter the pelvic nerve. Thus, sympathetic signals are conveyed in both the hypogastric and pelvic nerves [Lincoln and Burnstock, 1993].

The predominant effects of the sympathetic innervation of the lower urinary tract are inhibition of the parasympathetic pathways at spinal and ganglion levels (demonstrated in animals), and mediation of contraction of the bladder base and the urethra (shown in animals and man, see Andersson, 1993). However, the adrenergic innervation of the bladder body is believed to inactivate the contractile mechanisms in the detrusor directly. Noradrenaline (norepinephrine) is released in response to electrical stimulation of detrusor tissues in vitro, and the normal response of detrusor tissues to released noradrenaline is relaxation [Andersson, 1993].

Figure 1: Components of the micturition reflex.
Figure 2: Activity in the micturition reflex during storage. The pontine micturition center is inhibited by impulses from the prefrontal cortex, afferent impulses unable to initiate micturition. Activities in the hypogastric and pudendal nerves keep the bladder relaxed and the outflow region contracted.

Figure 3: Activity in the micturition reflex during voluntary voiding. The inhibitory impulses from the prefrontal cortex pontine micturition center are removed and afferent impulses are able to initiate micturition. Activities in the hypogastric and pudendal nerves are inhibited, the outflow region is relaxed, and the bladder is contracted by the activity in the pelvic nerve.

Figure 4: Detrusor overactivity. Despite the inhibitory impulses from the prefrontal to the cortex pontine micturition center the enhanced (?) afferent impulses are able to initiate micturition.
The somatic innervation of the urethral rhabdosphincter and of some perineal muscles (for example compressor urethrae and urethrovaginal sphincter), is provided by the pudendal nerve. These fibers originate from sphincter motor neurons located in the ventral horn of the sacral spinal cord (levels S2-S4) in a region called Onuf’s (Onufrowicz’s) nucleus).

Most of the sensory innervation of the bladder and urethra reaches the spinal cord via the pelvic nerve and dorsal root ganglia. In addition, some afferents travel in the hypogastric nerve. The sensory nerves of the striated muscle in the rhabdosphincter travel in the pudendal nerve to the sacral region of the spinal cord [Lincoln and Burnstock, 1993]. The most important afferents for the micturition process are myelinated Aδ-fibres and unmyelinated C-fibres travelling in the pelvic nerve to the sacral spinal cord, conveying information from receptors in the bladder wall to the spinal cord. The Aδ-fibres respond to passive distension and active contraction, thus conveying information about bladder filling [Janig and Morrison, 1986]. C-fibres have a high mechanical threshold and respond primarily to chemical irritation of the bladder mucosa [Habler et al., 1990] or cold [Fall et al., 1990]. Following chemical irritation, the C-fibre afferents exhibit spontaneous firing when the bladder is empty and increased firing during bladder distension [Habler et al., 1990]. These fibres are normally inactive and are therefore termed "silent fibres".

IV. PATHOGENESIS OF BLADDER CONTROL DISORDERS

As pointed out previously, bladder control disorders can be divided into two general categories: disorders of filling/storage and disorders of voiding [Wein, 2007]. Storage problems can occur as a result of weakness or anatomical defects in the urethral outlet, causing stress urinary incontinence. Failure to store also occurs if the bladder is overactive, as in the overactive bladder (OAB) syndrome. The prevalence varies with the criteria used for diagnosis, but according to Irwin et al. (2006), using the ICS definition of 2002 [Abrams et al., 2002], the overall prevalence of OAB, based on computer assisted telephone interviews (the EPIC study) was 11.8%; rates were similar in men and women and increased with age [Irwin et al., 2006]. A similar study based on a cross Canada telephone survey found the prevalence of OAB to be 13 % in men and 14.7% in women [Herschorn et al., 2008]. OAB (symptomatic diagnosis) is often assumed to be caused by detrusor overactivity (DO; urodynamic diagnosis), even if this does not always seem to be the case [Hyman et al., 2001; Digesu et al., 2003; Hashim and Abrams, 2004; Aschkenazi et al., 2007].

DO/OAB can occur as a result of sensitization of afferent nerve terminals in the bladder or outlet region, changes of the bladder smooth muscle secondary to denervation, or consequent upon damage to the central nervous system (CNS) inhibitory pathways (Figure 5), as can be seen in various neurological disorders, such as multiple sclerosis, cerebrovascular disease, Parkinson’s disease, brain tumors, and spinal cord injury [Ouslander, 2004]. Urinary retention and overflow incontinence can be observed in patients with urethral outlet obstruction (e.g. prostate enlargement), decreased detrusor contractility, or both), neural injury, and/or diseases that damage nerves (e.g. diabetes mellitus), or in those who are taking drugs that depress the neural control of the bladder or bladder smooth muscle directly [Wein, 2007].
V. BLADDER CONTRACTION

Normal bladder contraction in humans is mediated mainly through stimulation of muscarinic receptors in the detrusor muscle. Atropine resistance, i.e. contraction of isolated bladder muscle in response to electrical nerve stimulation after pretreatment with atropine, has been demonstrated in most animal species, but seems to be of little importance in normal human bladder muscle [Andersson, 1993; Bayliss et al., 1999]. However, atropine-resistant (non-adrenergic, non-cholinergic: NANC) contractions have been reported in normal human detrusor and may be caused mainly by adenosine triphosphate (ATP) [Andersson, 1993; Bayliss et al., 1999, Andersson and Wein, 2004; Kennedy et al., 2007]. ATP acts on two families of purinergic receptors: an ion channel family (P2X) and a G-protein-coupled receptor family (P2Y). Seven P2X subtypes and eight P2Y subtypes have been identified. In several species (rabbit, cat, rat, and human), various studies suggested that multiple purinergic excitatory receptors are present in the bladder [de Groat and Yoshimura, 2001]. Immunohistochemical experiments with specific antibodies for different P2X receptors showed that P2X1 receptors are the dominant subtype in membranes of rat detrusor muscle and vascular smooth muscle in the bladder. Excitatory receptors for ATP are present in parasympathetic ganglia, afferent nerve terminals, and urothelial cells [de Groat and Yoshimura, 2001]. P2X3 receptors, which have been identified in small-diameter afferent neurons in dorsal root ganglia, have also been detected immunohistochemically in the wall of the bladder and ureter in a suburothelial plexus of afferent nerves. In P2X3 knockout mice, afferent activity induced by bladder distension was significantly reduced [Cockayne et al., 2000; Ford et al., 2006; Ruggieri et al., 2006]. These data indicate that purinergic receptors are involved in mechanosensory signaling in the nonprimate mammalian bladder.

A significant degree of atropine resistance may exist in morphologically and/or functionally changed bladders, and has been reported to occur in hypertrophic bladders [Stjögren et al., 1982], interstitial cystitis [Palea et al., 1993], neurogenic bladders [Wammack et al., 1995], and in the aging bladder [Yoshida et al., 2001]. The importance of the NANC component to detrusor contraction in vivo, normally, and in different micturition disorders, remains to be established.

VI. MUSCARINIC RECEPTORS

The neurotransmitter ACh acts on two classes of receptors, the nicotinic and the muscarinic receptors. While the former play a role in the signal transduction between neurones or between neurones and skeletal muscle (e.g. in the distal urethra), the signal transduction between parasympathetic nerves and smooth muscle of the detrusor involves muscarinic receptors [Abrams and Andersson, 2007]. Importantly, the endogenous muscarinic receptor agonist ACh is not necessarily derived only from parasympathetic nerves in the urinary bladder, but can also be formed and released non-neuronally by the urothelium [Bschleiper et al., 2007; Mansfield et al., 2005; Zarghooni et al., 2007]. Five subtypes of muscarinic receptors have been cloned in humans and other mammalian species, which are designated M1-5 [Caulfield and Birdsal 1998]. Based upon structural criteria and shared preferred signal transduction pathways, the subtypes can be grouped into M1, M3 and M5 on the one hand and the subtypes M2 and M4 on the other. The former prototypically couple via pertussis toxin-insensitive Gq proteins to stimulation of a phospholipase C followed by elevation of intracellular calcium and activation of a protein kinase C, whereas the latter prototypically couple via pertussis toxin-sensitive Gt proteins to inhibition of adenyl cyclase and modulation of several ion channels [Caulfield and Birdsal 1998]. While sensitive molecular techniques such as reverse transcriptase polymerase chain reaction can detect mRNA for all five subtypes in the mammalian bladder [Abrams et al., 2006: Hegde, 2006], studies at the protein level, e.g. based upon radioligand binding, have typically detected only M2 and M3 receptors, with the former dominating quantitatively [Abrams et al., 2006: Hegde, 2006]. Functional studies have implicated an involvement of M1 and M4 receptors (alongside with M2 receptors) in the prejunctional regulation of neurotransmitter release in the mammalian bladder, with M1 receptors enhancing and M2 and M4 receptors inhibiting ACh release [Braverman et al., 1998; D’Agostini et al., 1997]. However, most muscarinic receptors in the urinary bladder are located on smooth muscle and urothelial cells.

Apparently, most muscarinic receptors in the bladder are found on the smooth muscle cells of the detrusor. While the detrusor expresses far more M2 than M3 receptors, it appears that detrusor contraction under physiological conditions is largely if not exclusively mediated by the M3 receptor [Hegde et al., 1997; Chess-Williams et al., 2001; Fetscher et al., 2002; Kories et al., 2003; Schneider et al., 2004a, b]. Studies in knock-out mice confirm this conclusion [Matsui et al., 200; 2002; Stengel et al., 2002; Ehler et al., 2007]. Under physiological conditions M2 receptor-selective stimulation causes little contraction [Schneider et al., 2005a], but rather appears to act mainly by inhibiting β-adrenoceptor-mediated detrusor relaxation [Hegde et al., 1997; Ehler et al., 2007; Matsui et al., 2003]. It has been proposed that M2 receptors can also directly elicit bladder contraction under pathological conditions [Braverman et al., 1998; 2002; 2003; 2006; Pontari et al., 2003], but such observations have not
been confirmed by other investigators using distinct methodological approaches [Schneider et al., 2005a; b].

Based upon the prototypical signalling pathway of M₃ receptors [Cauldfield and Birdsall, 1998] and the presence of phospholipase C stimulation by muscarinic agonists in the bladder [Kories et al., 2003; Schneider et al., 2005a] it had originally been believed that muscarinic receptor-mediated contraction is largely mediated by an activation of phospholipase C [Ouslander, 2004]. While some earlier data had supported this concept, it now appears clear that, at least in rat, mice and humans, muscarinic receptor-mediated bladder contraction occurs largely independent of phospholipase C [Schneider et al., 2004; Wegener et al., 2004; Frazier et al., 2007]. Rather, alternative signalling pathways such as opening of L-type calcium channels and activation of a rho-kinase (Figure 6) appear to contribute to muscarinic receptor-mediated bladder contraction in a major way [Frazier et al., 2008].

More recently, muscarinic receptors have also been identified in the urothelium [Chess-Williams, 2002; Kumar et al., 2005]. Similarly to the findings in bladder smooth muscle, the muscarinic receptors in the urothelium mainly belong to the M₂ and M₃ subtype, with the former dominating quantitatively [Mansfield et al., 2005; Bschleiper et al., 2007]. At present the functional role of muscarinic receptors in the urothelium has largely been studied indirectly, i.e. by investigating the effects of urothelium removal or of administration of pharmacological inhibitors. These data indicate that muscarinic stimulation of the urothelium causes release of an as yet unidentified factor which inhibits detrusor contraction [Hawthorn et al., 2000; Wuest et al., 2005; Sadananda et al., 2008]. Some data indicate that muscarinic receptors in the urothelium may partly act by releasing nitric oxide (NO) [Andersson et al., 2008a]. Thus, it appears that muscarinic receptors in the urothelium also contribute to the regulation of overall bladder function but their specific roles in health and disease have not been fully established [Andersson et al., 2008b].

Based upon the involvement of muscarinic receptors in physiological voiding contractions of the bladder, numerous studies have explored whether an overactivity of the muscarinic system may play a causative role in bladder dysfunction. This could involve, e.g., an enhanced expression of such receptors and/or an increased functional responsiveness. In vitro, an increased sensitivity to muscarinic receptor stimulation was found in both idiopathic and neurogenic overactive human detrusors (Stevens et al. 2006). However, according to Michel and Barendrecht [2008] the overall balance of available studies suggests that the muscarinic receptor system is not hyperactive under conditions of DO and, if anything, can be even hypoactive [Michel and Barendrecht, 2008]. This does not exclude a contribution to DO of ACh and muscarinic receptor stimulation during bladder filling (see below). It appears that the contribution of muscarinic mechanisms to the overall regulation of bladder contractility decreases in favour of non-cholinergic mechanisms under pathological conditions [Yoshida et al., 2001; 2008; Rapp et al 2005]. These observations may help to explain the moderate efficacy of muscarinic receptor antagonists relative to placebo in controlled clinical studies [Herbison et al., 2003; Chapple et al., 2005; 2008; Novara et al., 2008; Shamiyan et al., 2008].

![Figure 6](image-url)
It has been estimated that more than 50 million people in the developed world are affected by urinary incontinence, and an abundance of drugs has been used for treatment (Table 2). As underlined by several other subcommittees, drugs may be efficacious in some patients, but they do have side effects, and frequently are not continued indefinitely. Hence it would be worth considering them as an adjunct to conservative therapy.

**I. ANTIMUSCARINIC (ANTICHOLINERGIC) DRUGS**

**Mechanism of action.** Antimuscarinics block, more or less selectively, muscarinic receptors [Abrams and Andersson, 2007]. The common view is that in OAB/DO, the drugs act by blocking the muscarinic receptors on the detrusor muscle, which are stimulated by ACh, released from activated cholinergic (parasympathetic) nerves. Thereby, they decrease the ability of the bladder to contract. However, antimuscarinic drugs act mainly during the storage phase, decreasing urgency and increasing bladder capacity, and during this phase, there is normally no parasympathetic input to the lower urinary tract [Andersson, 2004]. Furthermore, antimuscarinics are usually competitive antagonists. This implies that when there is a massive release of ACh, as during micturition, the effects of the drugs should be decreased, otherwise the reduced ability of the detrusor to contract would eventually lead to urinary retention. Undeniably, high doses of antimuscarinics can produce urinary retention in humans, but in the dose range used for beneficial effects in OAB/DO, there is little evidence for a significant reduction of the voiding contraction [Finney et al., 2006; Figure 7]. However, there is good experimental evidence that the drugs act during the storage phase by decreasing the activity in afferent nerves (both C- and Aδ-fibres) from the bladder [De Laet et al., 2006; Ijima et al., 2007].

As mentioned previously, muscarinic receptors are found on bladder urothelial cells where their density can be even higher than in detrusor muscle. The role of the urothelium in bladder activation has attracted much interest [Andersson, 2002; Birder and de Groat, 2007], but whether the muscarinic receptors on urothelial cells can influence micturition has not yet been established. Yoshida and colleagues [2004; 2006; 2008] found that there is basal ACh release in human bladder. This release was resistant to tetrodotoxin and much diminished when the urothelium was removed; thus, the released ACh was probably of non-neuronal origin and, at least partly, generated by the urothelium. There is also indirect clinical evidence for release of ACh during bladder filling. Smith and co-workers [1974] found that in patients with recent spinal-cord injury, inhibition of ACh breakdown by use of cholinesterase inhibitors could increase resting tone and induce rhythmic contractions in the bladder. Yossepowitch and colleagues [2001] inhibited ACh breakdown with edrophonium in a series of patients with disturbed voiding or urinary incontinence. They found a significant change in sensation and decreased bladder capacity, induction or amplification of involuntary detrusor contractions, or significantly decreased detrusor compliance in 78% of the patients with the symptom pattern of overactive bladder, but in no patients without specific complaints suggesting DO. Thus, during the storage phase, ACh and ATP may be released from both neuronal and non-neuronal sources (eg, the urothelium) and directly or indirectly

---

**Figure 7 : Rationale for use of antimuscarinics for treatment of OAB/DO. Blockade of muscarinic receptors at both detrusor and non-detrusor sites may prevent OAB symptoms and DO without depressing the contraction during voiding.**

(by increasing detrusor smooth muscle tone, Figures 8, 9 and 10) excite afferent nerves in the suburothelium and within the detrusor. These mechanisms may be important in the pathophysiology of OAB/DO and represent possible targets for antimuscarinic drugs.

**Pharmacologic properties.** Generally, antimuscarinics can be divided into tertiary and quaternary amines [Guay, 2003, Abrams and Andersson, 2007]. They differ with regards to lipophilicity, molecular charge, and even molecular size, tertiary compounds generally having higher lipophilicity and molecular charge than quaternary agents. Atropine, darifenacin, fesoterodine (and its active metabolite 5-hydroxymethyl-tolterodine), oxybutynin, propiverine, solifenacin, and tolterodine, are tertiary amines. They are generally well absorbed from the gastrointestinal tract and should theoretically be able to pass into the CNS, dependent on their individual physicochemical properties. High lipophilicity, small molecular size, and less charge will increase the possibilities to pass the blood brain barrier, but in some cases, such as trospium, darifenacin, and fesoterodine, that is compensated by active transport out of the CNS by the product of the MDR1 gene (P-glycoprotein, see Table 3). Quaternary ammonium compounds, like propantheline and trospium, are not well absorbed, pass into the CNS to a limited extent, and have a low incidence of CNS side effects [Guay 2003]. They still produce well-known peripheral antimuscarinic side effects, such as accommodation paralysis, constipation, tachycardia, and dryness of mouth.

Many antimuscarinics are metabolized by the P450 enzyme system to active and/or inactive metabolites [Guay 2003]. The most commonly involved P450 enzymes are CYP2D6, and CYP3A4. The metabolic conversion creates a risk for drug-drug interactions, resulting in either reduced (enzyme induction) or increased (enzyme inhibition, substrate competition) plasma concentration/effect of the antimuscarinic and/or interacting drug. Antimuscarinics secreted by the renal tubules (eg trospium) may theoretically be able to interfere with the elimination of other drugs using this mechanism.

Antimuscarinics are still the most widely used treatment for urgency and urgency incontinence [Andersson, 2004]. However, currently used drugs lack selectivity for the bladder, and effects on other organ systems (Figure 11) may result in side effects, which limit their usefulness. For example, all antimuscarinic drugs are contraindicated in untreated narrow angle glaucoma.

Theoretically, drugs with selectivity for the bladder could be obtained if the subtype(s) mediating bladder contraction and those producing the main side effects of antimuscarinic drugs were different. Unfortunately, this does not seem to be the case. One way of avoiding many of the antimuscarinic side effects is to administer the drugs intravesically. However, this is practical only in a limited number of patients.

Several antimuscarinic drugs are and have been used for treatment of OAB/DO. For some of them, documentation of effects is not based on randomized controlled trials (RCTs) satisfying currently required criteria, and some drugs can be considered as obsolete (e.g., emepronium). Information on these drugs has not been included, but can be found elsewhere [Andersson, 1988; Andersson et al., 1999].

The clinical relevance of efficacy of antimuscarinic drugs relative to placebo has been questioned. Herbison et al. [2003] stated in a widely discussed article: “Anticholinergics produce significant improvements in overactive bladder symptoms compared with placebo.”

**Figure 8 :** The hypothetical role of acetylcholine (ACh) in the generation of DO and OAB. During bladder filling, there is no activity in the parasympathetic outflow from the bladder. However, the myocytes have a spontaneous (myogenic) contractile activity that generates afferent nerve activity (C-fibres and Ad-fibres). In DO bladders, there are areas of “patchy denervation” and ACh in low concentrations is “leaking” from the nerves. This enhances the spontaneous activity and the basal afferent nerve activity (“afferent noise”). This means that the Ad-fibre activity, generated by bladder distension, can initiate the micturition reflex at low degrees of bladder filling. Antimuscarinics in therapeutically recommended doses can inhibit the effects of these low concentrations of acetylcholine, but not of the high concentrations necessary for the generating the voiding contraction (requiring efferent nerve activity). Structural changes in the bladder (e.g., secondary to outflow obstruction) can generate local factors, such as prostaglandins and endothelins, which also can contribute to enhancement of the spontaneous activity.
Figure 9: The hypothetical role of acetylcholine (ACh) in the generation of DO and OAB. During bladder filling, there is no activity in the parasympathetic outflow from the bladder. However, the myocytes have a spontaneous (myogenic) contractile activity that generates afferent nerve activity (C-fibres and Ad-fibres). In DO bladders, there are areas of “patchy denervation” and ACh in low concentrations is “leaking” from the nerves. This enhances the spontaneous activity and the basal afferent nerve activity (“afferent noise”). This means that the Ad-fibre activity, generated by bladder distension, can initiate the micturition reflex at low degrees of bladder filling. Antimuscarinics in therapeutically recommended doses can inhibit the effects of these low concentrations of acetylcholine, but not of the high concentrations necessary for the generating the voiding contraction (requiring efferent nerve activity). Structural changes in the bladder (e.g., secondary to outflow obstruction) can generate local factors, such as prostaglandins and endothelins, which also can contribute to enhancement of the spontaneous activity.

Figure 10: Distension of the bladder and shape-change of the urothelium (U) will generate and release different signaling molecules, including ATP and acetylcholine (ACh), which either directly or by action via the interstitial cells (IC) will initiate activity in the suburothelial afferent nerves. Antimuscarinics may inhibit this ACh-induced activation. GC = glycocalix layer; DRG = dorsal root ganglion.

Figure 11: Important sites of action of antimuscarinics.
The benefits are, however, of limited clinical significance" Large meta-analyses of studies performed with the currently most widely used drugs [Chapple et al., 2005; 2008; Novara et al., 2008], clearly show that antimuscarinics are of significant clinical benefit. Novara et al. [2008] reviewed 50 RCTs and 3 pooled analyses, which they considered of good methodological quality. They concluded that still more clinical studies are needed to decide which of the drugs should be used as first-, second-, or third-line treatment. Reviewing information from more than 12,000 references (Figure 12), Chapple et al. [2008], based their conclusions ("antimuscarinics are efficacious, safe, and well tolerated treatments") on 73 RCTs selected for their meta-analysis. It was recommended that since the profiles of each drug (see below) and dosage differ, these factors should be considered in making treatment choices.

The consequence of this is that none of the antimuscarinic drugs in common clinical use (darifenacin, fesoterodine, oxybutynin, propiverine, solifenacin, tolterodine or trospium) is ideal as a first-line treatment. Reviewing information from more than 12,000 references (Figure 12), Chapple et al. [2008], based their conclusions ("antimuscarinics are efficacious, safe, and well tolerated treatments") on 73 RCTs selected for their meta-analysis. It was recommended that since the profiles of each drug (see below) and dosage differ, these factors should be considered in making treatment choices.

Reviewing information from more than 12,000 references (Figure 12), Chapple et al. [2008], based their conclusions ("antimuscarinics are efficacious, safe, and well tolerated treatments") on 73 RCTs selected for their meta-analysis. It was recommended that since the profiles of each drug (see below) and dosage differ, these factors should be considered in making treatment choices.

The consequence of this is that none of the antimuscarinic drugs in common clinical use (darifenacin, fesoterodine, oxybutynin, propiverine, solifenacin, tolterodine or trospium) is ideal as a first-line treatment for all OAB/DO patients. Optimal treatment should be individualized, implying that the patient’s co-morbidities and concomitant medications, and the pharmacological profiles of the different drugs, should be taken into consideration [Chapple et al., 2008].

Below data on the different antimuscarinics are presented. The amount of information for the individual drugs varies, and so does the degree of details from the different studies presented. However, the information has been chosen to give a reasonable efficacy and adverse effect profile of each individual drug.

1. ATROPINE SULFATE

Atropine (di-hyoscynamine) is rarely used for treatment of OAB/DO because of its systemic side effects, which preclude its use as an oral treatment. However, in patients with neurogenic DO, intravesical atropine may be effective for increasing bladder capacity without causing any systemic adverse effects, as shown in open pilot trials [Ekström et al., 1992; Glickman et al., 1995; Deaney et al., 1998; Enskat et al., 2001; Fader et al, 2007]. It appears that intravesical atropine may be as effective as intravesical oxybutynin in patients with neurogenic DO [Fader et al., 2007].

The pharmacologically active antimuscarinic component of atropine is l-hyoscynamine. Although still used, few clinical studies are available to evaluate the antimuscarinic activity of l-hyoscynamine sulfate [Muskat et al., 1996]. For assessment, see Table 2.

2. PROPANTHELINE BROMIDE

Propantheline is a quaternary ammonium compound, non-selective for muscarinic receptor subtypes, which has a low (5 to 10%) and individually varying biological availability. It is metabolized (metabolites inactive) and has a short half-life (less than 2 h) [Beermann et al., 1972]. It is usually given in a dose of 15 to 30 mg 4 times daily, but to obtain an optimal effect, individual titration of the dose is necessary, and often higher dosages are required. Using this approach in 26 patients with detrusor overactivity contractions [Blivas et al., 1980] in an open study obtained a complete clinical response in all patients but one, who did not tolerate more than propantheline 15 mg four times daily. The range of dosages varied from 7.5 to 60 mg four times daily. In contrast, Thüroff et al. [1991] comparing the effects of oxybutynin 5 mg three times daily, propantheline 15 mg three times daily, and placebo, in a randomized, double-blind, multicenter trial on the treatment of frequency, urgency and incontinence related to DO (154 patients), found no differences between the placebo and propantheline groups. In another randomized comparative trial with crossover design (23 women with idiopathic DO), and with dose titration, Holmes et al. [1991] found no differences in efficacy between oxybutynin and propantheline. Controlled randomised trials (n=6) reviewed by Thüroff et al[1998], confirmed a positive, but varying, response to the drug.

Although the effect of propantheline on OAB/DO has not been well documented in controlled trials satisfying standards of today, it can be considered effective, and may, in individually titrated doses, be clinically useful (Table 2). No new studies on the use of this drug for treatment of OAB/DO seem to have been performed during the last decade.

3. TROSPIUM CHLORIDE

Trospium is a quaternary ammonium compound with a biological availability less than 10% [Fusgen and Hauri, 2000; Doroshyenko et al., 2005]. The drug has a plasma half-life of approximately 20 h, and is mainly (60% of the dose absorbed) eliminated unchanged in the urine. The concentration obtained in urine seems to be enough to affect the mucosal signaling system in a rat model [Kim et al., 2006]. Whether or not it contributes to the clinical efficacy of the drug remains to be established.

Trospium is not metabolized by the cytochrome P450 enzyme system [Beckmann-Knopp et al., 1999; Doroshyenko et al., 2005]. It is expected to cross the blood-brain to a limited extent and seems to have no negative cognitive effects [Fusgen and Hauri, 2000; Todorova et al., 2001; Widemann et al., 2002].

Trospium has no selectivity for muscarinic receptor subtypes. In isolated detrusor muscle, it was more potent than oxybutynin and tolterodine to antagonize carbachol-induced contractions [Uckert et al., 2000]. Several RCTs have documented positive effects of trospium both in neurogenic [Stöhrer, et al., 1991;

The effect of trospium in urgency incontinence has been documented in several RCTs. Allousi et al. [1998] compared the effects of the drug with those of placebo in 309 patients in a urodynamic study of 3 weeks duration. Trospium 20 mg was given twice daily. Significant increases were noted in volume at first involuntary contraction and in maximum bladder capacity. Cardozo et al. [2000] investigated 208 patients with DO, who were treated with trospium 20 mg twice daily for two weeks. Also in this study, significant increases were found in mean volume at first unstable contraction (from 233 to 299 ml; placebo 254 to 255 ml) and in maximum bladder capacity (from 329 to 356 ml; placebo 345 to 335 ml) in the trospium treated group. Trospium was well tolerated with similar frequency of adverse effects as in the placebo group. Jünemann et al. [2000] compared trospium 20 mg twice daily with tolterodine 2 mg twice daily in a placebo-controlled double-blind study on 232 patients with urodynamically proven DO, urgency incontinence without demonstrable DO, or mixed incontinence. Trospium reduced the frequency of micturition, which was the primary endpoint, more than tolterodine and placebo, and also reduced the number of incontinence episodes more than the comparators. Dry mouth was comparable in the trospium and tolterodine groups (7 and 9%, respectively).

Halaska et al. [2003] studied the tolerability and efficacy of trospium chloride in doses of 20 mg twice daily for long-term therapy in patients with urgency syndrome. The trial comprised a total of 358 patients with urgency syndrome or urgency incontinence. After randomisation in the ratio of 3:1, participants were treated continuously for 52 weeks with either trospium chloride (20 mg twice daily) or oxybutynin (5 mg twice daily). Urodynamic measurements were performed at the beginning, and at 26 and 52 weeks to determine the maximal cystometric bladder capacity. Analysis of the micturition diary clearly indicated a reduction of the micturition frequency, incontinence frequency, and a reduction of the number of urgency episodes in both treatment groups. Mean maximum cystometric bladder capacity increased during treatment with trospium chloride by 92 ml after 26 weeks and 115 ml after 52 weeks (P=0.001). Further comparison with oxybutynin did not reveal any statistically significant differences in urodynamic variables between the drugs. Adverse events occurred in 65% of the patients treated with trospium and 77% of those treated with oxybutynin. The main symptom encountered in both treatment groups was dryness of the mouth. An overall assessment for each of the drugs revealed a comparable efficacy level and a better benefit-risk ratio for trospium than for oxybutynin due to better tolerability.

Zinner et al. [2004] treated 523 patients with symptoms associated with OAB and urgency incontinence with 20 mg trospium twice daily or placebo in a 12-week, multicenter, parallel, double-blind, placebo controlled trial. Dual primary end points were change in average number of toilet voids and change in urgency incontinence episodes per 24 hours. Secondary efficacy variables were change in average of volume per void, voiding urgency severity, urinations during day and night, time to onset of action and change in Incontinence Impact Questionnaire. By week 12, trospium significantly decreased average frequency of toilet voids per 24 hours (-2.37; placebo -1.29) and urgency incontinence episodes (-59%; placebo -44%). It significantly increased average volume per void (32 ml; placebo: 7.7 ml), and decreased average urgency severity and daytime frequency. All effects occurred by week 1 and all were sustained throughout the study. Nocturnal frequency decreased significantly by week 4 (-0.43; placebo: 0.17) - and Incontinence Impact Questionnaire scores improved at week 12. Trospium was well tolerated. The most common side effects were dry mouth (21.8%; placebo 6.5%), constipation (9.5%; placebo 3.8%) and headache (6.5%; placebo 4.6%).

In a large US multicenter trial with the same design, and including 658 patients with OAB, Rudy et al. [2006] confirmed the data by Zinner et al. [2004], both with respect to efficacy and adverse effects.

An extended release formulation of trospium allowing once daily dosing, has been introduced and and its effects tested in controlled trials [Staskin et al., 2008; Dmochowski et al., 2008]. These RCTs demonstrated similar efficacy as found with previous formulations. The most frequent side effects were dry mouth (12.9%; placebo 6.5%) and constipation (7.5%; placebo 3.8%) [Dmochowski et al., 2008].

Intravesical application of trospium may be an interesting alternative. Frölich et al. [1998] performed a randomised, single-blind, placebo-controlled, monocentre clinical trial in 84 patients with urgency or urgency incontinence. Compared to placebo, intra-
vesical trospium produced a significant increase in maximum bladder capacity and a decrease of detrusor pressure accompanied by an increase of residual urine. There was an improvement in uninhibited bladder contractions. No adverse events were reported. Interestingly, intravesical trospium does not seem to be absorbed [Walter et al., 1999], thus offering an opportunity for treatment with minimal systemic antimuscarinic effects.

Trospium has a well-documented effect in OAB/DO, and tolerability and safety seems acceptable (Table 2).

4. TOLTERODINE TARTRATE

Tolterodine is a tertiary amine, rapidly absorbed and extensive metabolized by the cytochrome P450 system (CYP 2D6). The major active 5-hydroxymethyl metabolite (5-HMT) has a similar pharmacological profile as the mother compound [Nilvebrant et al., 1997], and significantly contributes to the therapeutic effect of tolterodine [Brynne et al., 1997; Brynne et al., 1998]. Both tolterodine and 5-HMT have plasma half-lives of 2-3 h, but the effects on the bladder seem to be more long-lasting than could be expected from the pharmacokinetic data. Urinary excretion of tolterodine accounted for <1-2.4 % of the dose; 5 – 14% of 5-HMT is eliminated in the urine [Brynne et al., 1997]. Whether or not the total antimuscarinic activity of unchanged tolterodine and 5-HMT excreted in urine is sufficient to exert any effect on the mucosal signaling mechanisms has not been established. However, the preliminary studies by Kim et al. [2005] and Chuang et al., [2008], do not support such an effect.

The relatively low lipophilicity of tolterodine and even lesser one of 5-HMT, implies limited propensity to penetrate into the CNS, which may explain a low incidence of cognitive side effects [Hills et al., 1998; Clemett et al., 2001; Salvatore et al., 2008]. Comparative RCTs such as the OBJECT (Overactive Bladder: Judging Effective Control and Treatment), and the OPERA (Overactive Bladder; Performance of Extended Release Agents) studies have further supported its effectiveness.

The OBJECT trial compared oxybutynin ER (OXY-ER) 10 mg once daily with TOLT-IR 2 mg twice daily [Appell et al., 2001] in a 12-week randomized, double blind, parallel-group study including 378 patients with OAB. Participants had between 7 and 50 episodes of urgency incontinence per week and 10 or more voids in 24 hours. The outcome measures were the number of episodes of urgency incontinence, total incontinence, and micturition frequency at 12 weeks adjusted for baseline. At the end of the study, OXY-ER was found to be significantly more effective than TOLT-IR in each of the main outcome measures adjusted for baseline (see also below: oxybutynin chloride). Dry mouth, the most common adverse event, was reported by 28% and 33% of participants taking OXY-ER and TOLT-IR, respectively. Rates of central nervous system and other adverse events were low and similar in both groups. The authors concluded that OXY-ER was more effective than TOLT-IR and that the rates of dry mouth and other adverse events were similar in both treatment groups.

In the OPERA study [Dionko et al., 2003], OXY-ER at 10 mg/d or TOLT-ER at 4 mg/d were given for 12 weeks to women with 21 to 60 urgency incontinence episodes per week and an average of 10 or more voids per 24 hours. Episodes of incontinence episodes (primary end point), total (urgency and non urgency) incontinence, and micturition were recorded in seven 24-hour urinary diaries at baseline and at weeks 2, 4, 8 and 12 and compared. Adverse events were also evaluated. Improvements in weekly urgency incontinence episodes were similar for the 790 women who received OXY-ER (n=391) or TOLT-ER (n=399). OXY-ER was significantly more effective than TOLT-ER in reducing micturition frequency, and 23.0% of women taking OXY-ER reported no episodes of urinary incontinence compared with 16.8% of women taking TOLT-ER. Dry mouth, usually mild, was more common with OXY-ER. Adverse events were generally mild and occurred at low rates, with both groups having similar discontinuation of treatment due to adverse events. The conclusions were that reductions in weekly urgency incontinence and total incontinence episodes were similar with the two drugs. Dry mouth was more common with OXY-ER, but tolerability was otherwise comparable; including adverse events involving the central nervous system.
In the ACET (Antimuscarinic Clinical Effectiveness Trial) [Sussman and Garely, 2002] study, which consisted of two trials, patients with OAB were randomized to 8 weeks of open-label treatment with either 2 mg or 4 mg of once-daily TOLT-ER (study one) and to 5 mg or 10 mg of OXY-ER (study two). A total of 1289 patients were included. Fewer patients prematurely withdrew from the trial in the TOLT-ER 4 mg group (12%) than either the OXY-ER 5 mg (19%) or OXY-ER 10 mg groups (21%). More patients in the OXY-ER 10 mg group than the TOLT-ER 4 mg group withdrew because of poor tolerability (13% vs. 6%). After 8 weeks, 70% of patients in the TOLT-ER 4 mg group perceived an improved bladder condition, compared with 60% in the TOLT-ER 2 mg group, 59% in the OXY-ER 5 mg group and 60% in the OXY-ER 10 mg group. Dry mouth was dose-dependent with both agents, although differences between doses reached statistical significance only in the oxybutynin trial (OXY-ER 5 mg vs. OXY-ER 10 mg; p=0.05). Patients treated with TOLT-ER 4 mg reported a significantly lower severity of dry mouth compared with OXY-ER 10 mg. The conclusion that the findings suggest improved clinical efficacy of TOLT-ER (4 mg) than of OXY-ER (10 mg) is weakened by the the open label design of the study.

Zinner et al. [2002] evaluated the efficacy, safety, and tolerability of TOLT-ER in older (> or =65) and younger (<65) OAB patients, in a 12-week RCT including 1015 patients with urgency incontinence and urinary frequency. Patients were randomized to treatment with TOLT-ER 4 mg once daily (n = 507) or placebo (n = 508) for 12 weeks. Efficacy, measured with micturition charts (incontinence episodes, micturitions, volume voided per micturition) and subjective patient assessments, safety, and tolerability endpoints were evaluated, relative to placebo. Compared with placebo, significant improvements in micturition chart variables with TOLT-ER showed no age-related differences. Dry mouth (of any severity) was the most common adverse event in both the TOLT-ER and placebo treatment arms, irrespective of age (<65: ER 22.7%, placebo 8.1%; > or =65: ER 24.3%, placebo 7.2%). A few patients (< 2%) experienced severe dry mouth. No central nervous system (cognitive functions were not specifically studied), visual, cardiac (per electrocardiogram), or laboratory safety concerns were noted in this study. Withdrawal rates due to adverse events on TOLT-ER 4 mg once daily were comparable in the two age cohorts (<65: 5.5%; > or =65: 5.1%).

The central symptom in the OAB syndrome is urgency. Freeman et al. [2003] presented a secondary analysis of a double-blind, placebo-controlled study evaluating the effect of once-daily TOLT-ER on urinary urgency in patients with OAB. Patients with urinary frequency (eight or more micturitions per 24 hours) and urgency incontinence (five or more episodes per week) were randomized to oral treatment with TOLT-ER 4 mg once daily (n=398) or placebo (n=374) for 12 weeks. Efficacy was assessed by use of patient perception evaluations. Of patients treated with TOLT-ER, 44% reported improved urgency symptoms (compared with 32% for placebo), and 62% reported improved bladder symptoms (placebo, 48%). The proportion of patients unable to hold urine upon experiencing urgency was decreased by 58% with TOLT-ER, compared with 32% with placebo (P<.001).

In the IMPROVE in Patients: Assessing symptomatic Control with Tolterodine ER (IMPACT) study [Elinoff et al., 2005], the efficacy of TOLT-ER for patients' most bothersome OAB symptom was investigated in an open label, primary care setting. Patients with OAB symptoms for ≥3 months received TOLT-ER (4 mg once daily) for 12 weeks. By week 12, there were significant reductions in patients’ most bothersome symptom: incontinence, urgency episodes, nocturnal and daytime frequency. The most common adverse events were dry mouth (10%) and constipation (4%), and it was concluded that in primary care practice, bothersome OAB symptoms can be effectively and safely treated with TOLT-ER, even in patients with comorbid conditions.

Various aspects of the efficacy and tolerability of tolterodine have been further documented in a number of RCTs [Dmochowski et al., 2007a; 2007; Barucha et al., 2008; Choo et al., 2008; Coyne et al., 2008; Rogers et al., 2008; Rovner et al., 2008a; see further: Novara et al., 2008, Chapple et al., 2008]. Importantly, the QTc effects of tolterodine were determined in a crossover-designed QT study of recommended (2 mg twice daily) and supratherapeutic (4 mg twice daily) doses of tolterodine, moxifloxacin (400 mg once daily), and placebo was performed. No subject receiving tolterodine exceeded the clinically relevant thresholds of 500 ms absolute QTc or 60 ms change from baseline, and it was concluded that tolterodine does not have a clinically significant effect on QT interval [Malhotra et al., 2007].

Olsansky et al. [2008] compared in a randomized, placebo-controlled, double blind, crossover study, the effects on heart rate of TOLT-ER 4 mg/day with those of darifenacin 15 mg/day and placebo in 162 healthy volunteers. They found that tolterodine, but not darifenacin and placebo, significantly increased mean heart rate per 24 hours. The proportion of subjects with an increase > 5 beats/min was significantly greater in those receiving TOLT-ER (1 out of 4) than with darifenacin (1 out of 10).

In a prospective, open study, Song et al. [2006] compared the effects of bladder training and or tolterodine as first line treatment in female patients with OAB. One hundred and thirty-nine female patients with OAB were randomized to treatment with bladder training (BT), tolterodine (2 mg twice daily) or both for 12 weeks. All treatments were efficacious, however,
combination therapy was the most effective. Mattiasson et al. [2003] compared the efficacy of tolterodine 2 mg twice daily plus simplified bladder training (BT) with tolterodine alone in patients with OAB in a multicenter single-blind study. At the end of the study the median percentage reduction in voiding frequency was greater with tolterodine + BT than with tolterodine alone (33% vs. 25%; p<0.001), while the median percentage increase in volume voided per void was 31% with tolterodine + BT and 20% with tolterodine alone (p<0.001). There was a median of 81% fewer incontinence episodes than at baseline with tolterodine alone, which was not significantly different from that with tolterodine + BT (~87%). It was concluded that the effectiveness of tolterodine 2mg twice daily can be augmented by a simplified BT regimen. However, Millard et al. [2004] investigated whether the combination of tolterodine plus a simple pelvic floor muscle exercise program would provide improved treatment benefits compared with tolterodine alone in 480 patients with OAB. Tolterodine therapy for 24 weeks resulted in significant improvement in urgency, frequency, and incontinence, however, no additional benefit was demonstrated for a simple pelvic floor muscle exercise program.

The beneficial effect of TOLT-ER in men with benign prostatic enlargement (BPE) and LUTS, including the beneficial effect of TOLT-ER in men with benign pelvic floor muscle exercise program.

Darifenacin is a relatively selective muscarinic M3 receptor antagonist. In vitro, it is selective for human cloned muscarinic M3 receptors relative to M1, M2, M4 or M5 receptors. Theoretically, drugs with selectivity for the M3 receptor can be expected to have clinical efficacy in OAB/DO with reduction of the adverse events related to the blockade of other muscarinic receptor subtypes [Andersson, 2002]. However, the clinical efficacy and adverse effects of a drug are dependent not only on its profile of receptor affinity, but also on its pharmacokinetics, and on the importance of muscarinic receptors for a given organ function.

Darifenacin has been developed as a controlled-release formulation, which allows once-daily dosing. Recommended dosages are 7.5 and 15 mg per day. The clinical effectiveness of the drug has been documented in several RCTs [Haab et al., 2004; Cardozo and Dixon 2005; Steers et al., 2005; Chapple et al., 2005; Foote et al., 2005; Hill et al., 2006; Haab et al., 2006; Zinner et al., 2006; Chapple et al., 2007; Abrams et al., 2008, Chancellor et al., 2008; Dwyer et al., 2008; for reviews, see Guay, 2005; Zinner, 2007; Novara et al., 2008; Chapple et al., 2008]. Haab et al. [2004] reported a multicentre, double-blind, placebo-controlled, parallel-group study which enrolled 561 patients (19–88 years; 85% female) with OAB symptoms for more than 6 months, and included some patients with prior exposure to antimuscarinic agents. After washout and a 2-week placebo run-in, patients were randomised (1:4:2:3) to once-daily oral darifenacin controlled-release tablets: 3.75 mg (n=53), 7.5 mg (n=229) or 15 mg (n=115) or matching placebo (n=164) for 12 weeks. Patients recorded daily incontinence episodes, micturition frequency, bladder capacity (mean volume voided), frequency of urgency, severity of urgency, incontinence episodes resulting in change of clothing or pads and nocturnal awakenings due to OAB using an electronic diary during weeks 2, 6 and 12 (directly preceding clinic visits). Tolerability data were evaluated from adverse event reports. Darifenacin 7.5 mg and 15 mg had a rapid onset of effect, with significant improvement compared with placebo being seen for most parameters at the first clinic visit (week 2). Darifenacin 7.5 mg and 15 mg, respectively, was significantly superior to placebo for (median) improvements in micturition frequency (7.5 mg: -1.6; 15 mg: -1.7; placebo -0.8, frequency of urgency per day (-2.0; -2.0; -0.9), and number of incontinence episodes leading to a change in clothing or pads (-4.0; -4.7; -2.0). There was no significant reduction in nocturnal awakenings due to OAB. The most common adverse events were mild-to-moderate dry mouth and constipation with a CNS and cardiac safety profile comparable to placebo. No patients withdrew from the study as a result of dry mouth and discontinuation related to constipation was rare (0.6% placebo versus 0.9% darifenacin).
In a dose titration study on 395 OAB patients, darifenacin, allowing individualized dosing (7.5 or 15 mg), was found to be effective and well-tolerated [Steers et al., 2005]. A 2-year open-label extension study of these investigations [i.e., Haab et al., 2004; Steers et al., 2005], confirmed a favorable efficacy, tolerability and safety profile [Haab et al., 2006].

A review of the pooled darifenacin data from the three phase III, multicentre, double blind clinical trials in patients with OAB was reported by Chaplle et al. [2005] After a 4-week washout/run-in period, 1,059 adults (85% female) with symptoms of OAB (urgency incontinence, urgency and frequency) for at least six months were randomized to once-daily oral treatment with darifenacin: 7.5 mg (n = 337) or 15 mg (n = 334) or matching placebo (n = 388) for 12 weeks. Efficacy was evaluated using electronic patient diaries that recorded incontinence episodes (including those resulting in a change of clothing or pads), frequency and severity of urgency, micturition frequency, and bladder capacity (volume voided). Safety was evaluated by analysis of treatment-related adverse events, withdrawal rates and laboratory tests. Relative to baseline, 12 weeks of treatment with darifenacin resulted in a dose-related significant reduction in median number of incontinence episodes per week (7.5 mg, -8.8 [-68.4%; placebo -54%, P<004]; 15 mg, -10.6 [-76.8%; placebo 58%, P<0.001]. Significant decreases in the frequency and severity of urgency, micturition frequency, and number of incontinence episodes resulting in a change of clothing or pads were also apparent, along with an increase in bladder capacity. Darifenacin was well tolerated. The most common treatment-related adverse events were dry mouth and constipation, although together these resulted in few discontinuations (darifenacin 7.5 mg 0.6% of patients; darifenacin 15 mg 2.1%; placebo 0.3%). The incidence of CNS and cardiovascular adverse events were comparable to placebo. The results were confirmed in other RCTs, including also a pooled analysis of three phase III studies in older patients (≥65 years), showing that darifenacin (7.5 and 15 mg) had an excellent efficacy, tolerability and safety profile [Foote et al., 2005, Zinner et al., 2005; Hill et al. 2006].

One of the most noticeable clinical effects of antimuscarinics is their ability to reduce urgency and allow patients to postpone micturition. A study was conducted to assess the effect of darifenacin, on the ‘warning time’ associated with urinary urgency. This was a multicenter, randomized, double-blind, placebo-controlled study consisting of 2 weeks’ washout, 2 weeks’ medication-free run-in and a 2-week treatment phase [Cardozo and Dixon, 2005]. Warning time was defined as the time from the first sensation of urgency to voluntary micturition or incontinence and was recorded via an electronic event recorder at baseline (visit 3) and study end (visit 4) during a 6-hour clinic-based monitoring period, with the subject instructed to delay micturition for as long as possible. During each monitoring period, up to three urgency-void cycles were recorded. Of the 72 subjects who entered the study, 67 had warning time data recorded at both baseline and study end and were included in the primary efficacy analysis (32 on darifenacin, 35 on placebo). Darifenacin treatment resulted in a significant (p<0.004) increase in mean warning time with a median increase of 4.3 minutes compared with placebo (darifenacin group from 4.4 to 1.8 minutes; placebo from 7.0 to -1.0 minutes). Overall, 47% of darifenacin-treated subjects compared with 20% receiving placebo achieved a ≥30% increase in mean warning time. There were methodological problems associated with this study; it utilized a dose of 30 mg (higher than the dose recommended for clinical use), the treatment period was short, it was conducted in a clinical-centred environment, the methodology carried with it a significant potential training effect, and the placebo group had higher baseline values than the treatment group. In another warning time study [Zinner et al., 2006] on 445 OAB patients, darifenacin treatment (15 mg) resulted in numerical increases in warning time, however, these were not significant compared to placebo.

Further studies have demonstrated that darifenacin treatment is associated with clinically relevant improvements on health related quality of life (HRQoL) in patients with OAB [Abrams et al., 2008], and such improvements were sustained as shown in a two-year extension study [Dwyer et al., 2008]. It was shown that neither the positive effects on micturition variables, nor on HRQoL produced by darifenacin (7.5 and 15 mg) were further enhanced by a behavioural modification programme including timed voiding, dietary modifications and Kegel exercises [Chancellor et al., 2008].

Several studies have been devoted to study possible effect on cognition by darifenacin. Neither in healthy volunteers (19-44 years) and healthy subjects (≥60 years), nor in volunteers 65 years or older, could any effect of darifenacin (3.75-15mg daily) be demonstrated, compared to placebo [Kay and Wesnes, 2005; Lipton et al., Kay et al., 2006; Kay and Ebinger 2008].

To study whether darifenacin had any effect on QT/QTc intervals [Serra et al., 2005] performed a 7-day, randomized, parallel-group study (n = 188) in healthy volunteers receiving once-daily darifenacin at steady-state therapeutic (15 mg) and supratherapeutic (75 mg) doses, alongside controls receiving placebo or moxifloxacin (positive control, 400 mg) once daily. No significant increase in QTcF interval could be demonstrated compared with placebo. Mean changes from baseline at pharmacokinetic T_max versus placebo were -0.4 and -2.2 milliseconds in the darifenacin 15mg and 75 mg groups, respectively, compared with
Darifenacin 15 mg per day given to healthy volunteers did not change heart rate significantly compared to placebo [Olshansky et al., 2008]. Darifenacin has a well-documented beneficial effect in OAB/DO (Table 2), and tolerability and safety seems acceptable.

6. SOLIFENACIN SUCCINATE

Solifenacin succinate (YM905) is a tertiary amine and well absorbed from the gastrointestinal tract (absolute bioavailability 90%). The mean terminal half-life is 45-68 hours [Kuipers et al., 2002; Smulders et al., 2002; 2004]. It undergoes hepatic metabolism involving the cytochrome P450 enzyme system (CYP3A4). In subjects who received a single oral dose of 10 mg solifenacin on day 7 of a 20-day regimen of ketoconazole administration (200 mg) Cmax and AUC0-inf were increased by only approximately 40% and 56%, respectively [Swart et al., 2006]. Solifenacin has a modest selectivity for M3 over M2 (and M1) receptors [Abrams and Andersson, 2007].

Two large-scale phase 2 trials with parallel designs, comprising men and women, were performed [Chapple et al., 2004a, Smith et al., 2002]. The first dose-ranging study evaluated solifenacin 2.5 mg, 5 mg, 10 mg, and 20 mg and tolterodine (2 mg twice daily) in a multinational placebo-controlled study of 225 patients with urodynamically confirmed DO [Chapple et al., 2004a]. Patients received treatment for 4 weeks followed by 2 weeks of follow-up. Inclusion criteria for this and subsequent phase 3 studies of patients with OAB included at least 8 micturitions per 24 hours and either one episode of incontinence or one episode of urgency daily as recorded in 3-day micturition diaries. Micturition frequency, the primary efficacy variable, was statistically significantly reduced in patients taking solifenacin 5 mg (-2.21), 10 mg (-2.47), and 20 mg (-2.75), but not in patients receiving placebo (-1.03) or tolterodine (-1.79). This effect was rapid with most of the effect observed at the earliest assessment visit, 2 weeks after treatment initiation. In addition, there was a numerically greater reductions in episodes of urgency and incontinence when compared with placebo. Study discontinuations due to adverse events were similar across treatment groups, albeit highest in the 20-mg solifenacin group. As the 5 mg and 10 mg doses caused lower rates of dry mouth than tolterodine, and superior efficacy outcomes relative to placebo, these dosing strengths were selected for further evaluation in large-scale phase 3 studies.

The second dose-ranging study of solifenacin 2.5 mg to 20 mg was carried out in the United States (USA) [Smith et al., 2002]. This trial included 261 evaluable men and women receiving solifenacin or placebo for 4 weeks followed by a 2-week follow-up period. Micturition frequency was statistically significantly reduced relative to placebo in patients receiving 10 mg and 20 mg solifenacin. The number of micturitions per 24 hours showed reductions by day 7 and continued to decrease through day 28; day 7 was the earliest time point tested. Efficacy was demonstrated at this time. The 5 mg, 10 mg, and 20 mg dosing groups experienced significant increases in volume voided; the 10 mg solifenacin dose was associated with significant reductions in episodes of incontinence.

In one of the early RCTs, a total of 1077 patients were randomized to 5 mg solifenacin, 10 mg solifenacin, tolterodine (2 mg twice daily), or placebo [Chapple et al., 2004b]. It should be noted that this study was powered only to compare active treatments to placebo. Compared with placebo (-8%), mean micturitions/24 h were significantly reduced with solifenacin 10 mg (20%), solifenacin 5 mg (17%), and tolterodine (15%). Solifenacin was well tolerated, with few patients discontinuining treatment. Incidences of dry mouth were 4.9% with placebo, 14.0% with solifenacin 5 mg, 21.3% with solifenacin 10 mg, and 18.6% with tolterodine 2 mg twice daily.

Cardozo et al. [2004] randomized 911 patients to 12-week once daily treatment with solifenacin 5 mg, solifenacin 10 mg or placebo. The primary efficacy variable was change from baseline to study end point in mean number of micturitions per 24 hours. Secondary efficacy variables included changes from baseline in mean number of urgency, nocturia and incontinence episodes per 24 hours, and mean volume voided per micturition. Compared with changes obtained with placebo (-1.6), the number of micturitions per 24 hours was statistically significantly decreased with solifenacin 5 mg (-2.37) and 10 mg (-2.81). A statistically significant decrease was observed in the number of all incontinence episodes with both solifenacin doses (5 mg: -1.63, 61%; 10 mg: -1.57, 52%), but not with placebo (-1.25, 28%). Of patients reporting incontinence at baseline, 50% achieved continence after treatment with solifenacin (based on a 3-day micturition diary, placebo responses not given). Episodes of nocturia were statistically significantly decreased in patients treated with solifenacin 10 mg versus placebo. Episodes of urgency and mean volume voided per micturition were statistically significantly reduced with solifenacin 5 mg and 10 mg. Treatment with solifenacin was well tolerated. Dry mouth, mostly mild in severity, was reported in 7.7% of patients receiving solifenacin 5 mg and 23% receiving solifenacin 10 mg (vs 2.3% with placebo). A 40-week follow up of these studies [i.e., Chapple et al., 2004b and Cardozo et al., 2004] demonstrated that the favourable profile, both in terms of efficacy and tolerability was maintained over the study period [Haab et al., 2005].
The STAR trial [Chapple et al., 2005; 2007] was a prospective, double blind, double-dummy, two-arm, parallel-group, 12-week study conducted to compare the efficacy and safety of solifenacin 5 or 10 mg and TOLT-ER 4 mg once daily in OAB patients. The primary effect variable was micturition frequency. After 4 weeks of treatment patients had the option to request a dose increase, but were dummed throughout as approved product labelling only allowed an increase for those on solifenacin. The results showed that solifenacin, with a flexible dosing regimen, was “non-inferior” to tolterodine concerning the primary effect variable, micturition frequency. However, solifenacin showed significant greater efficacy to tolterodine in decreasing urgency episodes (-2.85 vs -2.42), incontinence (-1.60 vs -0.83), urgency incontinence (-1.42 vs -0.83), and pad usage (-1.72 vs -1.19). More solifenacin treated patients became continent by study endpoint (59 vs 49%) and reported improvements in perception of bladder condition (1.51 vs -1.33) assessments. However, this was accompanied by an adverse event incidence which was greater with solifenacin than with tolterodine. Dry mouth and constipation (mild + moderate + severe) were the most common (solifenacin 30% and 6.4%, tolterodine 23% and 2.5%). The majority of side effects were mild to moderate in nature, and discontinuations were comparable and low (5.9 and 7.3%) in both groups.

A number of studies and reviews have further documented the effects of solifenacin [Cardozo et al., 2006; Chapple et al., 2006; 2007; Maniscalco et al., 2006, see also Chapple et al., 2008; Novara et al., 2008]. In a pooled analysis of four RCTs, Abrams and Swift (2005) demonstrated positive effects on urgency, frequency and nocturia symptoms in OAB dry patients. In an analysis of four phase III clinical trials, Brubaker and FitzGerald [2007] confirmed a significant effect of solifenacin 5 and 10 mg on nocturia in patients with OAB (reductions of nocturia episodes with 5 mg: -0.6, p<0.025; with 10 mg: -0.6, p<0.001 vs placebo: -0.4) but without nocturnal polyuria.

Kelleher et al. [2006] and Staskin and Te [2006] presented data showing efficacy in patients with mixed incontinence. A pooled analysis of four studies confirmed the efficacy and tolerability of solifenacin 5 and 10 mg in elderly (≥65 years) patients, and also showed a high level of persistence in a 40 week extension trial [Wagg et al., 2005]. Improvement of QoL by solifenacin treatment has been documented in several studies [Kelleher et al., 2005; Garely et al., 2006].

In female volunteers, aged 19 to 79 years, the effect of 10 mg and 30 mg solifenacin on the QT interval was evaluated at the time of peak solifenacin plasma concentration in a multi-dose, randomized, double-blind, placebo and positive-controlled (moxifloxacin 400 mg) trial. The QT interval prolonging effect appeared greater for the 30 mg (8 msec, 4.13; 90%CI) compared to the 10 mg (2 msec, -3, 6) dose of solifenacin. Although the effect of the highest solifenacin dose (three times the maximum therapeutic dose) studied did not appear as large as that of the positive control moxifloxacin at its therapeutic dose, the confidence intervals overlapped. This study was not designed to draw direct statistical conclusions between the drugs or the dose levels.

Michel et al. [2008] studied cardiovascular safety and overall tolerability of solifenacin in routine clinical use in a 12-week, open-label, post-marketing surveillance study. They concluded that “in real-life conditions, i.e. with inclusion of large numbers of patients with cardiovascular co-morbidities and taking comediations, therapeutically effective doses of solifenacin did not increase heart rate or blood pressure”.

Solifenacin has a well-documented beneficial effect in OAB/DO (Table 2), and the adverse event profile seems acceptable.

7. FESOTERODINE FUMARATE

Fesoterodine functions as an orally active prodrug that is converted to the active metabolite 5-hydroxymethyltolterodine (5-HMT) by non-specific esterases [Michel, 2008]. This compound, which is chemically identical to the 5-hydroxy metabolite of tolterodine, is a non-subtype selective muscarinic receptor antagonist [Ney et al., 2008]. All of the effects of fesoterodine in man are thought to be mediated via 5-HMT, since the parent compound remains undetectable upon oral dosing. 5-HMT is metabolized in the liver, but a significant part of 5-HMT is excreted renally without additional metabolism. Since the renal clearance of 5-HMT is about 250 mL/min, with >15% of the administered fesoterodine dose excreted as unchanged 5-HM, this raises the possibility that 5-HMT also could work from the luminal side of the bladder [Michel, 2008].

Fesoterodine is indicated for use at doses of 4 and 8 mg once daily. In clinical studies both doses of fesoterodine were consistently superior to placebo in improving the symptoms of OAB [Chapple et al., 2007; Nitti et al., 2007], with 8 mg/day having significantly greater effects than 4 mg/day [Khullar et al., 2008]. Analysis of pooled data on QoL, using King’s Health Questionnaire and ICI Questionnaire-short Form, showed that both doses of the drug caused a significant improvement of QoL. Compared to TOLT-ER (4 mg), fesoterodine (8 mg) had statistically significant advantages for improving incontinence episodes, severe urgency with incontinence, mean voided volumes and number of continent days a week [Chapple et al., 2008; Khullar et al., 2008]. Adverse events were characteristic for an antimuscarinic, dry mouth being the most frequently reported – it was
was rated as mild to moderate in most cases. In one phase III study it was seen in 7%, 16% and 36% of patients receiving placebo, 4 and 8 mg/d fesoterodine, respectively [Nitti et al., 2007], whereas in the other phase III study it was 7.1%, 21.7% and 33.8% in the same groups (16.8% for 4 mg/day TOLT-ER) [Chapple et al., 2007].

Kelleher et al. [2008] evaluated the effect of fesoterodine on HRQoL in patients with OAB syndrome. Pooled data from two randomized placebo-controlled phase III studies were analysed. Eligible patients were randomized to placebo or fesoterodine 4 or 8 mg for 12 weeks; one trial also included tolfenedine extended release (tolfenedine-ER) 4 mg. By the end of treatment, all active-treatment groups had significantly improved HRQoL compared with those on placebo.

A study on possible effects on QT-intervals has been performed [Michel, 2008]. This included parallel groups of 64-68 subjects each who were treated for 3 days with 4 mg/d fesoterodine, the highly supratherapeutic dose of 28 mg/d fesoterodine, the active control moxifloxacin 400 mg/day or placebo. Both the standard dose of 4 mg/day and the highly supratherapeutic dose of 28 mg/d did not provide any evidence of QT-prolongation (e.g., QTc for 28 mg/day from 404.5 ± 16.7 to 400.1 ± 14.0 ms, delta: -5.0 ± 7.9 ms).

Fesoterodine has a well-documented beneficial effect in OAB (Table 2), and the adverse event profile seems acceptable.

II. DRUGS ACTING ON MEMBRANE CHANNELS

1. CALCIUM ANTAGONISTS

Calcium channels play an important role in the regulation of free intracellular calcium concentrations and thereby contribute to the regulation of smooth muscle tone. Two major groups of calcium channels include the voltage-gated [Caterall et al., 2003] and the store-operated channels (Leung et al., 2008). While both can contribute to the maintenance of smooth tone in general, store-operated calcium channels apparently contribute only to a limited if any extent to the regulation of bladder smooth muscle tone [Schneider et al., 2004 a; b]. On the other hand, various types of voltage-operated calcium channels have been implicated in the regulation of bladder smooth muscle tone including including Q-type [Frew and Lundy, 1995] and L-type channels [Wuest et al., 2007]. The latter appears to be of particular importance as inhibitors of L-type channels have repeatedly been shown to inhibit bladder contraction in vitro with tissue from multiple mammalian species, including humans [Frazier et al., 2008]. However, the relative importance of L-type channels may be somewhat less in humans than in other mammalian species [Wuest et al., 2007]. In confirmation of the role of L-type calcium channels, it has been shown that knock-out mice lacking a crucial subunit of this channel exhibit a markedly impaired bladder contractility [Wegener et al., 2004].

While these in vitro data suggest a possible role for calcium channel inhibitors, particularly those of L-type channels, in the treatment of DO and incontinence, only limited clinical studies are available in this regard. One urodynamic study compared the effects of intravesical instillation of the calcium channel inhibitor verapamil, the muscarinic receptor antagonists oxybutynin and trospium and placebo to patients with urgency or urgency incontinence. While the two muscarinic receptor antagonists significantly increased bladder capacity, verapamil treatment was not associated with relevant changes in bladder function [Fröhlich et al., 1998]. In a clinical study of limited size the calcium channel inhibitor nimodipine (30 mg per day) did not significantly improve the number of incontinence episodes as compared to placebo [Nagle et al., 2002]. Larger studies with clinical endpoints related to effects of calcium channel inhibitors have not been reported in incontinent patients (based upon a Medline search using the MeSH terms “calcium channel blockers” and “urinary incontinence”). Moreover, it should be noted that despite a long-standing and wide-spread use of calcium channel inhibitors in the treatment of cardiovascular disease, there are no major reports on impaired bladder contractility as a side effect of such treatment. The reasons for the discrepancy between the promising in vitro and the lack of clinical data are not fully clear, but it may relate to pharmacokinetic properties of the currently used drugs which may insufficiently either reach or penetrate bladder tissue in therapeutically administered doses. At present, there is no clinical evidence to support a possible use of calcium channel inhibitors in the treatment of bladder dysfunction (Table 2).

2. POTASSIUM CHANNEL OPENERS

In a similar fashion to calcium channels, potassium channels also contribute to the membrane potential of smooth muscle cells and hence to the regulation of smooth muscle tone. Numerous types of potassium channels exist [Gutman et al., 2003]. With regard to bladder function, ATP-dependent (KATP) and big calcium-activated (BKCa) channels have been studied most intensively. The BKCa channels also appear to be important physiologically as their activation can cause hyperpolarization of bladder smooth muscle cells and by this mechanism they can contribute to the relaxation of bladder smooth muscle by, e.g., β-adrenoceptor agonists [Frazier et al., 2008]. Openers of both KATP [Howe et al., 1995; Hu et al., 1997; Martin et al., 1997] and BKCa channels [Hu et al.,
randomized, placebo-controlled clinical study on the channel openers in OAB patients. Nevertheless, one has led to a considerable hesitancy to study potassium therapeutic window for clinical use. This consideration the degree of selectivity offers a sufficiently large cardiovascular system, it remains unclear whether compounds of this class have a certain degree of et al., 1995; Shieh et al., 2007]. While some doses may considerably lower blood pressure [Howe also affect cardiovascular function, and in effective muscle. Therefore, potassium channel openers may not only in bladder, but also e.g. in vascular smooth channel openers to inhibit non-voiding contractions in vivo in animal models of DO [Howe et al., 1997; Martin et al., 1997; Tanaka et al., 2003] and this also includes activators of the KCNQ type of potassium channels [Streng et al., 2004]. Although potassium channel openers are believed to mainly act directly on smooth muscle cells [Gopalakrishnan and Shieh, 2004], they may also at least in part affect bladder function by modulating the activity of afferent neurones [Tanaka et al., 2003].

While the above data demonstrate the potential of potassium channel openers to inhibit non-voiding detrusor contractions, these channels are expressed not only in bladder, but also e.g. in vascular smooth muscle. Therefore, potassium channel openers may also affect cardiovascular function, and in effective allows considerable lowering blood pressure [Howe et al., 1995; Shieh et al., 2007]. While some compounds of this class have a certain degree of selectivity for the bladder as compared to the cardiovascular system, it remains unclear whether the degree of selectivity offers a sufficiently large therapeutic window for clinical use. This consideration has led to a considerable hesitancy to study potassium channel openers in OAB patients. Nevertheless, one randomized, placebo-controlled clinical study on the KATP opener ZD0947 has been reported [Chapple et al., 2006]. While ZD0947 at the chosen dose did not lower blood pressure or cause adverse events typical for a vasodilating drug, it also failed to achieve superiority relative to placebo for the treatment of OAB symptoms. Therefore, despite promising preclinical efficacy data, potassium channel openers at present are not a therapeutic option and may never become one due to a lack of selectivity for bladder over cardiovascular tissues (Table 2).

III. DRUGS WITH “MIXED” ACTION

Some drugs used to block DO have been shown to have more than one mechanism of action. They all have a more or less pronounced antimuscarinic effect and, in addition, an often poorly defined “direct” action on bladder muscle. For several of these drugs, the antimuscarinic effects can be demonstrated at much lower drug concentrations than the direct action, which may involve blockade of voltage operated Ca\(^{2+}\) channels. Most probably, the clinical effects of these drugs can be explained mainly by an antimuscarinic action. Among the drugs with mixed actions was terodiline, which was withdrawn from the market because it was suspected to cause polymorphic ventricular tachycardia (torsade de pointes) in some patients [Connolly et al., 1991; Stewart et al., 1992].

1. OXYBUTYNIN CHLORIDE

Oxybutynin is a tertiary amine that is well absorbed, and undergoes extensive upper gastrointestinal and first-pass hepatic metabolism via the cytochrome P-450 system (CYP3A4) into multiple metabolites. The primary metabolite, N-desethyloxybutynin (DEO) has pharmacological properties similar to the parent compound [Waldeck et al., 1997], but occurs in much higher concentrations after oral administration [Hughes et al., 1992]. It has been implicated as the major cause of the troublesome side effect of dry mouth associated with the administration of oxybutynin. It seems reasonable to assume that the effect of oral oxybutynin to a large extent is exerted by the metabolite. The occurrence of an active metabolite may also explain the lack of correlation between plasma concentration of oxybutynin itself and side effects in geriatric patients reported by Ouslander et al. [1988]. The plasma half-life of the oxybutynin is approximately 2 hours, but with wide interindividual variation [Hughes et al., 1992; Douchamps et al., 1988].

Oxybutynin has several pharmacological effects in vitro, some of which seem difficult to relate to its effectiveness in the treatment of DO. It has both an antimuscarinic and a direct muscle relaxant effect, and, in addition, local anesthetic actions. The latter effect may be of importance when the drug is administered intravesically, but probably plays no role when it is given orally. In vitro, oxybutynin was 500 times weaker as a smooth muscle relaxant than as an antimuscarinic agent [Kachur et al., 1988]. Most probably, when given systemically, oxybutynin acts mainly as an antimuscarinic drug. Oxybutynin has a high affinity for muscarinic receptors in human bladder tissue and effectively blocks carbachol-induced contractions [Waldeck et al., 1997; Nilvebrant et al., 1988]. The drug was shown to have slightly higher affinity for muscarinic M1 and M3 receptors than for M2 receptors [Nilvebrant et al., 1986; Norhona-Blob et al., 1991], but the clinical significance of this is unclear.

The immediate release (IR) form of oxybutynin (OXY-IR) is recognized for its efficacy and most of the newer anti-muscarinic agents have been compared to it once efficacy over placebo has been determined. In general, the new formulations of oxybutynin and other anti-muscarinic agents offer patients efficacy roughly equivalent to that of OXY-IR, and the advantage of the newer formulations lies in improved dosing schedules and side-effect profile [Appell et al., 2001; Diokno et al., 2003; Dmochowski et al., 2002]. An extended release oxybutynin (OXY-ER) once daily oral formulation and an oxybutynin transdermal delivery system (OXY-TDS) are available. OXY-TDS offers a twice-weekly dosing regimen and the potential for improved patient compliance and tolerability.

Available formulations of oxybutynin were overviewed by McCrery and Appell [2006].
**a) Immediate-release oxybutynin (OXY-IR)**

Several controlled studies have have shown that OXY-IR is effective in controlling DO, including neurogenic DO [Yarker et al., 1995; Andersson and Chapelle, 2001]. The recommended oral dose of the IR form is 5 mg three times daily or four times daily, even if lower doses have been used. Thüroff et al. [1998] summarized 15 randomized controlled studies on a total of 476 patients treated with oxybutynin. The mean decrease in incontinence was recorded as 52% and the mean reduction in frequency per 24 h was 33% (data on placebo not presented). The overall “subjective improvement” rate was reported as 74% (range 61% - 100%). The mean percent of patients reporting an adverse effect was 70% (range 17% - 93%). Oxybutynin, 7.5 to 15 mg/day, significantly improved quality of life of patients suffering from overactive bladder in a large open multicenter trial. In this study, patients’ compliance was 97% and side effects, mainly dry mouth, were reported by only 8% of the patients [Amaranco et al., 1998]. In nursing home residents (n=75), Ouslander et al. [1995] found that oxybutynin did not add to the clinical effectiveness of prompted voiding in a placebo-controlled, double blind, cross-over trial. On the other hand, in another controlled trial in elderly subjects (n=57), oxybutynin with bladder training was found to be superior to bladder training alone [Szorny et al., 1995].

Several open studies in patients with spinal cord injuries have suggested that oxybutynin, given orally or intravesically, can be of therapeutic benefit [Szoller et al., 1996; Kim et al., 1996].

The therapeutic effect of OXY-IR on DO is associated with a high incidence of side effects (up to 80% with oral administration). These are typically antimuscarinic in nature (dry mouth, constipation, drowsiness, blurred vision) and are often dose-limiting [Baigrie et al., 1988; Jonville et al., 1992]. The effects on the electrocardiogram of oxybutynin were studied in elderly patients with urinary incontinence [Hussain et al., 1998]; no changes were found. It cannot be excluded that the commonly recommended dose 5 mg x 3 is unnecessarily high in some patients, and that a starting dose of 2.5 mg x 2 with following dose-titration would reduce the number of adverse effects [Amaranco et al., 1998].

**b) Extended release oxybutynin (OXY-ER)**

This formulation was developed to decrease liver metabolite formation of desethyloxybutynin (DEO) with the presumption that it would result in decreased side effects, especially dry mouth, and improve patient compliance with remaining on oxybutynin therapy. The formulation utilizes an osmotic system to release the drug at a controlled rate over 24 hours distally primarily into the large intestine where absorption is not subject to first-pass metabolism in the liver. This reduction in metabolism is meant to improve the rate of dry mouth complaints when compared to OXY-IR. DEO is still formed through the hepatic cytochrome P-450 enzymes, but clinical trials have indeed demonstrated improved dry mouth rates compared with OXY-IR [Appell et al., 2003]. Salivary output studies have also been interesting. Two hours after administration of OXY-IR or TOLT-IR, salivary production decreased markedly and then gradually returned to normal. With OXY-ER, however, salivary output was maintained at predose levels throughout the day [Chancellor et al., 2001].

The effects of OXY-ER have been well documented [Siddiqui et al., 2004]. In the OBJECT study [Appell et al., 2001], the efficacy and tolerability of 10 mg OXY-ER was compared to a twice daily 2 mg dose of TOLT-IR. OXY-ER was statistically more effective than the TOLT-IR in weekly urgency incontinence episodes (OXY-ER from 25.6% to 6.1%; TOLT-IR 24.1% to 7.8%), total incontinence (OXY-ER from 28.6% to 7.1%; TOLT-IR 27.0% to 9.3%), and frequency (OXY-ER from 91.8% to 67.1%; TOLT-IR 91.6% to 71.5%) and both medications were equally well tolerated. The basic study was repeated as the OPERA study [Diochno et al., 2003] with the difference that this study was a direct comparison of the two extended-release forms, OXY-ER (10 mg) and TOLT-ER (4 mg) and the results were quite different. In this study there was no significant difference in efficacy for the primary endpoint of urgency incontinence, however, TOLT-ER had a statistically lower incidence of dry mouth. OXY-ER was only statistically better at 10 mg than TOLT-ER 4 mg in the reduction of the rate of urinary frequency. These studies made it clear that in comparative studies IR entities of one drug should not be compared with ER entities of the other.

Greater reductions in urgency and total incontinence have been reported in patients treated in dose-escalation studies with OXY-ER. In two randomized studies, the efficacy and tolerability of OXY-ER were compared with OXY-IR. In the 1999 study [Anderson et al., 1999], 105 patients with urgency or mixed incontinence were randomized to receive 5-30 mg OXY-ER once daily or 5 mg of OXY-IR 1-4 times/day. Dose titrations began at 5 mg and the dose was increased every 4-7 days until one of three endpoints was achieved. These were 1) the patient reported no urgency incontinence during the final two days of the dosing period; 2) the maximum tolerable dose was reached; the maximum allowable dose (30 mg for OXY-ER or 20 mg for OXY-IR) was reached. The mean percentage reduction in weekly urgency and total incontinence episodes was statistically similar between OXY-ER and OXY-IR but dry mouth was reported statistically more often with OXY-IR. In the 2000 study [Versi et al., 2000], 226 patients were randomized between OXY-ER and OXY-IR with weekly increments of 5 mg daily up to 20 mg daily. As in the 1999 study,
OXY-ER again achieved a >80% reduction in urgency and total incontinence episodes and a significant percentage of patients became dry. A negative aspect of these studies is that there were no naive patients included, as all patients were known responders to oxybutynin. Similar efficacy results have been achieved, however, with OXY-ER in a treatment-naive population [Gleason et al., 1999].

In an RCT comparing different daily doses of oxybutynin (5, 10 and 15 mg), Corcos et al. [2006] found a significant dose-response relationship for both urgency incontinence episodes and dry mouth. The greatest satisfaction was with 15 mg oxybutynin/day.

c) Transdermal oxybutynin (OXY-TDS)

Transdermal delivery also alters oxybutynin metabolism reducing DEO production to an even greater extent than OXY-ER. A study [Davila et al., 2001] comparing OXY-TDS with OXY-IR demonstrated a statistically equivalent reduction in daily incontinent episodes (from 7.3 to 2.3: 66% for OXY-TDS, and 7.4 to 2.6: 72% for OXY-IR), but much less dry mouth (38% for OXY-TDS and 94% for OXY-IR). In another study [Dmochowski et al., 2002] the 3.9-mg daily dose patch significantly (vs placebo) reduced the mean number of daily incontinence episodes (from 4.7 to 1.9; placebo from 5.0 to 2.9), while reducing average daily urinary frequency confirmed by an increased average voided volume (from 165 to 198 ml; placebo from 175 to 182 ml). Furthermore, dry mouth rate was similar to placebo (7% vs 8.3%). In a third study [Dmochowski et al., 2003] OXY-TDS was compared not only to placebo but to TOLT-ER. Both drugs equivalently and significantly reduced daily incontinence episodes and increased the average voided volume, but TOLT-ER was associated with a significantly higher rate of antimuscarinic adverse events. The primary adverse event for OXY-TDS was application site reaction pruritis in 14% and erythema in 8.3% with nearly 9% feeling that the reactions were severe enough to withdraw from the study, despite the lack of systemic problems.

The pharmacokinetics and adverse effect dynamics of OXY-TDS (3.9 mg/day) and OXY-ER (10 mg/day) were compared in healthy subjects in a randomized, 2-way crossover study [Appell et al., 2003]. Multiple blood and saliva samples were collected and pharmacokinetic parameters and total salivary output were assessed. OXY-TDS administration resulted in greater systemic availability and minimal metabolism to DEO compared to OXY-ER which resulted in greater salivary output in OXY-TDS patients and less dry mouth symptomatology than when taking OXY-ER.

Dmochowski et al. [2005] analyzing the combined results of two RCTs concluded that transdermal oxybutynin was shown to be efficacious and well tolerated. The most common systemic side effect was dry mouth (7.0 % vs placebo 5.3%). Application site erythema occurred in 7% and pruritus in 16.1 %. Also Cartwright and Cardozo [2008], reviewing published and presented data concluded that transdermal oxybutynin has a good balance between efficacy and tolerability with a rate of systemic antimuscarinic side effects lower that with oral antimuscarinics – however, this benefit was offset by the rate of local skin reaction. Sahai et al. [2008] in a recent review largely confirmed these conclusions.

d) Other administration forms

Rectal administration [Collas and Malone-Lee, 1997] was reported to have fewer adverse effects than the conventional tablets. Administered intravesically, oxybutynin has in several studies been demonstrated to increase bladder capacity and produce clinical improvement with few side effects, both in neurogenic and in other types of DO, and both in children and adults [Lose and Norgaard, 2001; Fader et al., 2007; George et al., 2007; Guerra et al., 2008], although adverse effects may occur [Kasabian et al., 1994; Palmer et al., 1997].

e) Effects on cognition

Several studies have documented the possibility that oxybutynin may have negative effects on cognitive functions, particularly in the elderly population but also in children [see, e.g., Kay et al., 2006; Klausner al Steers, 2007; Kay and Ebinger, 2008], although adverse effects should be taken into consideration when prescribing the drug.

Oxybutynin has a well-documented efficacy in the treatment of OAB/DO (Table 2). Despite the adverse effect profile, it is still an established therapeutic option.

2. PROPIVERINE HYDROCHLORIDE

Several aspects of the preclinical, pharmacokinetic, and clinical effects of propiverine have been reviewed by Madersbacher and Murz [2001]. The drug is rapidly absorbed (t_{max} 2 h), but has a high first pass metabolism, and its biological availability is about 50%. Propiverine is an inducer of hepatic cytochrome P450 enzymes in rats in doses about 100-times above the therapeutic doses in man [Walter et al., 2003]. Several active metabolites are formed which quantitatively and qualitatively differ from the mother compound [Haustein et al., 1988; Muller et al., 1993; Wuest et al., 2006; Zhu et al., 2008; Sugiyama et al., 2008]. Most probable these metabolites contribute to the clinical effects of the drug, but their individual contributions have not been clarified [Michel and Hegde, 2006]. The half-life of propiverine itself is about 11-14 h. An extended release preparation was shown to be effective [Junemann et al., 2006; May et al., 2008].
Propiverine has combined antimuscarinic and calcium antagonistic actions [Haruno, 1992; Tokuno et al., 1993]. The importance of the calcium antagonistic component for the drug’s clinical effects has not been established. Propiverine has no selectivity for muscarinic receptor subtypes.

Propiverine has been shown to have beneficial effects in patients with DO in several investigations. Thüroff et al [1998] collected 9 randomized studies on a total of 230 patients, and found a 17% reduction in micturitions per 24 hours, a 64 ml increase in bladder capacity, and a 77% (range 33-80%) subjective improvement. Side effects were found in 14% (range 8-42%). In patients with neurogenic DO, controlled clinical trials have demonstrated propiverine’s superiority over placebo [Stöhrer et al., 1999]. Propiverine also increased bladder capacity and decreased maximum detrusor contractions. Controlled trials comparing propiverine, flavoxate and placebo [Wehnert et al., 1989], and propiverine, oxybutynin and placebo [Wehnert et al., 1992; Madersbacher et al., 1999], have confirmed the efficacy of propiverine, and suggested that the drug may have equal efficacy and fewer side effects than oxybutynin. In a comparative RCT including 131 patients with neurogenic DO, propiverine and oxybutynin were compared [Stöhrer et al., 2007]. The drugs were found to be equally effective in increasing bladder capacity and lowering bladder pressure. Propiverine caused a significantly lower frequency of dry mouth than oxybutynin.

Also in children and adolescents with neurogenic DO, propiverine was found to be effective [Schulte-Baukloh et al., 2006; Grigoleti et al., 2006], with a low incidence rate of adverse events: <1.5% [Grigoleti et al., 2006].

Madersbacher et al. [1999] compared the tolerability and efficacy of propiverine (15 mg three times daily) oxybutynin (5 mg twice daily) and placebo in 366 patients with urgency and urgency incontinence in a randomized, double-blind placebo-controlled clinical trial. Urodynamic efficacy of propiverine was judged similar to that of oxybutynin, but the incidence of dry mouth and the severity of dry mouth were judged less with propiverine than with oxybutynin. Dorschner et al. [2000] investigated in a double-blind, multicentre, placebo-controlled, randomized study, the efficacy and cardiac safety of propiverine in 98 elderly patients (mean age 68 years), suffering from urgency, urgency incontinence or mixed urgency-stress incontinence. After a 2-week placebo run-in period, the patients received propiverine (15 mg three times daily) or placebo (three times daily) for 4 weeks. Propiverine caused a significant reduction of the micturition frequency (from 8.7 to 6.5) and a significant decrease in episodes of incontinence (from 0.9 to 0.3 per day). The incidence of adverse events was very low (2% dryness of the mouth under propiverine – 2 out of 49 patients). Resting and ambulatory electrocardiograms indicated no significant changes.

In a randomised, double-blind, multicentre clinical trial, patients with idiopathic DO were treated with 15 mg propiverine twice daily or 2 mg TOLT-IR twice daily over a period of 28 days [Junemann et al., 2005]. The maximum cystometric capacity was determined at baseline and after 4 weeks of therapy. The difference of both values was used as the primary endpoint. Secondary endpoints were voided volume per micturition, evaluation of efficacy (by the investigator), tolerability, post void residual urine, and quality of life. It was found that the mean maximum cystometric capacity increased significantly (p < 0.01) in both groups. The volume at first urgency and the frequency/volume chart parameters also showed relevant improvements during treatment. The most common adverse event, dry mouth, occurred in 20 patients in the propiverine group and in 19 patients in the tolterodine group. The scores for the quality of life improved comparably in both groups.

Abrams et al. [2006] compared the effects of propiverine and oxybutynin on ambulatory urodynamic monitoring (AUM) parameters, safety, and tolerability in OAB patients. Patients (n=77) received two of the following treatments during two 2-week periods: propiverine 20 mg once daily, propiverine 15 mg three times daily, oxybutynin 5 mg three times daily, and placebo. They found that oxybutynin 15 mg was more effective than propiverine 20 mg in reducing symptomatic and asymptomatic involuntary detrusor contractions in ambulatory patients. Oxybutynin had a higher rate of dry mouth, and propiverine had a more pronounced effect on gastrointestinal, cardiovascular, and visual function.

A randomized, double-blind, placebo-controlled trial with parallel-group design in children aged 5–10 yr was performed by Marschall-Kehrel et al. [2008]. Of 171 randomized children, 87 were treated with propiverine and 84 with placebo. Decrease in voiding frequency per day was the primary efficacy parameter; secondary endpoints included voided volume and incontinence episodes. There was a significant decrease in voiding frequency episodes for propiverine versus placebo. Superiority could also be demonstrated for voided volume and incontinence episodes per day. Propiverine was well-tolerated: 23% of side-effects were reported for propiverine and 20% for placebo.

Yamaguchi et al. [2008] performed a multicentre, 12-week, double-blind phase III trial in Japanese men and women with OAB (1593 patients were randomized and 1584 were treated), comparing solifenacin 5 or 10 mg, propiverine 20 mg, and placebo. Changes at endpoint in number of voids/24 hours, urgency, incontinence, urgency incontinence and nocturia episodes, volume voided/void, restoration of continence and quality of life (QoL) were examined. It was found that at endpoint, there were greater reductions in mean (SD) voids/24 hours with all drug regimens than with placebo. All active treatments
improved the volume voided and QoL vs placebo; solifenacin 10 mg reduced nocturia episodes and significantly improved urgency episodes and volume voided vs propiverine 20 mg, and solifenacin 5 mg caused less dry mouth. Solifenacin 10 mg caused more dry mouth and constipation than propiverine 20 mg.

Propiverine has a documented beneficial effect in the treatment of OAB/DO (Table 2), and seems to have an acceptable side effect profile.

3. FLAVOXATE HYDROCHLORIDE

Flavoxate is well absorbed, and oral bioavailability appeared to be close to 100% [Guay, 2003]. The drug is extensively metabolized and plasma half-life was found to be 3.5 h [Sheu et al., 2001]. Its main metabolite (3-methylflavone-8-carboxylic acid, MFCA) has been shown to have low pharmacological activity [Cazzulani et al., 1988; Caine et al., 1991]. The main mechanism of flavoxate’s effect on smooth muscle has not been established. The drug has been found to possess a moderate calcium antagonistic activity, to have the ability to inhibit phosphodiesterases, and to have local anesthetic properties; no antimuscarinic effect was found [Guarneri et al., 1994]. Uckert et al. [2000], on the other hand, found that in strips of human bladder, the potency of flavoxate to reverse contraction induced by muscarinic receptor stimulation and by electrical field stimulation was comparable. It has been suggested that pertussis toxin-sensitive G-proteins in the brain are involved in the flavoxate-induced suppression of the micturition reflex, since intracerebroventricularly or intrathecally administered flavoxate abolished isovolumetric rhythmic bladder contractions in anesthetized rats [Oka et al., 1996].

The clinical effects of flavoxate in patients with DO and frequency, urgency and incontinence have been studied in both open and controlled investigations, but with varying rates of success [Ruffman, 1988]. Stanton [1973] compared emepronium bromide and flavoxate in a double-blind, cross-over study of patients with detrusor overactivity and reported improvement rates of 83% and 66% after flavoxate or emepronium bromide, respectively, both administered as 200 mg 3 times daily. In another double-blind, cross-over study comparing flavoxate 1200 mg/day with that of oxybutynin 15 mg daily in 41 women with idiopathic motor or sensory urgency, and utilising both clinical and urodynamic criteria, Milani et al. [1993] found both drugs effective. No difference in efficacy was found between them, but flavoxate had fewer and milder side effects. Other investigators, comparing the effects of flavoxate with those of placebo, have not been able to show any beneficial effect of flavoxate at dosages up to 400 mg three times daily [Briggs et al., 1980; Chapple et al., 1990; Dahm et al., 1995].

In general, few side effects have been reported during treatment with flavoxate. On the other hand its efficacy, compared to other therapeutic alternatives, is not well documented (Table 2).

No RCTs seem to have been performed with flavoxate during the last decade.

IV. α-ADRENOCEPTOR (AR) ANTAGONISTS

Even if it is well known that α1-AR antagonists can ameliorate lower urinary tract symptoms in men with BPE [Andersson et al., 2002], there are no controlled clinical trials showing that they are an effective alternative in the treatment of OAB/DO in this patient category. In an open label study, Arnold [2001] evaluated the clinical and pressure-flow effects of tamsulosin 0.4 mg once daily in patients with lower urinary tract symptoms (LUTS) caused by benign prostatic obstruction (BPO). He found that tamsulosin produced a significant decrease in detrusor pressure, increase in flow rate and a symptomatic improvement. In a study where tamsulosin was given alone, or together with tolterodine, to patients with male LUTS, monotherapy with the drug was not effective [Kaplan et al., 2006]. An RCT, comprising 364 women with OAB, revealed no effect of tamsulosin vs placebo [Robinson et al., 2007]. On the other hand, voiding symptoms in women with functional outflow obstruction, or LUTS, were successfully treated with an α1-AR antagonist [Kessler et al., 2006, Low et al., 2008].

α1-AR antagonists have been used to treat patients with neurogenic DO [Abrams et al., 2003]; however, the success has been moderate. Thus, there is no convincing evidence that α1-AR antagonists are effective in patients with storage symptoms. Although α1-AR antagonists may be effective in selected cases, convincing effects documented in RCTs are lacking (Table 2). In women, these drugs may produce stress incontinence [Dwyer and Teele, 1992].

V. β-ADRENOCEPTOR AGONISTS

In isolated human bladder, non-subtype selective β-AR agonists like isoprenaline have a pronounced inhibitory effect, and administration of such drugs can increase bladder capacity in man [Andersson, 1993]. However, the β-ARs of the human bladder were shown to have functional characteristics typical of neither β1-, nor β2- ARs, since they could be blocked by propranolol, but not by practolol or metoprolol (β1) or butoxamine (β2) [Nergard et al., 1977; Larsen, 1979]. On the other hand, early receptor binding studies using subtype selective ligands, suggested that the β-ARs of the human detrusor are primarily of β2 subtype [Andersson 1993], and favourable effects on DO were reported in open studies with selective
β2-AR agonists such as terbutaline [Lindholm and Lose, 1988]. In a double-blind investigation clenbuterol 0.01 mg 3 times daily was shown to have a good therapeutic effect in 15 of 20 women with DO [Grunenberger, 1984]. Other investigators, however, have not been able to show that β-ARs agonists represent an effective therapeutic principle in elderly patients with DO [Castleden and Morgan, 1980], or in young patients with myelodysplasia and DO [Naglo et al., 1981].

However, three subtypes (β1, β2, and β3) have been identified in the detrusor of most species, including humans [Andersson and Arner, 2004; Michel and Vrydag, 2006]. Also the human urothelium contains all three receptor subtypes [Otsuka et al., 2008]. Studies, using real-time RT-PCR, have revealed a predominant expression of β3-AR mRNA in human detrusor muscle [Nomiyama and Yamaguchi, 2003; Michel and Vrydag, 2006] and the functional evidence for an important role in both normal and neurogenic bladders is convincing [Fujimura et al., 1999; Igawa et al., 1999; Takeda et al., 1999; Morita et al., 2000; Igawa et al., 2001; Biers et al., 2006; Michel and Vrydag, 2006; Badawi et al., 2007; Leon et al., 2008]. The human detrusor also contains β2-ARs, and most probably both receptors are involved in the physiological effects (relaxation) of noradrenaline in this structure [Andersson and Arner 2004; Michel and Vrydag, 2006].

The generally accepted mechanism by which β-ARs induce detrusor relaxation in most species, is activation of adenyl cyclase with the subsequent formation of cAMP. However, there is evidence suggesting that in the bladder K+ channels, particularly BKCa channels, may be more important in β-AR mediated relaxation than cAMP [Hudman et al., 2000; Frazier et al., 2005; Uchida et al., 2005; Frazier et al., 2008].

Since β-ARs are present in the urothelium, their possible role in bladder relaxation has been investigated [Murakami et al., 2007; Otsuka et al., 2008]. Murakami et al. [2007] found that the relaxation responses of the detrusor were not influenced by the urothelium. However, isoprenaline was more potent at inhibiting carbachol contractions in the presence of the urothelium than in its absence. It was suggested that this might reflect the release of an inhibitory factor from the urothelium. Further support for this hypothesis was given by Otsuka et al. [2008]. However, to what extent a urothelial signaling pathway contributes in vivo and in vitro to the relaxant effects of β-AR agonists in general, and β3-AR agonists specifically, remains to be elucidated.

The in vivo effects of β3-AR agonists on bladder function have been studied in several animal models. It has been shown that compared with other agents (including antimuscarinics), β3-AR agonists increase bladder capacity with no change in micturition pressure and the residual volume [Fujimura et al., 1999; Woods et al., 2001; Takeda et al., 2002; Koidoh et al., 2002]. For example, Hicks et al. [2007] studied the effects of the selective β3-AR agonist, GW427353, in the anesthetized dog and found that the drug evoked an increase in bladder capacity under conditions of acid evoked bladder hyperactivity, without affecting voiding.

A number of β3-AR selective agonists are currently being evaluated as potential treatment for OAB in humans including GW427353 (solabegron) and YM178 [Colli et al., 2007]. Takaku et al. [2007] found that the selective β3-AR agonist, YM187, mediated muscle relaxation of human bladder strips. Chapple et al. [2008] reported the results of a controlled clinical trial with this drug in patients with OAB. Tolterodine and placebo served as controls. The primary efficacy analysis showed a statistically significant reduction in mean micturition frequency, compared to placebo (-2.19 vs -1.18). With respect to secondary variables YM178 (100 mg) was significantly superior to placebo concerning mean volume voided per micturition (26 vs 11 ml), mean number of incontinence episodes (-2.17 vs -1.01), and urgency episodes per 24 hour (-2.30 vs -1.03). The drug was well tolerated, and the most commonly reported side effects were headache and gastrointestinal adverse effects. The results of this proof of concept study showed that the principle of β3-AR agonism may be useful for treatment of patients with OAB (Table 2). However, to show that this class of drugs offers a viable therapeutic alternative or complement to current treatment of LUTS/OAB requires further well designed RCTs.

VI. PHOSPHODIESTERASE (PDE) INHIBITORS

Drugs stimulating the generation of cAMP are known to relax smooth muscles, including the detrusor [Andersson 1999; Andersson and Arner, 2004]. It is also well established that drugs acting through the NO/cGMP system can relax the smooth muscle of the bladder outflow region [Andersson and Arner, 2004]. Use of PDE inhibitors to enhance the presumed cAMP- and cGMP-mediated relaxation of LUT smooth muscles (detrusor prostate, urethra) should then be a logical approach [Andersson et al., 2007]. There are presently 11 families of PDEs, some of which preferentially hydrolyse either cAMP or cGMP [Andersson et al. 2007].

As a basis for PDE inhibitor treatment of LUTS, Uckert et al. [2001] investigated human bladder tissue, revealing messenger RNA for PDEs 1A, 1B, 2A, 4A, 4B, 5A, 7A, 8A, and 9A; most of these PDEs preferably hydrolyse either cAMP or cGMP.
detrusor muscle, paralleled by increases in cyclic nucleotide levels, was induced by papaverine, vinpocetine (a low affinity inhibitor of PDE 1), and forskolin (stimulating the generation of cAMP), suggesting that the cAMP pathway and PDE 1 may be important in regulation of detrusor smooth muscle tone. Significant dose-dependent relaxations were also induced by human cAMP analogs [Truss et al., 2001]. With these studies as a background, Truss et al. [2000] presented preliminary clinical data with vinpocetine in patients with urgency/urgency incontinence or low compliance bladders, and not responding to standard antimuscarinic therapy. This initial open pilot study suggested a possible role for vinpocetine in the treatment of OAB. However, the results of a larger RCT in patients with DO showed that vinpocetine showed statistically significant results only for one parameter [Truss et al., 2001]. Studies with other PDE 1 inhibitors than vinpocetin (which may not be an optimal drug for elucidation the principle) do not seem to have been performed.

PDE 4 (which also preferably hydrolyses cAMP) has been implicated in the control of bladder smooth muscle tone. PDE 4 inhibitors reduced the in vitro contractile response of guinea pig [Longhurst et al., 1997] and rat [Nishiguchi et al., 2006; Kaiho et al., 2008] bladder strips, and also suppressed rhythmic bladder contractions of the isolated guinea pig bladder [Gillespie, 2004]. Previous experiences with selective PDE 4 inhibitors showed emesis to be a dose-limiting effect [Giembycz, 2005]. If this side action can be avoided, PDE 4 inhibition seems to be a promising approach.

Nitric oxide (NO) has been demonstrated to be an important inhibitory neurotransmitter in the smooth muscle of the urethra and its relaxant effect is associated with increased levels of cyclic GMP [Andersson and Wein, 2004]. However, few investigations have addressed the cAMP- and cGMP-mediated signal transduction pathways and its key enzymes in the mammalian urethra. Morita et al. [1994] examined the effects of isoproterenol, prostaglandin E1 and E2, and SNP on the contractile force and tissue content of cAMP and cGMP in the rabbit urethra. They concluded that both cyclic nucleotides can produce relaxation of the urethra. Werkström et al. [2006] characterized the distribution of PDE 5, cGMP and PKG1 in female pig and human urethra, and evaluated the effect of pharmacological inhibition of PDE-5 in isolated smooth muscle preparations. After stimulation with the NO donor, DETA NONO-ate, the cGMP-immunoreactivity (IR) in urethral and vascular smooth muscles increased. There was a wide distribution of cGMP- and vimentin-positive interstitial cells between pig urethral smooth muscle bundles. PDE-5 IR could be demonstrated within the urethral and vascular smooth muscle cells, but also in vascular endothelial cells that expressed cGMP-IR. Nerve-induced relaxations of urethral preparations were enhanced at low concentrations of sildenafil, vardenafil and tadalafl, whereas there were direct smooth muscle relaxant actions of the PDE-5 inhibitors at high concentrations.

The distribution of PDEs in the male urethral structures does not seem to have been studied. The observation that patients treated for erectile dysfunction with PDE 5 inhibitors had an improvement of their LUTS, has sparked a new interest in using these drugs also for treatment of LUTS and OAB. After the report in an open study [Sairam et al., 2002] that treatment with sildenafil appeared to improve urinary symptom scores in men with ED and LUTS, this observation has been confirmed in several well-designed and conducted RCTs [McVary et al., 2007a,b; Stief et al., 2008].

McVary et al. [2007a] evaluated the effects of sildenafil (50-100 mg daily for 12 weeks) on erectile dysfunction and LUTS in men 45 years or older who scored 25 or less on the erectile function domain of the International Index of Erectile Function (IIEF) and 12 or greater on the International Prostate Symptom Score (IPSS). In 189 men receiving sildenafil significant improvements were observed in IPPS (-6.32 vs -1.93, p<0.0001), Benign Prostatic Hyperplasia Impact Index (-2.0 vs -0.9, p<0.0001), mean IPSS quality of life score (-0.97 vs -0.29, p<0.0001) and total Self-Esteem and Relationship questionnaire scores (24.6 vs 4.3, p<0.0001). Interestingly, there was no difference in urinary flow between the groups (p=0.08). Significantly more sildenafil vs placebo treated patients were satisfied with treatment (71.2 vs 41.7, p<0.0001). Sildenafil was well tolerated.

In an RCT, treatment with tadalafl once daily, in addition to improving erectile function in men with LUTS, was demonstrated to produce a clinically meaningful and statistically significant symptomatic improvement of LUTS [McVary et al., 2007b]. In another RCT, vardenafil given twice daily for eight weeks to men with ED and LUTS, was shown to significantly improve LUTS, erectile function, and quality of life Stief et al. [2008].

The mechanism behind the beneficial effect of the PDE inhibitors on LUTS/OAB and their site(s) of action largely remain to be elucidated. If the site of action were the smooth muscles of the outflow region (and the effect relaxation), an increase in flow rate should be expected. In none of the trials referred to such an effect was found. However, there are several other structures in the LUT that may be involved, including those in the urothelial signaling pathway (urothelium, interstitial cells, and suburothelial afferent nerves).

PDE-5 inhibitors have a documented effect in men with LUTS/OAB (Table 2). The place of PDE-5 inhibitors in the treatment of OAB/DO remains to be established. Specifically, there seems to be no published information the effects of these drugs in women with OAB/DO.
VII. ANTIDEPRESSANTS

1. IMIPRAMINE

Several antidepressants have been reported to have beneficial effects in patients with DO [Martin and Schiff, 1984, Lose et al., 1989]. However, imipramine is the only drug that has been widely used clinically to treat this disorder.

Imipramine has complex pharmacological effects, including marked systemic antimuscarinic actions [Baldessarini, 1985] and blockade of the reuptake of serotonin and noradrenaline [Maggi et al., 1989], but its mode of action in DO has not been established [Hunsballe and Djurhuus, 2001]. Even if it is generally considered that imipramine is a useful drug in the treatment of DO, no good quality RCTs that can document this have been retrieved.

It has been known for a long time that imipramine can have favourable effects in the treatment of nocturnal enuresis in children with a success rate of 10-70% in controlled trials [Hunsballe and Djurhuus, 2001; Glazener et al., 2003]. It is well established that therapeutic doses of tricyclic antidepressants, including imipramine, may cause serious toxic effects on the cardiovascular system (orthostatic hypotension, ventricular arrhythmias). Imipramine prolongs QTc intervals and has an antiarrhythmic (and proarrhythmic) effect similar to that of quinidine [Bigger et al., 1977; Giradina et al., 1979]. Children seem particularly sensitive to the cardiotoxic action of tricyclic antidepressants [Baldessarini, 1985].

The risks and benefits of imipramine in the treatment of voiding disorders do not seem to have been assessed. Very few studies have been performed during the last decade [Hunsballe and Djurhuus, 2001]. No good quality RCTs have documented that the drug is effective in the treatment DO (Table 2). However, a beneficial effect has been documented in the treatment of nocturnal enuresis.

2. DULOXETINE

Duloxetine is a combined noradrenaline and serotonin reuptake inhibitor, which has been shown to significantly increase sphincteric muscle activity during the filling/storage phase of micturition in the cat acetic acid model of irritated bladder function [Thor et al., 1995; Katofiasc et al., 2002]. Bladder capacity was also increased in this model, both effects mediated centrally through both motor efferent and sensory afferent modulation [Fraser et al., 2003]. The effects of duloxetine were studied in a placebo-controlled study comprising 306 women (aged 21-84 years) with OAB, randomly treated with placebo (153) or duloxetine (80-mg/day for 4 weeks, which was increased to 120-mg/day for eight weeks [Steers et al., 2008]. The primary efficacy analysis compared the treatment effects on mean change from baseline to endpoint in the mean number of voiding episodes per 24 hours. Patients randomized to duloxetine had significant improvements over those randomized to placebo for decreases in voiding and incontinence episodes (-1.81 vs -0.62), for increases in the daytime voiding intervals (29 vs 7 minutes), and for improvements in I-QoL scores at both doses of the drug. Urodynamic studies showed no significant increases in maximum cystometric capacity or in the volume threshold for DO. The most common treatment-emergent adverse events with duloxetine (nausea, 31%, placebo, 4.6; dry mouth, 16%, placebo, 1.3; dizziness, 14%, placebo 0.7; constipation, 14%, placebo, 3.3; insomnia, 13%, placebo1.3; and fatigue, 11%, placebo 2.0) were the same as those reported by women with SUI (see below) and were significantly more common with duloxetine than placebo. Also in females with mixed incontinence, improvement of the OAB component has been demonstrated [Bent et al., 2008; Schagen van Leeuwen et al., 2008]. For assessment, see Table 2.

VIII. CYCLOOXYGENASE (COX) INHIBITORS

Human bladder mucosa has the ability to synthesize eicosanoids [Jeremy et al., 1987], and these agents can be liberated from bladder muscle and mucosa in response to different types of trauma [Downie and Karmazyn, 1984; Leslie et al., 1984]. Even if prostaglandins cause contraction of human detrusor [Andersson, 1993], it is still unclear whether prostaglandins contribute to the pathogenesis of DO. More important than direct effects on the bladder muscle may be sensitization of sensory afferent nerves, increasing the afferent input produced by a given degree of bladder filling. Involuntary bladder contractions can then be triggered at a small bladder volume. If this is an important mechanism, treatment with prostaglandin synthesis inhibitors could be expected to be effective. However, clinical evidence for this is scarce.

Cardozo et al. [1980] performed a double-blind controlled study of 30 women with DO using the prostaglandin synthesis inhibitor flurbiprofen at a dosage of 50 mg three times daily. The drug was shown to have favourable effects, although it did not completely abolish DO. There was a high incidence of side effects (43%) including nausea, vomiting, headache and gastrointestinal symptoms. Palmer [1983] studied the effects of flurbiprofen 50 mg x 4 versus placebo in a double-blind, cross-over trial in 37 patients with idiopathic DO (27% of the patients did not complete the trial). Active treatment significantly increased maximum contractile pressure, decreased the number of voids and decreased the number of urgent voids compared to baseline. Indomethacin 50 to 100 mg daily was reported to give symptomatic relief in patients with DO, compared with bromocriptine in a randomized, single-blind, cross-over study.
Botulinum toxin (BONT) is a neurotoxin produced by Clostridium botulinum. Of the seven subtypes of BONT, sub-type A (BONT-A) is the most relevant clinically. Most of the intravesical experience reported on BONT-A deals with Dyspor®, however, BONT-A toxin is also available under the trade names of Dyspor®, and Xeomin. Bladder experience with the latter was, however, never reported. Available information indicates that Botox® is roughly three times more potent than Dyspor® [Cruz and Silva, 2004; Nitti et al., 2006]. However this relation has never been clearly defined. Therefore at a bladder setting these equivalents should be approached with caution for clinical reviews, see Nitti et al., 2006; Patel et al., 2006; Cruz and Dinis, 2007; Karsenty et al, 2008. In addition to sub-type A, recent reports have investigated the detrusor injection of BONT sub-type B (Neurobloc®, Miobloc®). For further details see section 9.1.9.

BONT consists of a heavy and a light chain linked by a disulphide bond. In the synaptic cleft the toxin binds to synaptic vesicle protein or SV2 [Dong et al., 2006] through its heavy chain and is internalized by the nerve terminal. Upon cleavage, the light chain is released in the cytosol, where it impedes binding of neurotransmitter-containing synaptic vesicles to the plasma membrane. This is achieved through the N-ethylmaleimide-sensitive factor attachment protein (SNARE) complex made up of synaptosome associated protein 25 kD (SNAP 25), synaptobrevin (vesicle associated membrane protein -VAMP) and syntaxin. BONT-A cleaves SNAP 25 rendering the SNARE complex inactive [Humeau et al., 2000; Chancellor et al., 2008]. Subtype B, acts preferentially through the inactivation of VAMP [Humeau et al., 2000].

BONT-A application was extensively evaluated in striated muscle. Paralysis occurs by prevention of ACh release from cholinergic motor nerve endings [Humeau et al, 2000]. Accumulation of neurotransmitter containing synaptic vesicles is followed by terminal axonal degeneration. Muscular paralysis recovers within two to four months time. During this time axons are developing lateral sprouts and eventually regenerate completely [de Paiva et al., 1999]. As parasympathetic cholinergic nerves are also fundamental for detrusor contraction the blockade of ACh release was immediately put forward as the rationale for the neurotoxin effect when injected in the bladder. However axon sprouting concomitant with clinical remission has not been documented in the detrusor [Haferkamp et al., 2004]. Furthermore fragments of cleaved SNAP 25 are detectable in bladder biopsy specimens of patients treated intravesically with BONT-A long after they become undetectable in striated muscle [Schulte-Baukloh et al., 2007]. These facts indicate that additional mechanisms of action are probably operative in the bladder. BONT-A inhibits the spinal cord release of glutamate, Substance P (SP) and CGRP by sensory nerves [Aoki et al., 2005; Purkiss et al., 2000; Meng et al., 2007] as well as the release of neuropeptides at the peripheral extremities [Lucioni et al., 2008; Rapp et al., 2006]. In the bladder, BONT-A has been shown to reduce the suburothelial immunoreactivity for TRPV1 or P2X3 [Apostolidis et al, 2005]. Furthermore BONT-A has been shown to inhibit ATP release from urothelium in animal models of spinal cord injury [Khera et al, 2004; Smith et al., 2008]. Morenilla Palao et al. [2004] have shown co-localization of SNARE proteins and TRPV1 in sensory nerves and that BONT-A impedes TRPV1 trafficking from intracellular vesicles to the plasma membrane during inflammation.

BONT-A may decrease the levels of neurotrophic agents in the bladder tissue. Neurogenic DO (NDO) patients produce more Nerve Growth Factor (NGF) in the bladder than control individuals [Giannantoni et al, 2006; Liu et al, 2008] and a significant decrease can be detected after intravesical the application of...
the toxin. As NGF is paramount for sensory nerve growth, maintenance and plasticity, this finding may point toward another mechanism whereby BONT-A acts upon the bladder.

**b) BONT-A injection protocol**

When the treatment was first described in 1999, BONT-A (Botox®) was diluted in normal saline in order to obtain a concentration of 10 Units/ml [Schurch et al., 2000]. Under visual control through a rigid cystoscope and a flexible 6 Fr injection needle, 30 injections of 1 ml (10 Units (U) of BONT-A toxin) were done in 30 different locations above the trigone to prevent vesico-urethral reflux (**Figure 13**). Additional refinements have been added to this technique along the following years, including the use of a local anaesthetic agent (4% lidocaine) and a flexible cystoscope [Harper et al., 2003]. For Dyspor® the technique was similar, including the number of injection sites. Only the dilutions were different taking in consideration that 500-1000 U were used [Cruz and Silva, 2004].

The effect of BONT-A after increasing the dose per injection site and decreasing the number of injected sites was investigated in one study. Patients were randomized to receive 300 U either in 10 or 30 sites [Karsenty et al., 2005]. The authors reported that 10-site injection was quicker and less painful and that no differences in efficacy between the two procedures could be detected up to 24 weeks. Another variation is the neurotoxin injection in the trigone. The suggested risks of injecting bladder trigone has never been demonstrated, whether Botox® or Dyspor® was used [Karsenty et al., 2007; Mascarenhas et al., 2008; Citeri et al., 2008]. However, this does not mean that trigonal injections bring marked benefits to the treatment. One trial concluded that 100 U of Botox® injected only in the trigone were less effective and durable than when administered in the detrusor [Kuo et al., 2007]. Injection in the sub-urothelial space was also assayed on the suggestion that in this position the BONT-A effect could be more pronounced in sensory than in parasympathetic motor fibers (Kuo et al., 2005). However, in one comparative study injection of 100 U of Botox® in the suburothelial space was less effective than in the detrusor [Kuo et al., 2007]. Another variable of the injection technique is the diluent volume. Most studies used 1.0 mL per injection, although a few used 0.5 mL [Grosse et al., 2005; Schulte-Baukloh et al., 2005], 0.2 mL (Kuo et al., 2004), or even 0.1 mL per injection site [Rapp et al., 2004]. In conclusion, at this point it must be concluded that further controlled studies designed to compare different number and locals of injections sites are necessary.

c) **Effect of BONT-A on NDO adult patients**

Following the preliminary report of BONT-A (Botox®, 200 or 300U) detrusor application in 21 patients with traumatic spinal cord injury resistant to antimuscarinic drugs [Schurch et al., 2000a; b], a large multicenter non-controlled clinical trial was conducted in Europe enrolling 231 NDO patients, most with spinal cord injury [Reitz et al., 2004]. Botox®, 300 U was injected in 30 points in the detrusor above the trigone. Data were available for 200 patients. In 180 incontinent patients, this study, which still represents the largest trial conducted with BONT-A, brought urinary continence to 132 and a marked improvement to 48 patients. A marked increment of the volume for first detrusor contraction and decline of maximal detrusor pressure were observed during urodynamic evaluations up to 36 weeks after injection. No injection related complications or toxin side effects were reported. Several other non-controlled studies
published subsequently confirmed these observations [see, Patel et al., 2006; Dmochowski et al., 2007; Karsenty et al., 2008 for review].

Botox® and Dyspor® efficacy in NDO was also demonstrated in small double blind placebo controlled trials [Schurch et al., 2005; Ehren et al., 2007]. Fifty-nine NDO patients due to spinal cord injury were randomized to receive Botox®, 200 U, 300 U or placebo. BONT-A treated patients showed a significant reduction in incontinence episodes and amelioration of urodynamic parameters versus placebo that were maintained in the 6 month observation period. Unfortunately the study was not powered to detect differences between 200 and 300 U of BONT-A [Schurch et al., 2005]. In a further subanalysis, a single dose of BONT-A 300 U significantly improved total and subscale I-QoL scores compared with placebo at all time points [Schurch et al., 2007].

Another small single center study randomized a total of 31 NDO patients due to spinal cord injury, myelomeningocele, trauma at birth, multiple sclerosis and myelitis to intravesical injections of either 500 U of Dyspor® or placebo [Ehren et al., 2007]. Intake of tolterodine and episodes of urinary leakage were registered. Cystometry was performed after 6, 12 and 26 weeks and quality of life was assessed. Patients in the BONT-A arm had a significantly higher cystometric capacity at 6 and 12 weeks. Maximum detrusor pressure and episodes of urinary leakage and tolterodine consumption were significantly lower in the BONT-A than in the placebo group.

In general, the reported duration of BONT-A effect in NDO patients (Botox®, 300U) ranged between 6 and 9 months at the first injection [see, Cruz and Silva, 2004; Dmochowski et al., 2007; Karsenty et al., 2008 for reviews]. The duration of subsequent injections was investigated by three studies along several consecutive injections. Del Popolo et al. [2008] studied the long term effect of BONT-A (Dyspor®) in 199 spinal cord injured patients over a period of 6 years. Initial doses ranged from 500 to 1000 but subsequently the 1000 U dose was abandoned to avoid side effects (see below). The duration of the effect averaged 12 months and was similar for all the three doses. Urodynamic and clinical improvements detected at the first injection were maintained at each re-injection, associated with a highly significant improvement in patient’s satisfaction. Reitz and co-workers [2007] studied intradetrusor BONT-A (Botox®) injections in 20 patients who received at least five intradetrusor injections for long term treatment of NDO. Continence, volume to first detrusor contraction, maximum cystometric capacity, maximum detrusor pressure and compliance at baseline improved significantly after the first injection and at all re-injections. Injection intervals, in average 7 months, tended to lengthen with repeat injections albeit insignificantly. Another study used Botox® 300 U or Dyspor® 750 U in 44 and 22 spinal NDO patients, respectively. Although most of the patients had 2-4 injections, a few had up to 7 consecutive injections. The interval between subsequent injections averaged 9-11 months at all injections. The antimuscarinic use decreased substantially. Significant improvements were found in clinical parameters and in cystometric capacity, whereas compliance improved only after the second treatment. The incidence of DO was significantly reduced. Four patients had transient adverse events after Dyspor® [Grosse et al., 2005].

The onset of BONT-A effect starts within the first 2 weeks after neurotoxin injection [Cruz and Silva, 2004; Dmochowski et al., 2007; Karsenty et al., 2008]. This time course was further evaluated in a small open-label prospective study that specifically investigated the chronology of the BONT-A effects. Urgency, nocturia and frequency were shown to improve as soon as two days after neurotoxin injection in NDO patients [Kalsi et al., 2008].

The majority of the patients included in the BONT-A trials, whether open label or controlled, were spinal cord injured patients [Cruz Silva., 2004; Dmochowski et al., 2007; Karsenty et al., 2008]. The few patients with multiple sclerosis that were included were never analyzed separately. Such a gap was filled recently with the study of BONT-A in a MS cohort. Forty-three MS patients suffering from severe urgency and incontinence were treated with 300 U BONT-A (Botox®) [Kalsi et al., 2007]. Highly significant improvements in urgency, incontinence episodes, frequency and nocturia were observed. In addition, bladder capacity, volume to detrusor overactivity and maximal detrusor pressure also improved. The mean duration of the effect was 9.7 months. Similar results were seen with repeat treatments. However, all but one of the treated patients had to perform self-catheterization after treatment. In spite of this drawback, authors concluded that the treatment was likely to have a major impact on future management of multiple sclerosis patients with detrusor overactivity [Kalsi et al., 2007].

d) BONT-A and urinary tract infection (UTI) in adult NDO patients

A consequence of BONT-A treatment only recently noticed is a decrease in the incidence of urinary tract infections in NDO patients. In 30 SCI patients, Gamé et al. [2008] observed that the number of pyelonephritis, orchitis and prostatitis in the six months before BONT-A, 1.75±1.87 per patient, decreased to 0.2±0.41 in the first six months after treatment. In 17 SCI patients that received BONT-A (Botox®) injections for a period of six years, the number of urinary tract infection at the sixth year was 1.8±0.5 per year, significantly lower than at baseline, 6.7±2.1 [Giannantoni et al., 2008]. In a multicentre, cross-sectional retrospective cohort study, data from 214...
NDO patients treated in seven German centers were collected. The rate of urinary tract infections in 12 months preceding and in the 12 months following BONT-A (Botox®) treatment was 68% and 28%, respectively [Boy et al., 2008]. The reason for these findings is unclear but may lie in a decreased maximum detrusor pressure resulting in less bladder wall ischemia and vesico-ureteral reflux.

e) BONT-A in NDO children

In children, the dose of BONT-A (Botox®) should be calculated according to body weight. Doses of between 12 U/kg of weight up to a maximum dose of 300 U [Schulte-Baukloh et al., 2002] and four U/Kg [Corcos et al., 2002] have been used for Botox®. The maximum suggested Dysport® dose was 20 U/kg up to a maximum of 400 U [Altaweel et al., 2006, Akbar et al., 2007]. BONT-A has been essentially assayed in children with myelomeningocele [Schulte-Baukloh et al., 2002; Schulte-Baukloh et al., 2003; Corcos et al., 2002; Riccabona et al., 2004; Kajbafzadeh et al., 2006; Altaweel et al., 2006]. Like in adults, the toxin increased bladder capacity and decreased maximal detrusor pressure. In 26 children with a mean age of 6.9 years, 19 of them (73%) became completely dry between clean intermittent catheterizations while 88% reported a global improvement in urine incontinence. Interestingly, of the 15 children who had vesicoureteral reflux before the procedure, 11 (73%) found improvement, which either disappeared or decreased in grade. BONT-A also improved bowel function in 66% of the children with intestinal problems [Kajbafzadeh et al., 2006].

The success rate in terms of continence and cessation of antimuscarinic medication may, however, be substantially inferior to that seen in adults, potentially due to irreversible bladder wall changes associated with longstanding detrusor overactivity [Altaweel et al., 2006]. In a group of 20 children with myelomeningocele continence was achieved in only 13 children. At a second injection, this number also did not change appreciably [Altaweel et al., 2006].

f) BONT-A in idiopathic DO (IDO) patients

When compared to NDO, information existing on the use of BONT-A in IDO patients refractory to antimuscarinic agents is more scarce and based on small clinical trials. However, the results of BONT-A application in the bladder of NDO patients and the success of recent trials are pushing more and more clinicians to offer the neurotoxin to their patients before its approval for bladder administration.

In the first report, by Radziszewski and Borkowski [2002], 300 UI of Dyspor® were injected in 10-20 bladder sites of 12 IDO patients. Bladder capacity increased significantly, all patients became continent and no side effects were reported, including urinary retention. However subsequent studies reported in general a high incidence of voiding dysfunction. Kuo [2004] reported on 18 IDO patients detrusor injections of BONT-A (Botox®, 200 U). Continence was regained in seven patients (39%) and another seven (39%) reported some degree of clinical improvement. Mean duration of effect was 5.3 months. However, six (33%) patients required clean intermittent catheterization (CIC) at one month to empty their bladders [Kuo et al., 2004]. Popat et al. [2005] also injected 200 U of Botox® in the detrusor and reported at 16 weeks a clear improvement in urgency, urgency incontinence frequency and maximal cystometric capacity. Six patients (19.3%) required prolonged CIC. Suburothelial injections were suggested to decrease the incidence of urinary retention, by preferentially targeting suburothelial sensory fibers. However, in 20 patients who received suburothelial BONT-A (Botox®, 200 U) urinary retention occurred in six (30%) [Kuo et al., 2005].

The results of these open label studies were confirmed in two albeit small double-blind, placebo controlled trials in which patients were randomized to intradetrusor injections of 200 U BONT-A (Botox®) or placebo [Sahai et al., 2007; Brubaker et al., 2008]. Sahai et al. [2007] used maximum cystometric capacity as primary outcome measure and changes in overactive bladder symptoms, post-void residual, maximum detrusor pressure during filling cystometry, reflex detrusor volume and QoL questionnaires as secondary outcome measures. Follow-up occurred at four and 12 weeks after injection, at which point the study was unblinded. Further followup in the BONT-A group occurred at 24 weeks. Significant increases in maximum cystometric capacity were observed at four and 12 weeks in patients treated with BONT-A compared to placebo. BONT-A also reduced frequency and urgency incontinence episodes at four and 12 weeks. Urgency was significantly reduced only at four weeks in BONT-A group. Post-void residual increased at four weeks in patients receiving BONT-A, but differences to placebo became insignificant by 12 weeks. Despite significant improvements in quality of life observed among patients treated with BONT-A, 37.5% of them required intermittent self-catheterization to empty the bladder. Brubaker et al. [2008] randomized 28 women to Botox® 200 U and 15 for placebo. Approximately 60% of the women who received BONT-A had a clinical response based on the Patient Global Impression of Improvement. The median duration of their responses was 373 days, significantly longer than the 62 days or less for placebo. Post-void residual urine increased in 43% of the women in the BONT-A group (12 out of 26 women) and urinary tract infection developed in 75% of these women (9 of 12). These numbers exceeded by far the expected ranges and forced the suspension of screening and injection. Median duration of urinary retention after the first injection was approximately 664
confirmed these data [Schurch et al., 2007]. Fifty-
randomized, double blind placebo controlled trial
similar for both groups of patients. A multicenter,
obsverved. Percent improvement in QoL score was
weeks for both the NDO and IDO subgroups were
significant decreases in QoL scores at four and 16
Incontinence Impact Questionnaire (IIQ-7). Highly
of the Urinary Distress Inventory (UDI-6) and
32 NDO and 16 IDO patients, using the short forms
studies. Kalsi et al. [2006] examined QOL changes in
intravesical BONT-A has been addressed in several
Quality of life (QoL) in NDO patients treated with
g) Effect of BONT-A on quality of life
improved as soon as four days in IDO patients,
improvement after detrusor, suburothelial and bladder
and urgency sensation in 86% and 82% of patients,
respectively, during an average period of six months.
Temporary urinary retention occurred in four % of the
cases, with additional 15% reporting moderate voiding
difficulties. In a recent update of this experience
[Schmid et al., 2008] an increase in the duration of
BONT-A effect upon repeated injections was observed.
Kuo and co-workers [2007] randomly compared
detrusor, suburothelial and bladder base injections
of 100 U BONT-A (Botox®) in 45 IDO patients
refractory to antimuscarinic therapy. Urgency scores
improved significantly in all groups. However, duration
of clinical improvement was different in the three
groups. Percentage of patients with clinical
improvement after detrusor, suburothelial and bladder
base injections was 67%, 47% and 13% by six months
and to 20%, 20% and 6.7% at nine months,
respectively. At three months significant increases in
cystometric capacity and post-void residual compared
to baseline were found in the detrusor and suburothelial
but not in the bladder base group. Vesicouretal reflux was not identified in any patient after BONT-A
injection into the trigone.
The definition of an ideal dose of BONT-A for IDO
patients as well as the ideal local of injections will
require further well designed clinical trials. In addition
it is unclear at this time what percentage of IDO
patients can stop antimuscarinic medication. For
assessment, see Table 2).
A small open-label prospective study specifically
investigated the chronology of the BONT-A effects in
IDO patients. Urgency, nocturia and frequency
improved as soon as four days in IDO patients,
therefore slightly later than in NDO cases [Kalsi et
al., 2008].
g) Effect of BONT-A on quality of life
Quality of life (QoL) in NDO patients treated with
intravesical BONT-A has been addressed in several
studies. Kalsi et al. [2006] examined QOL changes in
32 NDO and 16 IDO patients, using the short forms
of the Urinary Distress Inventory (UDI-6) and
Incontinence Impact Questionnaire (IIQ-7). Highly
significant decreases in QoL scores at four and 16
weeks for both the NDO and IDO subgroups were
observed. Percent improvement in QoL score was
similar for both groups of patients. A multicenter,
randomized, double blind placebo controlled trial
confirmed these data [Schurch et al., 2007]. Fifty-
ine NDO patients with urinary incontinence received
a single dose of BONT-A (200U or 300 U, Botox®) or
placebo. I-QoL scores improved significantly with
BONT-A, whether 300U or 200 U were used. A single
center, double blind, placebo controlled study was
performed by Ehren et al. [2007] to evaluate the effect
of a single injection of 500 U of BONT-A (Dysport®)
on quality of life in 31 NDO patients with incontinence.
Patients were randomized to intravesical injections
of either 500 U of BONT-A or placebo. Patients in the
BONT-A group showed improved quality-of-life
parameters compared to the placebo group [Ehren et
al., 2007]. Unlike the previous studies, in which patients
had various neurological conditions, a recent study
measured the efficacy and impact on quality of life of
BONT-A (300 U of Botox® ®) in 43 patients with
multiple sclerosis [Kalsi et al., 2007]. There was a
45% decrease in urinary frequency, 77% decrease in
incontinence episodes, 78 % decrease in micturition
episodes associated with urgency and a 47 %
decrease in nocturia. Although 98% of patients had
to perform self-catheterization after treatment, there
were sustained improvements in all quality-of-life
scores with a mean duration of effect of 9.7 months.
Results were maintained with repeat treatments (two
injections in 18 and three in two patients) for 11.7
months.
h) Side effects of intradetrusor BONT-A
One of the most frequent side effects reported after
intradetrusor BONT-A injection is bladder pain
[Karsenty et al., 2008; Del Popolo et al., 2008].
Hematuria may also occur, most of the times mild in
nature. The most feared one, paralysis of the striated
musculature due to circulatory leakage of the toxin has
never been reported. Transient muscle weakness
was however reported with Dysport® application in
several studies [Wyndaele and Van Dromme, 2002;
Akbar et al., 2007; Del Popolo et al., 2008]. Among
199 NDO patients followed during 8 years, five
developed hypostenia when injected with 1000 U of
Dysport®. In another study with 44 patients, three
adults also treated with 1000 units developed muscular
weakness which subsided after 5 to 7 weeks [Akbar
et al., 2007]. No such cases were reported with Botox®
BONT-A [Karsenty et al., 2008]. The reason for the lack
of transient muscle weakness among Botox®-treated
patients is unclear but might be related with the larger
size of its molecule which limits diffusion into the blood
stream. The risk of hyposthenia associated with
Dysport® might be avoided by using lower doses of
the toxin, no more that 750 units for adults and 20 U/kg
for children [Akbar et al., 2007; Del Popolo et al.,
2008]. In addition, caution should be used in selecting
high risk patients for botulism including children,
patients with low pulmonary reserve or patients with
myasthenia gravis. Aminoglycosides should be
avoided during BONT-A treatment since they might
blockade motor plates and therefore enhance BONT-
A effect.
Fear of vesicoureteral reflux, which for long precluded trigone injections [Schuch et al., 2000a; Reitz et al., 2004] seems unfounded whether Botox® or Dysport® is used [Karsenty et al., 2007; Mascarenhas et al., 2008; Citeri et al., 2008; Eichel et al., 2008]. However trigonal injections may not enhance BONT-A effects, as observed in a study with IDO patients [Kuo et al., 2007].

In IDO patients the commonest complication is urinary retention. When injecting 200 U of Botox® a 20-30% rate of prolonged urinary retention might be expected which will require prolonged clean intermittent catheterization to ensure bladder emptying [Kuo et al., 2004; Popat et al., 2005; Kuo et al., 2005; Sahai et al., 2007]. Open-label trials which used lower doses (100 U of Botox®) reported a lower incidence of this complication [Schmid et al., 2006; Kuo et al., 2007].

Although it is a concern frequently raised, at this moment there is no evidence that repeated BONT-A injections cause detrusor atrophy or bladder wall fibrosis. Whether Dysport® or Botox® was used repeated injections in NDO patients in the short to medium term did not decrease bladder compliance, which would presumably be the case if fibrosis were to develop [Del Popolo et al., 2008; Reitz et al., 2007].

Histological inspection of injected bladders did not show inflammatory changes, fibrosis, or dysplasia after repeated treatments and independently of the neurogenic or non-neurogenic origin of the detrusor overactivity [Haferkamp et al., 2004; Compérat et al., 2006; Apostolidis et al., 2008]. Rather the reverse, one study demonstrated that NDO patients treated with BONT-A had less fibrosis than nontreated patients [Compérat et al., 2006]. Curiously, the presence of eosinophilic infiltrate was shown to increase in specimens of patients receiving multiple treatments, a finding that could not be fully explained [Apostolidis et al., 2008].

### i) Cost-effectiveness of BONT-A in NDO patients

Economic aspects of BONT-A are a concern due to the price of the drug and the need for repeated cystoscopies, very often performed under general anaesthesia and under close monitoring to detect and treat eventual episodes of autonomic dysreflexia. Nevertheless, in UK, in a cohort of 101 patients with detrusor overactivity, 63 of whom of neurogenic origin, BONT-A treatment was shown to be cost-effective in both NDO and IDO cases [Kalsi et al., 2006].

Costs were based on the resources used by typical patients in UK and in the cost-effectiveness of 200-300 U BONT-A (Botox®) compared with standard care [Kalsi et al., 2006]. In Germany BONT-A (Botox®) treatment halved costs for incontinence aids and for urinary tract infection treatment in 214 NDO patients [Boy et al., 2008].

### j) BONT-B

Some humans repeatedly injected with BONT-A may develop resistance to the toxin, possibly due to antibody formation. Although this event seems very rare in the case of bladder injections, a minimum interval of three months between two BONT-A injections is generally recommended to decrease its occurrence. If resistance appears, recent reports [Dykstra et al., 2003; Pistolesi et al., 2004; Reitz et al., 2004] investigated the replacement of BONT-A serotype by BONT-B. At this moment, empiric doses of BONT-B are being used, as there are no clear potency equivalents for the two serotypes and between BONT-B brands.

In three patients with spinal NDO, bladder injection of 5000 U [Pistolesi et al., 2004] or 7500 U [Reitz and Schuch, 2004] of BONT-B (Neurobloc®) restored bladder function for six months [Reitz and Schuch, 2004]. Interestingly, one patient experienced dry mouth and dry eyes that resolved within 20 days. As this side effect was not reported after bladder BONT-A application, it is possible that different toxin serotypes have some different degrees of organ affinity. Dykstra et al. [2003] carried on a dose escalation study with BONT-B (Miobloc®) in 15 female patients with OAB. They used doses of 2500, 3750, 5000, 10,000, and 15,000 U injected at 10 sites. Only one patient failed to respond, and a clear dose-dependent effect was observed, with the longest response seen in those injected with 15,000 U. Two patients, both injected with 15,000 U, experienced dry mouth and general malaise. In another study involving IDO and NDO patients, in which BONT-B (Neurobloc®) 5000 U were used, Hirst and coworkers [2007] observed a limited duration of action, with most of the symptomatic beneficial effects wearing off by 10 weeks in most of the patients. The short duration of action for BONT-B at safe doses may, therefore, limit the clinic usefulness of this serotype.

### 2. CAPSAICIN AND RESINIFERATOXIN (RTX)

#### a) Rationale for intravesical vanilloids

The rationale for intravesical vanilloid application in patients with DO was offered by the demonstration that capsaicin, following bladder C-fiber desensitization, suppresses involuntary detrusor contractions dependent upon a sacral micturition reflex [de Groat et al., 1997]. The C-fiber micturition reflex is usually inactive but it was shown that it is enhanced in patients with chronic spinal-cord lesions above sacral segments [de Groat et al., 1997] in those with chronic bladder outlet obstruction [Chai et al., 1998] and in those with IDO [Silva et al., 2002]. In the bladders of NDO patients, the enhancement of the micturition reflex is accompanied by an increase in the number of suburothelial C-fibers expressing TRPV1 [Brady et al., 2004]. Curiously, NDO patients who responded better...
to intravesical RTX exhibited a significant decrease in the density of TRPV1 immunoreactive fibers, whereas non-responders experience a non-significant variation [Brady et al., 2004]. A decrease in TRPV1 expression in urothelial cells of NDO patients was also demonstrated after intravesical application of RTX [Apostolidis et al., 2005].

Changes in sub-urothelial C-fiber innervation expressing neuropeptides [Smet et al., 1997] or TRPV1 [Liu et al., 2007] were also reported in patients with sensory urgency. In IDO patients, responders to intravesical RTX are closely associated with the over-expression of the receptor in the bladder mucosa [Liu et al., 2007]. In women with sensory urgency, TRPV1 mRNA expressed in trigonal mucosa was not only decreased but also inversely correlated with the bladder volume at first sensation of filling during cystometry further indicating that TRPV1 plays a role in premature bladder sensation [Liu et al., 2007].

b) Intravesical capsaicin

Intravesical capsaicin for NDO was studied in six non-controlled [Fowler et al., 1992; Fowler et al., 1994; Geirsson et al., 1995; Das et al., 1996; Igawa et al., 1996, Cruz et al., 1997, De Ridder et al., 1997] and 1 controlled clinical trial [de Seze et al., 1998]. Capsaicin was dissolved in 30% alcohol and 100-125 ml (or half of the bladder capacity if lower than that volume) of 1-2 mM solutions were instilled into the bladder and left in contact with the mucosa for 30 minutes. Best clinical results were found among patients with incomplete spinal cord lesions, in whom clinical improvement could be observed in up to 70-90% of the patients [Fowler et al., 1994, Cruz et al., 1997; De Ridder et al., 1997]. In patients with complete spinal cord lesions the success rate was much lower [Geirsson et al., 1995].

Only one small randomized controlled study compared capsaicin against 30% ethanol, the vehicle solution. Ten patients received capsaicin and found a significant regression of the incontinence and urge sensation. In contrast, only 1 among the 10 patients that received ethanol had clinical improvement [de Seze et al., 1998].

The pungency of alcoholic capsaicin solutions has prevented the widespread use of this compound. In particular, the possibility of triggering autonomic dysreflexia with capsaicin, especially in patients with higher spinal cord lesions has progressively restrained its use. The relevance of capsaicin might however be back with a recent observation by de Sèze et al. [2006] with a new capsaicin formulation. They conducted a double blind placebo controlled study with a glucidic solution of capsaicin in 33 NDO patients. The glucidic-capsaicin treated group showed improvement both in symptoms and urodynamic parameters above the comparator arm [de Sèze et al., 2006]. The global tolerance of this new capsaicin formulation was excellent.

c) RTX in NDO

Resiniferatoxin (RTX) has the advantage over capsaicin in being much less pungent [Cruz et al., 1997]. Intravesical RTX application in NDO patients was evaluated in five small open-label studies [Cruz et al., 1997; Kuo, 2003; Lazzeri et a., 1997; Lazzeri et al., 1998; Silva et al., 2000]. Different RTX concentrations, 10 nM, 50 nM, 100 nM and 10 µM were tested. RTX brought a rapid improvement or disappearance of urinary incontinence in up to 80% of the selected patients and a 30% decrease in their daily urinary frequency.

Furthermore, RTX also increased the volume to first detrusor contraction and maximal cystometric capacity. In general, in patients receiving 50-100 nM RTX the effect was long-lasting, with a duration of more than six month being reported. In patients treated with 10 µM doses, transient urinary retention may occur [Lazzeri et al., 1998].

In a recent placebo-controlled study, the urodynamic effects of RTX in NDO patients were specifically evaluated. Only in the RTX arm was a significant increase in first detrusor contraction and maximal cystometric capacity found [Silva et al., 2005]. RTX also caused a significant improvement in urinary frequency and incontinence [Silva et al., 2005].

RTX, 600 nM was compared against BONT-A (Botox®, 300U) in a study involving 25 patients with NDO due to chronic spinal cord injury. Both neurotoxins were capable of significantly reducing the number of daily incontinence episodes and improving maximum bladder capacity, although BONT-A turned out to be more effective [Giannantoni et al., 2004].

d) RTX in IDO

The first study with intravesical RTX in IDO patients was designed as a proof-of-concept study and involved 13 patients. Intravesical RTX 50 nmol/L was associated with an improvement in volume to FDC from 170 ± 109 mL to 440 ± 153 mL at 30 days, and to 391 ± 165 mL at 90 days. An increase in mean MCC from 291 ± 160 mL to 472 ± 139 mL at 30 days and to 413 ± 153 mL at 90 days was also observed (Figure 14). These improvements were accompanied by a decrease in episodes of urgency incontinence and of daily frequency [Silva et al., 2002]. Subsequent small open label studies confirmed these observations using either a single high (50-100 nM) or multiple low (10 nM) dose approaches [Kuo et al., 2003; Dinis et al., 2004; Kuo et al., 2005].

The effect of RTX on refractory IDO was evaluated in two randomized clinical trials. One, involved 54 patients randomized to receive four weekly instillations of a low concentration RTX solutions (10 nmol/L) or the vehicle
solution, 10% ethanol in saline [Kuo et al., 2006]. Three months after completing the four intravesical treatments, the RTX treated group had 42.3% and 19.2% of patients feeling much better or improved, respectively. This was significantly more than in the placebo group, 14.2% and 7.1% respectively. At six months treatment remained effective in 50% patients in the RTX group but only in 11% in the placebo group [Kuo et al., 2006]. Such clinical and urodynamic findings could not be reproduced in another study in which patients were randomly assigned to receive a single intravesical dose of 100 ml of either RTX 50 nM or placebo. Patients were followed-up only for four weeks. During this period a single 50 nM intravesical dose of RTX was not better than placebo for the treatment of women with IDO and urgency incontinence [Rios et al., 2007].

e) RTX and urgency

The involvement of bladder C-fibers in IDO has led some investigators to explore the role of these sensory afferents to the genesis of urgency. In a non-controlled study involving 12 male patients with LUTS associated with benign prostate enlargement (BPE), mean International Prostate Symptom Scores (IPSS) halved following intravesical administration of RTX (50 nmol/L). The decrease in IPSS was largely due to improvements in scores related to urgency, in addition to improvement in nocturia and frequency [Dinis et al., 2005]. In another open-label study 15 patients with intractable urgency and frequency, with or without urgency incontinence or bladder pain/discomfort, and without urodynamic evidence of DO received one single 50 nM RTX solution. A trend towards an improvement of urgency was noticed [Apostolidis et al., 2006]. In a more recent study involving first a placebo instillation and one month later a 50 nM RTX administration to 23 patients with refractory urgency, a significant decrease in the number of episodes of urgency were detected after RTX treatment when compared with the placebo treatment [Silva et al., 2007].

At the moment and probably in the near future, a lack of stable preparations of RTX available for easy bladder instillation will make further investigation of the compound difficult. Different origins of the vanilloid and different ways for preparation and storage of the solutions might have caused substantial differences in the amount of active compound effectively administered to the patients. In addition, RTX adheres to plastics, another reason to the enormous discrepancies have been observed among RTX studies, with some claiming good results and others not demonstrating any superiority of RTX over placebo. Development of new, user-friendly formulations is needed.

Capsaicin and RTX will also face the concurrence of small molecule TRPV1 antagonists that act as a blockade of TRPV1 receptors rather than desensitizing them. Some of these compounds are already entering preliminary clinical trials. The interested reader might find an extensive review on small molecule TRPV1 antagonists elsewhere [Szallasi et al., 2006]. Very recently an experimental study was presented showing that one of these compounds (GRC 6211) active by oral route could reduce frequency of bladder reflex contractions as well as spinal c-fos expression in rat models of cystitis (Figure 15). Interestingly in the optimal therapeutic doses, this TRPV1 antagonist had no effect on the bladder activity of intact animals [Cruz et al., 2008; Charrua et al., 2008].

X. OTHER DRUGS

1. BACLOFEN

Gamma-amino-butyric acid (GABA) is a ubiquitous inhibitory neurotransmitter in the CNS that can inhibit the micturition reflex in several points along its central pathway [De Groat, 1997; Pehrson et al., 2002]. As a GABA agonist on GABA(B) receptors, baclofen was used orally in IDO patients. However, its efficacy was poor, eventually dictated by the fact that baclofen does not cross the blood-brain barrier [Taylor and Bates, 1979]. To overcome this inconvenience, intrathecal baclofen was shown to be useful in some patients with spasticity and bladder dysfunction [Bushman et al., 1993]. Baldo et al. [2000] could find a rapid (24 hours) and persistent increment in the volume to first detrusor contraction and of the maximal cystometric whereas maximal detrusor pressure decreased. At ten days the volume to first detrusor contraction had increased from 143 ml to 486 ml. Contrasting with the limited published clinical experience, some recent experimental data may revive the GABAergic system as a target for bladder dysfunction therapy. Baclofen intrathecally attenuated oxyhemoglobin induced detrusor overactivity, suggesting that the inhibitory actions of GABA(B) receptor agonists in the spinal cord may be useful for controlling micturition disorders caused by C-fiber activation in the urothelium and/or suburothelium [Pehrson et al, 2002]. In spinally intact rats, intrathecal application of bicuculline induced detrusor-sphincter dyssynergia (DSD)-like changes whereas intrathecal application of baclofen induces urethral relaxation during isovolumetric bladder contractions. These results indicate not only that GABA receptor activation in the spinal cord exerts inhibitory effects on DSD after SCT but also that decreased activation of GABA(A) receptors due to hypofunction of GABAergic mechanisms in the spinal cord might be responsible at least in part for the development of DSD after spinal cord transaction (SCT) [Miyazato et al., 2008a]. These findings are reinforced by the observation that glutamate decarboxylase 67 mRNA levels in the spinal cord and dorsal root ganglia were decreased after
Figure 14: Effect of intravesical resiniferatoxin in patients with idiopathic DO

Figure 15: Effects of the TRPV1 receptor antagonists, GRC-6211, on rat spinal c-fos expression induced by instillation of acetic acid into the bladder. Unpublished information, courtesy F. Cruz
spinal cord transection. Therefore, stimulation of spinal GABAergic mechanisms can be useful for the treatment of detrusor overactivity after spinal cord injury [Miyazato et al., 2008b]. For assessment, see Table 2.

**XI. COMBINATIONS**

Combining the current $\alpha_1$-AR antagonists with other agents might theoretically provide improved symptom relief. One such example is the combination of $\alpha_1$-AR antagonists with 5$\alpha$-reductase inhibitors, which has proven to improve clinical outcomes and reduce the incidence of BPH and LUTS progression measured as symptom worsening, retention or progression to surgery [McConnell et al., 2003, Roehrborn et al., 2008]. Other combinations have also been tested with varying degrees of success. Traditionally muscarinic receptor antagonists have been contraindicated in patients with BPH due to fears of urinary retention. However, this dogma has been questioned and several studies have been performed in which $\alpha_1$-AR antagonists are combined with muscarinic receptor antagonists with promising results [Athanasopoulus et al., Lee et al., 2004; 2005; 2008; Ruggieri et al., 2006; Kaplan et al., 2006; Novara et al., 2006; Mc Vary, 2007; Rovner et al., 2008]. Speculatively, several other combinations can be suggested [Andersson, 2008].

**XII. FUTURE POSSIBILITIES**

**1. PERIPHERALLY ACTING DRUGS**

**a) Vitamin D$_3$ receptor analogues**

Rat and human bladders were shown to express receptors for vitamin D [Crescioli et al., 2005], which makes it conceivable that the bladder may also be a target for vitamin D. Analogues of vitamin D$_3$ have also been shown to inhibit benign prostatic hyperplasia (BPH) cell proliferation and to counteract the mitogenic activity of potent growth factors for BPH cells [Crescioli et al., 2002; 2003; 2004]. Experiments in rats with bladder outlet obstruction [Schröder et al., 2006] showed that one of the analogues, BXL-628 (elocalcitol), at non-hypercalcemic doses, did not prevent bladder hypertrophy, but reduced the decrease in contractility of the bladder smooth muscle which occurred with increasing bladder weight [Schröder et al., 2006]. The mechanism of action for the effects has not been clarified. However, elocalcitol was shown to have an inhibitory effect on the RhoA/Rho kinase pathway [Morelli et al., 2007]. Upregulation of his pathway has been associated with bladder changes associated with diabetes, outflow obstruction, and DO [Peters et al., 2006; Christ and Andersson, 2007]. The effect of elocalcitol on prostate volume was evaluated in patients with BPH, and it was found that elocalcitol was able to arrest prostate growth within 12 weeks in men aged $\geq$50 years with prostatic volume $> 40$ ml [Colli et al., 2006]. In an RCT enrolling 120 female patients with OAB, where the primary endpoint was an increase in the mean volume voided, a significant increase vs placebo (22% vs 11%) was demonstrated [Colli et al., 2007]. Whether or not vitamin D receptor agonism (monotherapy or in combination) will be a useful alternative for the treatment of LUTS/OAB, requires further RCTs.

**2. CENTRALLY ACTING DRUGS**

Many parts of the brain seem to be activated during storage and voiding [see, Griffiths 2007; Fowler et al., 2008; Griffiths and Tadic, 2008], and there is increasing interest in drugs modulating the micturition reflex by a central action [Andersson and Pehrson, 2003]. Several drugs used for pain treatment also affect micturition; morphine and some antiepileptic drugs being a few examples. However, central nervous mechanisms have so far not been preferred targets for drugs aimed to treat OAB, since selective actions may be difficult to obtain. Holstege [2005], reviewing some of the central mechanisms involved in micturition, including the periaqueductal gray (PAG) and the pontine micturition center (PMC), suggested that “the problem in OAB or urgency-incontinence is at the level of the PAG or PMC and their connections, and possible treatments for this condition should target the micturition pathways at that level.”

**a) Gonadotropin-releasing hormone antagonists**

The beneficial effects of the 5$\alpha$-reductase inhibitors, finasteride and dutasteride in the treatment of male LUTS are well documented. The efficacy of other hormonal treatments, for example, antiandrogens or gonadotropin-releasing hormone (GNRH; also known as luteinizing hormone-releasing hormone: LH-RH) agonists is either poor or at the expense of unacceptable side effects such as medical castration associated with hot flushes, decrease of potency and libido, and negative effects on bone density following long-term androgen ablation [Schroeder et al. 1986; Peters et al 1987; Bosch et al., 1989; Eri and Tveter, 1993]. With LH-RH antagonists submaximal, non-castrating blockade of the androgen testosterone and consequently of dihydrotestosterone (DHT) can be achieved, thus avoiding medical castration.

Debruyne et al. [2008] demonstrated in a phase 2 RCT that the LH-RH antagonist cetorelix, given subcutaneously weekly for 20 weeks to 140 men with LUTS (IPSS $\geq$ 13, peak urinary flow rates 5-13 ml/s), rapidly caused a significant improvement in the mean IPSS: the peak decrease was -5.4 to -5.9 vs -2.8 for placebo. All dosage regimens tested were well tolerated, and the authors concluded that the drug
offered a safe and effective treatment of male LUTS. Further studies are needed to assess whether or not this therapeutic principle is a useful addition to the current treatment alternatives.

**b) Gabapentin**

Gabapentin is one of the new first-generation antiepileptic drugs that expanded its use into a broad range of neurologic and psychiatric disorders [Striano and Striano 2008]. It was originally designed as an anticonvulsant GABA (y-aminobutyric acid) mimetic capable of crossing the blood-brain barrier [Maneuf et al., 2003]. The effects of gabapentin, however, do not appear to be mediated through interaction with GABA receptors, and its mechanism of action remains controversial [Maneuf et al., 2003]. It has been suggested that it acts by binding to a subunit of the αδ unit of voltage dependent calcium channels [Gee et al., 1996; Striano and Striano, 2008]. Gabapentin is also widely used not only for seizures and neuropathic pain, but for many other indications, such as anxiety and sleep disorders, because of its apparent lack of toxicity.

Carbone et al. [2006] reported on the effect of gabapentin on neurogenic DO. They found a positive effect on symptoms and significant improvement in urodynamic parameters, and suggested that the effects of the drug should be explored in further controlled studies in both neurogenic and non-neurogenic DO. Kim et al. [2004] studied the effects of gabapentin in patients with OAB and nocturia not responding to antimuscarinics. They found that 14 out of 31 patients improved with oral gabapentin. The drug was generally well tolerated, and the authors suggested that it can be considered in selective patients when conventional modalities have failed. It is possible that gabapentin and other αδ ligands (e.g., pregabalin and analogs) will offer new therapeutic alternatives.

**c) Tramadol**

Tramadol is a well-known analgesic drug [Grond and Sablotzki, 2004]. By itself, it is a weak μ-receptor agonist, but it is metabolized to several different compounds, some of them almost as effective as morphine at the μ-receptor. However, the drug (metabolites) also inhibits serotonin (5-HT) and noradrenaline reuptake [Grond and Sablotzki, 2004]. This profile is of particular interest, since both μ-receptor agonism and amine reuptake inhibition may be useful principles for treatment of LUTS/OAB/DO, as shown in a placebo controlled study with duloxetine [Steers et al., 2008].

In rats, tramadol abolished experimentally induced DO caused by cerebral infarction [Pehrson et al., 2003]. Tramadol also inhibited DO induced by apomorphine in rats [Pehrson and Andersson, 2003] – a crude model of bladder dysfunction in Parkinson’s disease. Singh et al. [2008] gave tramadol epidurally and found the drug to increase bladder capacity and compliance, and to delay filling sensations without adverse effects on voiding. Safarinejad and Hosseini [2006] evaluated in a double-blind, placebo-controlled, randomized study, the efficacy and safety of tramadol in patients with idiopathic DO. A total of 76 patients 18 years or older were given 100 mg tramadol sustained release every 12 h for 12 weeks. Clinical evaluation was performed at baseline and every two weeks during treatment. Tramadol significantly (p<001) reduced the number of incontinence periods per 24 hours from 3.2±3.3 to 1.6±2.8) and induced improvements in urodynamic parameters. The main adverse event was nausea. It was concluded that in patients with non-neurogenic DO, tramadol provided beneficial clinical and urodynamic effects. Even if tramadol may not be the best suitable drug for treatment of LUTS/OAB, the study suggests efficacy for modulation of micturition via the μ-receptor.

**d) NK1-receptor antagonists.**

The main endogenous tachykinins, substance P (SP), neurokinin A (NKA) and neurokinin B (NKB), and their preferred receptors, NK1, NK2, and NK3, respectively, have been demonstrated in various CNS regions, including those involved in micturition control [Lecci and Maggi, 2001; Saffroy et al., 2003; Covenas et al., 2003]. NK1 receptor expressing neurons in the dorsal horn of the spinal cord may play an important role in DO, and tachykinin involvement via NK1 receptors in the micturition reflex induced by bladder filling has been demonstrated [Ishizuka et al., 1994] in normal, and more clearly, rats with bladder hypertrophy secondary to BOO. Capsaicin-induced detrusor overactivity was reduced by blocking NK1 receptor-expressing neurons in the spinal cord, using intrathecally administered substance P-saponin conjugate [Seki et al., 2002]. Furthermore, blockade of spinal NK1 receptor could suppress detrusor activity induced by dopamine receptor (L-DOPA) stimulation [Ishizuka et al., 1995a].

In conscious rats undergoing continuous cystometry, antagonists of both NK1 and NK2 receptors inhibited micturition, decreasing micturition pressure and increasing bladder capacity at low doses, and inducing dribbling incontinence at high doses. This was most conspicuous in animals with outflow obstruction [Gu et al., 2000]. Intracerebroventricular administration of NK1 and NK2 receptor antagonists to awake rats suppressed detrusor activity induced by dopamine receptor (L-DOPA) stimulation [Ishizuka et al., 2000]. Taken together, available information suggests that spinal and supraspinal NK1 and NK2 receptors may be involved in micturition control.

Aprepitant, an NK-1 receptor antagonist used for treatment of chemotherapy-induced nausea and vomiting [Massaro and Lenz, 2005], significantly improved symptoms of OAB in postmenopausal women with a history of urgency incontinence or mixed
incontinence (with predominantly urgency urinary incontinence), as shown in a well designed pilot RCT [Green et al., 2006]. The primary end point was percent change from baseline in average daily micturitions assessed by a voiding diary. Secondary end points included average daily total urinary incontinence and urgency incontinence episodes, and urgency episodes. Aprepitant significantly (p<0.003) decreased the average daily number of micturitions (-1.3±1.9) compared with placebo (-0.4±1.7) at 8 weeks. The average daily number of urgency episodes was also significantly (p<0.047) reduced (-23.2±32%) compared to placebo (-9.3±40%), and so were the average daily number of urgency incontinence and total urinary incontinence episodes, although the difference was not statistically significant. Aprepitant was generally well tolerated and the incidence of side effects, including dry mouth, was low. The results of this initial proof of concept study suggest that NK-1 receptor antagonism holds promise as a potential treatment approach for OAB.

Many factors seem to be involved in the pathogenesis of stress urinary incontinence (SUI): urethral support, vesical neck function, and function of the nerves and musculature of the bladder, urethra, and pelvic floor [DeLancey, 1997; Mostwin et al., 2005]. Anatomical factors cannot be treated pharmacologically. However, women with SUI have lower resting urethral pressures than age-matched continent women [Henriksson et al, 1979; Hilton et al, 1983], and since it seems likely that there is a reduced urethral closure pressure in most women with SUI, it seems logical to increase urethral pressure to improve the condition.

Factors which may contribute to urethral closure include tone of urethral smooth and striated muscle and the passive properties of the urethral lamina propria, in particular its vasculature. The relative contribution to intraurethral pressure of these factors is still subject to debate. However, there is ample pharmacological evidence that a substantial part of urethral tone is mediated through stimulation of α-ARs in the urethral smooth muscle by released noradrenaline [Andersson, 1993; Andersson and Wein, 2004]. A contributing factor to SUI, mainly in elderly women with lack of estrogen, may be lack of mucosal function. The pharmacological treatment of SUI aims at increasing intraurethral closure forces by increasing the tone in the urethral smooth and striated muscles. Several drugs may contribute to such an increase [Andersson, 1988; Zinner et al., 2004], but relative lack of efficacy or and side effects have limited their clinical use. For assessments, see Table 4.

### C. DRUGS USED FOR TREATMENT OF STRESS URINARY INCONTINENCE

Several drugs with agonistic effects on α-ARs have been used in the treatment of SUI (Table 4). However, ephedrine and norephedrine (phenylpropanolamine; PPA) seem to have been the most widely used [Andersson et al., 2002]. The original Agency for Healthcare Policy and Research Guidelines (Agency for Healthcare Policy and Research, 1992) reported 8 randomized controlled trials with PPA, 50 mg twice daily for SUI in women. Percent cures (all figures refer to percent effect on drug minus percent effect on placebo) were listed as 0% to 14%, percent reduction in continence as 19% to 60%, and percent side effects and percent dropouts as 5% to 33% and 0% to 4.3% respectively. The most recent Cochrane review on the subject [Alhasso et al., 2005] assessed randomized or quasi-randomized controlled trials in adults with stress urinary incontinence which included an adrenergic agonist drug in at least one arm of the trial. There were no controlled studies reported on the use of such drugs in men. Twenty-two eligible trials were identified, 11 of which were crossover trials, which included 1099 women, 673 of whom received an adrenergic drug (PPA in 11, midrodrine in two, norepinephrine in three, clenbuterol in three, terbutaline in one, eskornade in one and RO 115-1240 in one). The authors concluded “there was weak evidence to suggest that use of an adrenergic agonist was better than placebo treatment”. The limited evidence suggested that such drugs were better than placebo in reducing the number of pad changes and incontinence episodes, and in improving subjective symptoms. There was not enough evidence to evaluate the merits of an adrenergic agonist compared with estrogen, whether used alone or in combination.

### I. α-ADRENERGOPETTOR AGONISTS

For assessments, see Table 4.
Regarding adverse events, the review reported similar numbers with adrenergic, placebo, or alternative drug treatment. Over 25% of subjects reported such effects, but when these consisted of effects due to adrenergic stimulation, they caused discontinuation in only 4% of the total.

The date of the most recent amendment to this review is listed as 15 May 2007; no new trials were identified at that time. The update of 2005 [Alhasso et al., 2005] included seven new randomized controlled trials over the 2003 report, cited in the last consultation. The final statement on "what's new" reads, "The conclusions still provide limited support for the use of adrenergics but side effects may cause dropout, and some side effects may be dangerous. Further trials are needed".

Ephedrine and PPA lack selectivity for urethral α-ARs and can increase blood pressure and cause sleep disturbances, headache, tremor, and palpitations [Andersson et al., 2002]. Kernan et al. [2000] reported the risk of hemorrhagic stroke to be 16 times higher in women less than 50 years of age who had been taking PPA as an appetite suppressant (statistically significant) and 3 times higher in women who had been taking the drug for less than 24 hours as a cold remedy (not statistically significant). There was no increased risk in men. PPA has been removed from the market in the United States.

Numerous case reports of adverse reactions due to ephedra alkaloids exist, and some [Bent et al., 2003] had suggested that sale of these compounds as a dietary supplement be restricted or banned. In December 2003, the Food and Drug Administration of the US decreed such a ban, a move which has survived legal appeal.

Midodrine and methoxamine stimulate α1-ARs with some degree of selectivity. According to the RCTs available, the effectiveness of these drugs is moderate and the clinical usefulness seems to be limited by adverse effects [Alhasso et al., 2003; Radley et al., 2001; Weil et al., 1998].

Attempts continue to develop agonists with relative selectivity for the human urethra. Musselman et al. [2004] reported on a phase two randomized crossover study with Ro 115-1240, a peripheral active selective α1L-AR adrenoceptor partial agonist [Blue et al., 2004] in 37 women with mild to moderate SUI. A moderate, positive effect was demonstrated, but side effects have apparently curtailed further development of the drug.

### II. β-ADRENOCEPTOR ANTAGONISTS

The theoretical basis for the use of β-AR antagonists in the treatment of stress incontinence is that blockade of urethral β-ARs may enhance the effects of noradrenaline on urethral α-ARs. Propranolol has been reported to have beneficial effects in the treatment of stress incontinence [Gleason et al., 1974; Kaisary, 1984] but there are no RCTs supporting such an action. In the Gleason et al. [1974] study the beneficial effects become manifest only after 4 to 10 weeks of treatment; a phenomenon difficult to explain. Donker and Van der Sluis [1976] reported that β-blockade did not change UPP in normal women. Although suggested as an alternative to β-AR agonists in patients with SUI and hypertension, these agents may have major potential cardiac and pulmonary side effects of their own, related to their therapeutic β-AR blockade.

### III. β-ADRENOCEPTOR AGONISTS

β-AR stimulation is generally conceded to decrease urethral pressure [Andersson, 1993], but β2-AR agonists have been reported to increase the contractility of some fast contracting striated muscle fibers and suppress that of slow contracting fibers of others [Fellenius et al., 1980]. Some β-AR agonists also stimulate skeletal muscle hypertrophy – in fast twitch more so than slow twitch fibers [Kim et al., 1992]. Clenbuterol has been reported to potentiate the field stimulation induced contraction in rabbit isolated periurethral muscle preparations, an action which is suppressed by propanolol and greater than that produced by isoproterenol [Kishimoto et al., 1991]. These authors were the first to report an increase in urethral pressure with clinical use of clenbuterol and to speculate on its potential for the treatment of SUI. Yaminishi et al. [1994] reported an inotropic effect of clenbuterol and terbutaline on the fatigued striated urethral sphincter of dogs, abolished by β-AR blockade.

Yasuda et al. [1993] described the results of a double blind placebo controlled trial with this agent in 165 women with SUI. Positive statistical significance was achieved for subjective evaluation of incontinence frequency, pad usage per day, and overall global assessment. Pad weight decreased from 11.7±17.9 g to 6.0±12.3 g for drug and from 18.3±29.0 g to 12.6±24.7 g for placebo, raising questions about the comparability of the 2 groups. The "significant" increase in maximum urethral closure pressure (MUCP) was from 46.0±18.2 cm H2O to 49.3±19.1 cm H2O, versus a change of -1.5 cm H2O in the placebo group. 56/77 patients in the clenbuterol group reported some degree of improvement versus 48/88 in the placebo group. The positive effects were suggested to be a result of an action on urethral striated muscle and/or the pelvic floor muscles. Ishiko et al. [2000] investigated the effects of clenbuterol on 61 female patients with stress incontinence in a 12-week randomized study, comparing drug therapy to pelvic floor exercises. The frequency and volume of stress incontinence and the patient’s own impression were used as the basis for
the assessment of efficacy. The improvement of incontinence was 76.9%, 52.6%, and 89.5% in the respective groups. In an open study, Noguchi et al. [1997] reported positive results with clenbuterol (20 mg twice daily for one month) in nine of 14 patients with mild to moderate stress incontinence after radical prostatectomy. No subsequent published reports have appeared. Further well-designed RTCs documenting the effects of clenbuterol are needed to adequately assess its potential as a treatment for stress incontinence.

IV. SEROTONIN-NORADRENALINE UPTAKE INHIBITORS

1. IMIPRAMINE

Imipramine, among other pharmacological effects, inhibits the re-uptake of noradrenaline and serotonin in adrenergic nerve endings. In the urethra this can be expected to enhance the contractile effects of noradrenaline on urethral smooth muscle. Gilja et al [1984] reported in an open study on 30 women with stress incontinence that imipramine, 75 mg daily, produced subjective continence in 21 patients and increased mean maximal urethral closure pressure (MUCP) from 34 to 48 mm Hg. A 35% cure rate was reported by pad test and, in an additional 25%, a 50% or more improvement.

Lin et al. [1999] assessed the efficacy of imipramine (25 mg imipramine three times a day for three months) as a treatment in 40 women with genuine stress incontinence. A 20-minute pad test, uroflowmetry, filling and voiding cystometry, and stress urethral pressure profile were performed before and after treatment. The efficacy of "successful treatment" was 60% (95% CI 11.8-75.2). There are no RCTs on the effects of imipramine on SUI. No subsequent published reports have appeared.

2. DULOXETINE

As mentioned previously, duloxetine is a combined serotonin and noradrenaline reuptake inhibitor, which has been shown to significantly increase sphincteric muscle activity during the filling/storage phase of micturition in the cat acetic acid model of irritated bladder function [Thor et al., 1995; Katofiasc et al., 2002]. The sphincteric effects were reversed by α1-AR (prazosin) and 5HT2 serotonergic (LY 53857) receptor antagonism, while the bladder effects were mediated by temporal prolongation of the actions of serotonin and noradrenaline in the synaptic cleft (Figure 16) (Fraser et al, 2003). Duloxetine is lipophilic, well absorbed, and extensively metabolized (CYP2D6). Its plasma half-life is approximately 12 hours [Sharma et al., 2000].

There are many studies, including RCTs, documenting the effects of duloxetine in SUI [Norton et al., 2002; Dmochowski et al., 2003; Millard et al., 2004; Van Kerrebroeck et al., 2004; Cardozo et al., 2004; Kinchen et al., 2005; Ghoneim et al., 2005; Hurley et al., 2006; Castro-Diaz et al., 2007; Bump, 2008]. A Cochrane review of the effects of duloxetine for stress urinary incontinence in women is available, the last substantive amendment listed as 25 May 2005 [Mariappan et al., 2005]. Fifteen reports were deemed eligible for analysis, nine primary studies and six additional reports related to one or two of the primary references. An additional analysis “performed under the auspices of the Cochrane Incontinence Group” was performed on just the nine primary trials comparing duloxetine and placebo, and published separately [Mariappan et al., 2007]. The results can be summarized as follows. Subjective “cure” in the duloxetine 80 mg daily (40 mg twice daily) was higher than in the placebo group (10.8 % vs 7.7%, overall relative risk (RR) = 1.42; 95% confidence interval (CI), 1.02-1.98; p = 0.04). The estimated absolute size of effect was about three more patients cured of every 100 treated. Objective cure data, available from only one trial, showed no clear drug/placebo difference. Duloxetine showed greater improvement in I-QoL (weighted mean difference (WMD) for 80 mg: 4.5; 95% CI 2.83-6.18, p < 0.00001). Patient global impression of improvement (PGI-I) data also favored the drug (RR for better health status 1.24, 95% CI 1.14-1.36; p < 0.00001). Adverse effects in six trials were analyzed. These were reported by 71% of drug subjects and 59% of those allocated to placebo. Nausea was the most common adverse event and the incidence ranged from 23 to 25% and was the main reason for discontinuation. Other side effects reported were vomiting, constipation, dry mouth, fatigue, dizziness and insomnia, overall RR 1.30 (95% CI, 1.23-1.37). Across these six trials 17% in the drug group withdrew, 4 % in the placebo arm. In the 2007 article the authors conclude by saying that further research is needed as to whether management policies incorporating duloxetine are clinically effective and cost effective compared to other current minimally invasive and more invasive approaches in patients with varying severity of SUI, and that “longer term experience is now a priority to determine whether there is sustained efficacy during and after duloxetine use and to rule out complications”. Hashim and Abrams [2006] suggested that in order to reduce the risk of nausea, begin with a dose of 20 mg twice daily for two weeks, then to increase to the recommended 40 mg twice daily dosage.

Duloxetine is licensed at 40 mg twice daily for the treatment of SUI in the European Union (European Medicines Agency, Scientific Discussion, 2005) for women with moderate to severe incontinence (defined as 14 or more episodes per week). It was withdrawn from the Food and Drug Administration (FDA) consideration process in the United States for the treatment of SUI, but is approved for the treatment of major depressive disorder (20-30 mg twice daily
initially, 60 mg once daily maintenance), diabetic peripheral neuropathic pain (60 mg once daily), and generalized anxiety disorder (60 mg once daily). The product information contains a “black box” warning of “increased risk of suicidal thinking and behavior in children, adolescents and young adults taking antidepressants for major depressive disorder and other psychiatric disorders”, noting also that “depression and certain other psychiatric disorders are themselves associated with increases in the risk of suicide” (Prescribing Information, revised December 2007, Eli Lilly and Company, Indianapolis, Indiana 46285).

Other warnings and precautions in the United States Product Information for psychiatric indications, not SUI, include hepatotoxicity (not to be used in patients with substantial alcohol use or chronic liver disease), orthostatic hypotension, serotonin syndrome (general statement regarding selective serotonin reuptake inhibitors (SSRIs) and SNRIs), abrupt discontinuation (may result in dizziness, paresthesias, irritability and headache), inhibitors of CYP1H2 or thioridazine (do not administer concomitantly), potent inhibitors of CYP2D6 (may increase concentration), and others.

### 3. MALE STRESS URINARY INCONTINENCE

Although a problem of significant magnitude, especially after total prostatectomy for cancer, the pharmacologic treatment of male SUI is an area that has received relatively little attention. Tsakiris et al. [2008] searched for articles on this subject published between 1966 and June 2007 and did a generalized database search in addition. Nine trials were identified using α1-AR agonists, β2-AR antagonists or SNRIs.

Only one of these included a comparison arm [Filocamo et al., 2007]. 40 mg twice daily duloxetine plus pelvic floor exercises vs pelvic floor exercises (PFE) with placebo. The results suggested a positive effect of drug, but were a bit confusing. Of those patients completing the four-month trial (92/112) 78% of the drug treated patients vs 52% of those in the placebo group were dry. However, one month after the end of the study, the corresponding figures were 46% vs 73%, a shift still observed two months later.

The authors of the review article suggest further larger and well designed studies on duloxetine for this potential usage.
Urinary incontinence most often results from too much pressure generated by the bladder and/or too little resistance generated by the bladder outflow tract during the storage phase of the micturition cycle (urgency incontinence and stress urinary incontinence, respectively). More rarely, incontinence can also occur in the presence of too little pressure and/or too much resistance being developed which can lead to a markedly distended bladder and urinary retention and, secondarily, to overflow incontinence [Abrams et al., 2002].

Based upon theoretical reasoning, animal studies [Kamo et al., 2005; Gu et al., 2004] or reports of drugs which can cause overflow incontinence [Anders et al., 1985], a variety of medical approaches to the treatment of overflow incontinence have been proposed [Chutka and Takahashi, 1998; Hampel et al., 2005].

These include direct or indirect muscarinic receptor agonists and $\alpha_1$-AR antagonists. The use of the former is based upon the idea that stimulation of muscarinic receptors may overcome a hypo-contractile state of the detrusor. However, a recent systematic review of controlled clinical studies on the use of direct and indirect parasympathetic agonists in patients with an underactive detrusor has shown that these drugs do not exhibit consistent benefit and may even be harmful [Barendrecht et al., 2007]. In contrast, the use of $\alpha_1$-AR antagonists has repeatedly been shown to beneficial in patients with acute urinary retention [McNeill et al., 2004; 2005].

However, neither parasympathomimetic drugs nor $\alpha_1$-AR antagonists have ever been tested systematically in the treatment of overflow incontinence. Accordingly, a Medline search using the keyword “overflow incontinence” did not yield a single randomized controlled trial for its treatment, and not even a case series with a meaningful number of patients was retrieved. Therefore, it must be concluded that there is no empirical basis to select medical treatments for overflow incontinence and all previously recommended treatments must be rated as “expert opinion” at best. Moreover, any medical treatment for overflow incontinence will have to be evaluated as compared to catherization or surgery but also for such comparison no clinical data are available.

---

1. ESTROGENS AND THE CONTINENCE MECHANISM

The estrogen sensitive tissues of the bladder, urethra and pelvic floor all play an important role in the continence mechanism. For women to remain continent the urethral pressure must exceed the intravesical pressure at all times except during micturition. The urethra has four estrogen sensitive functional layers all of which play a part in the maintenance of a positive urethral pressure 1) epithelium, 2) vasculature, 3) connective tissue, 4) muscle.

Two types of estrogen receptor, ($\alpha$ and $\beta$) have been identified in the trigone of the bladder, urethra and vagina as well as in the levator ani muscles and fascia and ligaments within the pelvic floor [Smith et al., 1990; Copas et al., 2001; Gebhardt et al., 2001]. After the menopause, estrogen receptor $\alpha$ has been shown to vary depending upon exogenous estrogen therapy [Fu et al., 2003]. In addition exogenous estrogens affect the remodeling of collagen in the urogenital tissues resulting in a reduction of the total collagen concentration with a decrease in the cross linking of collagen in both continent and incontinent women [Falconer et al., 1998; Keane et al., 1997]. Studies in both animals and humans have shown that estrogens also increase vascularity in the peri-urethral plexus which can be measured as vascular pulsations on urethral pressure profilometry [Robinson et al., 1996; Endo et al., 2000; Versi and Cardozo, 1986].

2. ESTROGENS FOR STRESS URINARY INCONTINENCE

The role of estrogen in the treatment of stress urinary incontinence has been controversial despite a number of reported clinical trials [Hextall, 2000]. Some have given promising results but this may have been because they were small observational and not randomized, blinded or controlled. The situation is further complicated by the fact that a number of different types of estrogen have been used with varying doses, routes of administration and duration of treatment. For assessment, see Table 4.

Fantl et al. [1996] treated 83 hypo-estrogenic women with urodynamic stress incontinence and/or detrusor overactivity with conjugated equine estrogens 0.625 mg and medroxyprogesterone 10 mg cyclically for three months. Controls received placebo tablets. At the end of the study period the clinical and quality of life variables did not change significantly in either...
group. Jackson et al. [1996] treated 57 post menopausal women with urodynamic stress or mixed incontinence with estradiol 2 mg or placebo daily for six months. There was no significant change in objective outcome measures although both the active and placebo groups reported subjective benefit.

There have been two meta-analyses performed. In the first, a report by the Hormones and Urogenital Therapy (HUT) committee the use of estrogens to treat all causes of incontinence in post menopausal women was examined [Fantl et al., 1994]. Of 166 articles identified, which were published in English between 1969 and 1992, only six were controlled trials and 17 uncontrolled series. The results showed that there was a significant subjective improvement for all patients and those with urodynamic stress incontinence. However, assessment of the objective parameters revealed that there was no change in the volume of urine lost, maximum urethral closure pressure increased significantly but this result was influenced by only one study showing a large effect.

In the second meta-analysis Sultana and Walters [1990] reviewed eight controlled and 14 uncontrolled prospective trials and included all types of estrogen treatment. They also found that estrogen therapy was not an efficacious treatment for stress urinary incontinence but may be useful for the often associated symptoms of urgency and frequency. Estrogen when given alone therefore does not appear to be an effective treatment for stress urinary incontinence.

Several studies have shown that estrogen may have a role in combination with other therapies e.g. α-AR agonists. However, PPA (the most widely used α-AR agonist in clinical practice) has now been restricted or banned by the US Food and Drug Administration (FDA). In a randomized trial Ishiko et al. [2001] compared the effects of the combination of pelvic floor exercise and estriol (1 mg per day) in 66 patients with post meno-pausal stress urinary incontinence. Efficacy was evaluated every three months based on stress scores obtained from a questionnaire. They found a significant decrease in stress score in mild and moderate stress incontinent patients in both groups three months after the start of therapy and concluded that combination therapy with estriol plus pelvic floor exercise was effective and could be used as first line treatment for mild stress urinary incontinence. Unfortunately this has not been reproduced in other clinical trials.

Thus even prior to the more recently reported secondary analyses of the heart and estrogens/progestogen replacement study (HERS) [Grady et al., 2001] and Women’s Health Initiative (WHI) [Hendrix et al., 2005] it was already recognized that estrogen therapy had little effect in the management of urodynamic stress incontinence [Al-Badr et al., 2003; Robinson and Cardozo, 2003].

3. ESTROGENS FOR URGENCY URINARY INCONTINENCE AND OVERACTIVE BLADDER SYMPTOMS

Estrogen has been used to treat post menopausal urgency and urgency incontinence for many years but there have been few controlled trials to confirm that it is of benefit [Hextall, 2000; for assessment, see Table 2]. A double blind multi centre study of 64 post menopausal women with “urgency syndrome” failed to show efficacy [Cardozo et al., 1993]. All women underwent pre-treatment urodynamic investigation to ensure that they had either “sensory urgency” or DO. They were randomized to treatment with oral estriol 3 mg daily or placebo for three months. Compliance with therapy was confirmed by a significant improvement in the maturation index of vaginal epithelial cells in the active but not the placebo group. Estriol produced subjective and objective improvements in urinary symptoms, but was not significantly better than placebo.

Another recent randomized controlled trial from the same group using 25 mg estradiol implants confirmed the previous findings [Rufford et al., 2003], and furthermore found a high complication rate in the estradiol treated patients (vaginal bleeding).

Evidence from large clinical trials

The HERS study included 763 post menopausal women under the age of 80 years with coronary heart disease and intact uteri [Grady et al., 2001]. It was designed to evaluate the use of estrogen in secondary prevention of cardiac events. In a secondary analysis 1525 participants who reported at least one episode of incontinence per week at baseline were included. Participants were randomly assigned to 0.625 mg of conjugated estrogens plus 2.5 mg of medroxyprogesterone acetate in one tablet (N=768) or placebo (N=757) and were followed for a mean of 4.1 years. Severity of incontinence was classified as improved, unchanged or worsened. The results showed that incontinence improved in 26% of the women assigned to placebo compared to 21% assigned to hormones whilst 27% of the placebo worsened compared with 39% of the hormone group (P=0.001).

This difference was evident by four months of treatment, for both urgency and stress urinary incontinence. The number of incontinent episodes per week increased an average of 0.7 in the hormone group and decreased by 0.1 in the placebo group (p<0.001). The authors concluded that daily oral estrogen plus progestogen therapy was associated with worsening urinary incontinence in older post menopausal women with weekly incontinence and did not recommend this therapy for treatment of incontinence. However, it is possible that the progestogen component may have had an influence on the results of this study.
The Women’s Health Initiative (WHI) was a multi-center double blind placebo controlled randomized clinical trial of menopausal hormone therapy in 27347 postmenopausal women age 50–79 years enrolled between 1992 and 1998 for whom urinary incontinence symptoms were known in 23296 participants at baseline and one year. The women were randomized based on hysterectomy status to active treatment or placebo. Those with a uterus were given 0.625 mg per day of conjugated equine estrogen (CEE) plus 2.5 mg per day of medroxyprogesterone acetate (CEE+MPA), whereas those who had undergone hysterectomy received estrogen alone (CEE). At one year hormone therapy was shown to increase the incidence of all types of urinary incontinence among women who were continent at baseline. The risk was highest for stress urinary incontinence CEE+MPA: RR, 1.7 95% confidence interval CI (1.61-2.18); CEE alone RR 2.15 mg, 95% CI, 1.77-2.62, followed by mixed urinary incontinence CEE+MPA: RR 1.49 95% CI 1.10-2.01. On CEE alone RR was 1.79 95% CI, 1.26-2.53. The combination of CEE and MPA had no significant effect on developing urgency urinary incontinence RR, 1.15; 95% CI, 0.99-1.34 but CEE alone increased the risk, RR 1.32; 95% CI, 1.10-1.58. For those women experiencing urinary incontinence at baseline frequency worsened in both active groups CEE+MPA; RR, 1.38 95% CI 1.28-1.48; CEE alone: RR, 1.47 95% CI, 1.35-1.61. Quantity of urinary incontinence worsened at one year in both active groups, CEE+MPA: RR, 1.20 95% CI, 1.06-1.76; CEE alone: RR, 1.59 95% CI, 1.39-1.82. Those women receiving hormone therapy were more likely to report that urinary incontinence limited their daily activities CEE+MPA: RR 1.18 95% CI, 1.06-1.32. CEE alone: RR 1.29 95% CI, 1.15-1.45 at one year. Thus based on this secondary analysis of data from a huge study conjugated equine estrogen alone or in combination with medroxyprogesterone acetate was shown to increase the risk of urinary incontinence amongst continent women and worsen urinary incontinence amongst asymptomatic women after one year of therapy.

The Nurses Health Study [Grodstein et al., 2004] was a biennial postal questionnaire starting in 1976. In 1996, 39436 post menopausal women aged 50–75 years who reported no urinary leakage at the start of the study were followed up for four years to identify incident cases of urinary incontinence. 5060 cases of occasional and 2495 cases of frequent incontinence were identified. The risk of developing urinary incontinence was increased amongst post menopausal women taking hormones compared to women who had never taken hormones (oral estrogen: RR1.54 95% CI 1.44, 1.65; transdermal estrogen: RR1.68, 95% CI 1.41, 2.00; oral estrogen with progestin: RR1.34, 95% CI 1.24, 1.44; transdermal estrogen with progestin: RR1.46, 95% CI 1.16, 1.84). After cessation of hormone therapy there was a decreased risk of incontinence such that 10 years after stopping hormones the risk was identical in women who had and who never had taken hormone therapy.

CONCLUSIONS

Estrogen has an important physiological effect on the female lower urinary tract and its deficiency is an etiological factor in the pathogenesis of a number of conditions. However the use of estrogen either alone or in combination with progestogen has yielded poor results. The current level 1 evidence against the use of estrogen for the treatment of urinary incontinence comes from studies powered to assess their benefit in the prevention of cardiovascular events, and therefore the secondary analyses have only been based on self reported symptoms of urinary leakage without any objective data. Despite this all of these large randomized controlled trials show a worsening of pre-existing urinary incontinence both stress and urgency, and an increased new incidence of urinary incontinence with both estrogen and estrogen plus progestogen. However, the majority of patients in all of these studies were taking combined equine estrogen and this may not be representative of all estrogens taken by all routes of administration.

In a systematic review of the effects of estrogens for symptoms suggestive of an overactive bladder the conclusion was that estrogen therapy may be effective in alleviating OAB symptoms, and that local administration may be the most beneficial route of administration [Cardozo et al., 2004].

It is quite possible that the reason for this is that the symptoms of urinary urgency, frequency and urgency incontinence may be a manifestation of urogenital atrophy in older post menopausal women rather than a direct effect on the lower urinary tract [Robinson and Cardozo, 2003]. Whilst there is good evidence that the symptoms and cytological changes of urogenital atrophy may be reversed by low dose (local) vaginal estrogen therapy there is currently no evidence that estrogens with or without progestogens should be used in the treatment of urinary incontinence.

II. OTHER STEROID HORMONE RECEPTOR LIGANDS

Progesterone and progestogens are thought to increase the risk of urinary incontinence. Lower urinary tract symptoms especially stress urinary incontinence, have been reported to increase in the progestogenic phase of the menstrual cycle [Hextall et al., 2001]. In similar studies progesterone has been shown to increase β-AR activity leading to a decrease in the urethral closure pressure in female dogs [Raz et al., 1973]. However, in the WHI there appeared to be no difference whether or not progestin was given in addition to estrogen [Hendrix et al., 2005].
Selective estrogen receptor modulators (SERMS) have been reported to have varying effects. Each of the SERMS has receptor ligand conformations that are unique and have both estrogenic and anti-estrogenic effects. In the clinical trials of levormeloxifene there was a fourfold increase in the incidence of incontinence leading to cessation of the clinical trial [Hendrix et al., 2001]. However raloxifene has not been shown to have any effect at all on urinary incontinence [Waetjen et al., 2004].

There are no reported clinical trials evaluating the effect of androgens, and in particular testosterone, on urinary incontinence in women.

### III. DESMOPRESSIN

The endogenous hormone vasopressin (also known as anti-diuretic hormone) fulfils two main functions, i.e. it can contract vascular smooth muscle and can stimulate water reabsorption in the renal medulla. These functions are mediated by specific vasopressin receptors of which two major subtypes exist, the V₁ and the V₂ receptors of which the V₂ subtype is particularly important for the anti-diuretic effects of vasopressin. A genetic or acquired defect in making and secreting vasopressin leads to a central diabetes insipidus, and genetic defects in the gene encoding the V₂ receptors can cause nephrogenic diabetes insipidus [Insel et al., 2007]. Accordingly, a (relative) lack of vasopressin is believed to be important in the pathophysiology of polyuria, specifically nocturnal polyuria, which can lead to symptoms such as nocturia [Matthiesen et al., 1996]. While it remains largely unknown in which fraction of patients nocturia can indeed be explained by too little vasopressin, the presence of nocturnal polyuria in the absence of behavioural factors explaining it (such as excessive fluid intake) is usually considered as an indication that a (relative) lack of vasopressin may exist.

Based upon these considerations, vasopressin receptor agonists have been explored for the treatment of the symptom nocturia (both in children and in adults) and, more recently, for the treatment of OAB in general. Most studies related to the treatment of nocturia with vasopressin analogues have been performed using desmopressin, which shows selectivity for anti-diuretic over vasopressor effects and is available in formulations for oral, parenteral and nasal administration: an oral lypohlsate formulation [Vande Walle et al., 2006] has recently been approved in some countries. Vasopressin receptor agonists with pronounced vasopressor effects such as terlipressin have mainly been tested in other indications, e.g., acute oesophageal variceal haemorrhage.

The use of desmopressin in children with nocturnal enuresis has been comprehensively reviewed by the Cochrane Collaboration in 2002 [Glazener and Evans, 2008]. Their analysis included 47 randomized controlled trials involving 3448 children, of whom 2210 received desmopressin. According to this analysis desmopressin was effective relative to placebo in reducing bed-wetting (for example at a dose of 20 µg there was a reduction of 1.34 wet episodes/night (95% CI 1.11; 1.57), and children were more likely to become dry with desmopressin (98%) than with placebo (81%). However, there was no difference to placebo after discontinuation of treatment, indicating that desmopressin suppresses the symptom enuresis but does not cure the underlying cause. Moreover, based upon limited data, there was no clear dose-related effect, and there were too few studies to conclusively compare oral vs. nasal administration.

A Medline search using the terms “desmopressin” and “enuresis” did not yield additional studies which would change these conclusions. However, not all children respond sufficiently to desmopressin treatment, and some studies indicate that non-responders may benefit from other medications including tricyclic antidepressants or loop diuretics whereas muscarinic receptor antagonists may be ineffective in such children [De Guchtenaere et al., 2007; Neveus and Tullus, 2008].

Other studies have explored a possible role of desmopressin in the treatment of nocturia in adults. The Medline search for such studies used the terms “desmopressin” and “nocturia” and was limited to clinical studies on de novo nocturia, i.e. excluded subjects in whom childhood enuresis persisted into adulthood. Early studies have mainly investigated the use of desmopressin in the treatment of nocturia in the context of multiple sclerosis. One study with single dose administration reported reductions of nocturnal polyuria, but by design did not assess nocturia [Eckford et al., 1995]. Three placebo-controlled double-blind studies with small patient numbers (16-33 patients total per study) reported a significant reduction of nocturia [Eckford et al., 1994; Valiquette et al., 1996; Hilton et al., 1983]. For example, in the study of Valiquette et al. [1996] performed in patients with multiple sclerosis, the number of nocturia episodes were reduced from 2.35 to 1.09 and the maximum hours of uninterrupted sleep form increased from 3.74 to 5.77 hours. Other controlled studies of similar size, mostly performed in crossover designs, and with treatment for up to two weeks used daytime micturition frequency and urgency incontinence within the first six hours after desmopressin administration rather than nocturia as their primary endpoint and consistently reported efficacy of desmopressin [Kinn and Larsson, 1990; Fredrikson, 1996; Hovend and Fowler, 1998]. While desmopressin treatment was generally well tolerated, at least in one study, four out of 17 patients discontinued treatment due to asymptomatic or minimally symptomatic hyponatremia [Valiquette et al., 1996].
Accordingly, desmopressin is now registered for the treatment of nocturia in multiple sclerosis patients [Cvetkovic and Plosker, 2005]. In a small open-label study desmopressin was also reported to reduce nocturnal polyuria in spinal cord injury patients [Zahariou et al., 2007]. Other studies have explored the use of desmopressin in adults with nocturia in the apparent absence of neurological damage. Most studies had a short double-blind period of only two to three weeks. The recruited patient populations were based upon different criteria including having at least two nocturia episodes per night or having nocturnal polyuria. The early studies mostly used desmopressin given either orally [Asplund et al., 1999] or intranasally [Hilton and Stanton, 1982; Cannon et al., 1999], and tended to be very small (725 patients). The original intranasal formulation has meanwhile been withdrawn from the market in several countries due to side effects and unpredictable absorption.

Later studies, as part of the NOCTUPUS program, were considerably larger, involving a total of 1003 screened patients, and applied higher oral doses (0.1-0.4 mg) for three weeks of double-blind treatment in adults [Mattiasson et al., 2002; Lose et al., 2004; van Kerrebroeck et al., 2007]. The three short-term placebo-controlled studies were of identical design and were designed to identify the most effective dose regimen as well as establishing criteria for selecting those patients most likely to respond safely to desmopressin. A total of 632 patients entered the dose-titration phase with 422 patients entering the double-blind phase of the three NOCTUPUS trials. The aim of the titration phase was to describe the antidiuretic effect in patients with nocturnal polyuria. It has been argued that while these studies consistently demonstrated efficacy over placebo in reducing nocturia episodes, they were performed in patients who were known to be desmopressin responders based upon initial dose-titration phases. To avoid this bias, all patients in the NOCTUPUS trials were washed out following the dose-titration and in order to be randomized it was a requirement that these patients should be back to baseline on their nocturnal diuresis before inclusion in the double-blind phase. Patients on desmopressin had a reduction in mean number of nocturnal voids (from 2.4-2.7 to 1.6-2.0), an increase in mean duration of the first sleep period (from 181-196 to 247-272 minutes) and a decrease in mean nocturnal diuresis (from 1.35 and 1.5 to 0.82 tand 0.9 ml per minute [Hashim and Abrams; 2008].

The efficacy of desmopressin for the treatment of nocturia was also confirmed in a long-term (10-12 months) open-label study involving 249 patients, which was an extension to the above mentioned randomized studies in known desmopressin responders [Lose et al., 2004]. The number of nocturnal voids was decreased throughout the study in males to 1.3-1.6 from a baseline of 3.1 and in females from 2.9 to 1.2-1.3. After the one-month follow-up at the end of the trial when treatment was stopped, the number of nocturnal voids increased following cessation of desmopressin. The mean duration of the first sleep period gradually increased in males from 157 minutes at baseline to 288 minutes at 12 months and in females from 142 at baseline to 310 minutes at 12 months. After follow-up the mean duration of the first sleep period decreased confirming that increased sleep is a real treatment related benefit of desmopressin. There was an improvement in QoL with more than 50% decrease in patients reporting nocturia as the most bothersome symptom as assessed by the ICSmale and BFLUTS questionnaires.

An open-label pilot study in a nursing home setting also reported beneficial effects of desmopressin [Johnson et al., 2006]. Taken together these data demonstrate that oral desmopressin treatment at doses of 0.1-0.4 mg reduces nocturia more effectively than placebo in known desmopressin responders. Hyponatremia appears to occur in few cases only and rarely becomes symptomatic. As the symptom of nocturia can result from many causes, it has also been studied whether desmopressin may be beneficial in patients characterized not only by nocturia. In a small, non-randomized pilot study of men believed to have BPE, desmopressin was reported to improve not only nocturia but also to reduce overall International Prostate Symptom Score (IPSS) [Chancellor et al., 1999].

An exploratory, placebo-controlled double-blind study in women with daytime urinary incontinence has reported that intranasal administration of 40 µg desmopressin increased the number of leakage-free episodes after drug administration [Robinson et al., 2004]. One double-blind, placebo-controlled pilot study in patients with OAB treated with 0.2 mg oral desmopressin reported a reduction in daytime voids and urgency episode along with an improvement of quality of life, in the first eight hours of the morning after taking desmopressin [Hashim et al., 2008]. These data indicate that desmopressin may be effective in storage symptoms, not limited to nocturia (Level 2, Grade C), and desmopressin may be used as a ‘designer’ drug in the treatment of OAB and incontinence during the daytime. Further studies are required to address this concept using the new oral lyophilisate ‘Melt’ formulation either on its own or in combination with antimuscarinics and/or alpha blockers in patients with OAB and/or BPE.

Desmopressin was well tolerated in all the studies and resulted in significant improvements compared to placebo in reducing nocturnal voids and increasing the hours of undisturbed sleep. There was also an improvement in QoL. However, one of the main clinically important side effects of demopressin usage is hyponatremia. Hyponatremia can lead to a variety of adverse events ranging from mild headache,
anorexia, nausea, and vomiting to loss of consciousness, seizures and death. The risk of hyponatraemia seems to increase with age, cardiac disease, and increasing 24-hour urine volume [Rembratt et al., 2003] and has been reported in a meta-analysis to be about 7.6% [Weatherall et al., 2004].

Currently, there are no predictive factors about who may be at increased risk of developing hyponatraemia. However, to reduce the risk of hyponatraemia, it is recommended that patients older than 79 years or with a 24-hour urine volume more than 28 ml/kg should not be given desmopressin [Rembratt et al., 2006]. In those over 65 years, serum sodium levels should be checked at baseline and at three days and seven days after commencing treatment or changing dose. It is probably good medical practice that these serum sodium measurements are also applied to those under 65 years of age, as well as checking sodium levels at three weeks post treatment or change of dose as there is the potential for levels of sodium to change within a three week period [Callreus et al., 2005]. One study showed that hyponatraemia can develop after six months of administration, although not clinically significant [Bae et al., 2007], and therefore serum sodium levels may be checked at six months following administration and then six monthly thereafter. Long-term use of desmopressin does not seem to affect baseline antidiuretic hormone secretion [Bae et al., 2007]. The fluid intake will need to be limited to a minimum from one hour before the dose until eight hours afterwards and there needs to be periodic blood pressure and weight measurements to monitor for fluid overload. Desmopressin is currently the only medication licensed and available for the treatment of nocturia. It is currently licensed for the treatment of nocturia in the oral ‘Melt’ form and in the oral tablet form. For assessment, see Table 2.

F. CONSIDERATIONS IN THE ELDERLY

Almost all randomized controlled trials of antimuscarinics for urinary incontinence include older adults, however only two efficacy sub-analyses of older adults have been reported. The first, TOLT-IR 2 mg twice daily vs. placebo, revealed a significant decrease of 0.7 episodes of incontinence per day (an approximate 25% reduction) among 131 participants with urgency incontinence (mean age 75, range 62-92) [Malone-Lee et al., 2001]. A second, larger study comparing older adults (mean age 74 ± 6) to younger adults (mean age 51± 10) taking TOLT-ER 4 mg, showed equivalent efficacy for the two age groups in reducing incontinence episodes (a mean decrease of 12 episodes per week, an approximate 55% reduction from baseline), with both groups showing significantly greater improvement compared to placebo (placebo response: younger 6, older 7 episodes per week) [Zinner et al., 2002].

A number of explanations exist for why antimuscarinic agents may show reduced efficacy for urgency incontinence in the elderly in the practice setting compared to the research setting. Exclusion criteria for antimuscarinic research trials generally include consumption of other antimuscarinic agents or cytochrome P450 3A4 inhibitors. In practice, older adults are a heterogeneous group, often consuming many medications that may desensitize or alter the response of the individual to antimuscarinics. As well, there is a higher prevalence of concomitant BPE among older men, with storage symptoms showing a variable response to antimuscarinics. Failure to acknowledge the multifactorial nature of urinary incontinence in the elderly often leads to sub-optimal treatment. Urgency symptoms may be exacerbated by consumption of caffeinated beverages, pelvic floor muscle weakness, diuretics or other functional and systemic dysfunctions. Treatment must address all possible etiologies, and not be limited to a solitary intervention.

The side effect profile of antimuscarinics appears to be the same for older and younger patients. Dry mouth is the most frequent adverse effect prompting discontinuation of the drug [Zinner et al., 2002]. Other more serious side effects, such as prolongation of the Q-T interval with some antimuscarinics, have not been systematically studied in the elderly population. The M2 receptor antimuscarinics in particular have the potential to increase resting heart rate (a predictor of mortality in the elderly), however the clinical significance of this remains uncertain [Andersson and Olshansky, 2007]. In practice, older patients may already be taking other antimuscarinic drugs and thus may be habituated or intolerant to the addition of another medication in the same class and the resultant cumulative antimuscarinic load. A number of commonly used medications in the elderly possess antimuscarinic properties [Chew et al., 2008]. These include, among others, amitriptyline, clozapine, olanzepine, paroxetine, furosemide, hydrocodone, lansoprazole, levofloxacin, and metformin.

Of particular concern in the elderly is the possibility that antimuscarinic agents used to treat urgency incontinence may induce subtle or not so subtle cognitive impairment. In experimental studies, administration of scopolamine has been shown to impair memory and attention in older adults [Flicker et al., 1992; Sperling et al., 2002]. Older adults are also prone to develop hallucinations and confusion with scopolamine, and experience significantly greater impairments in delayed memory and psychomotor speed compared to younger individuals.

Antimuscarinic drugs have also been associated with the presence of mild cognitive impairment, a precursor...
been induced. This is especially pertinent because therapy might reveal whether subtle impairments have who are concerned or at risk, before and after initiating neuropsychological test battery for those patients Montreal Cognitive Assessment) or even a full incontinence in the elderly. If antimuscarinics are to risk-benefit ratio in light of other therapeutic options prescribing these medications and fully weigh the linking antimuscarinics and cognition impairment, of three tests. In the absence of more definitive data reduced accuracy scores for immediate recall in one information processing speed. Oxybutynin also significantly slower reaction times than placebo in the second study, darifenacin was compared to oxybutynin compared with placebo [Lipton et al., 2005]. In the first study of 129 older adults aged 65-84, no significant effects on cognition were observed (memory scanning sensitivity, speed of reaction time, and word recognition) compared with placebo [Todorova et al., 2001]. There have also been several published case reports documenting the acute onset of delirium following initiation of tolterodine, incontinent adults with and without dementia [Womack and Heilman, 2003; Salvatore et al., 2007; Edwards et al., 2002; Williams et al., 2004; Tsao et al., 2003]. These deficits resolved upon discontinuation or dose reduction of tolterodine. Two studies have been conducted using darifenacin, but only in continent volunteers [Lipton et al., 2005; Kay et al., 2006]. In the first study of 129 older adults aged 65-84, no significant effects on cognition were observed (memory scanning sensitivity, speed of reaction time, and word recognition) compared with placebo [Lipton et al., 2005]. In the second study, darifenacin was compared to oxybutynin and placebo in a randomized multicentre double-blind parallel-group 3-week study design using 150 healthy volunteers aged 60-83 [Kay et al., 2006]. Darifenacin produced no impairments compared to placebo at 3-weeks, but oxybutynin caused significant memory deterioration in delayed recall compared to the other two groups. Darifenacin was associated with significantly slower reaction times than placebo in the Divided Attention Test, but not in other tests of information processing speed. Oxybutynin also reduced accuracy scores for immediate recall in one of three tests. In the absence of more definitive data linking antimuscarinics and cognition impairment, clinicians are suggested to proceed with caution in prescribing these medications and fully weigh the risk-benefit ratio in light of other therapeutic options that can be equally effective for urgency and mixed incontinence in the elderly. If antimuscarinics are to be prescribed, a short cognitive screen (such as the Montreal Cognitive Assessment) or even a full neuropsychological-test battery for those patients who are concerned or at risk, before and after initiating therapy might reveal whether subtle impairments have been induced. This is especially pertinent because patients are often unaware of their memory deficits [Kay et al., 2006]. A proxy informant, such as the patient's spouse or a relative, may be able to provide more reliable information on possible cognitive changes resulting from the drugs.

A frequently asked clinical question is whether antimuscarinic agents used to treat incontinence should be contraindicated in patients with dementia already taking cholinesterase inhibitors, as the mechanisms of these two medications are diametrically opposed. No studies have examined the cognitive consequences of antimuscarinics in patients with dementia. However, a number of small studies have shown the reverse mechanism to be true, that cholinesterase inhibitors used to improve cognition in Alzheimer's disease precipitate urinary incontinence [Hashimoto et al., 2000]. A Japanese study followed 94 patients with mild to moderate dementia treated with donepezil [Hashimoto et al., 2000]. Seven patients developed urinary incontinence, although the event was transient in most patients. In Scotland, among 216 patients with Alzheimer's disease initiating treatment with a cholinesterase inhibitor, incontinence was precipitated in 6.6%, and those with existing incontinence worsened [Starr, 2007]. Epidemiologic studies also show associations between cholinesterase inhibitors and incontinence [Gill et al., 2005; Roe et al., 2002]. In a large population-based cohort study of 44,884 adults with dementia carried out in Canada, those who were dispensed cholinesterase inhibitors were more likely to subsequently receive an antimuscarinic drug for incontinence compared to those not receiving cholinesterase inhibitors (hazard ratio 1.55, 95% confidence interval 1.39-1.72) [Gill et al., 2005]. This finding was confirmed by a separate study in the U.S. documenting a two-fold risk of taking oxybutynin in dementia patients treated with donepezil compared to those not treated with donepezil [Roe et al., 2002]. This evidence suggests the competing mechanisms of the antimuscarinics and cholinesterase inhibitors may indeed have clinical consequences in some, but not all patients. Should an adverse effect be suspected, then alternate therapeutic options should be pursued. None of the other drug classes used to treat stress, urgency or overflow incontinence have undergone rigorous evaluation in the elderly, however a number of general guidelines apply. Use of α-AR agonists and tricyclic antidepressants are discouraged in the elderly due to blood pressure considerations. Uncontrolled systolic hypertension could occur with the former agents and orthostatic hypotension leading to falls with the latter. There is no evidence that hormonal agents are of benefit for urgency or stress incontinence in older women, although local estrogens may be indicated to treat dysuria resulting from concomitant vaginal atrophy. Finally, removal of any offending agents that could be contributing to incontinence (benzodiazepines, narcotics, diuretics) should be considered.

In this chapter the diagnostic and treatment modalities of urinary incontinence in childhood will be discussed. In order to understand the pathophysiology of the most frequently encountered problems in children the normal development of bladder and sphincter control will be discussed.

The underlying pathophysiology will be outlined and the specific investigations for children will be discussed. For general information on epidemiology and urodynamic investigations the respective chapters are to be consulted.

Normal bladder storage and voiding involve low-pressure and adequate bladder volume filling followed by a continuous detrusor contraction that results in bladder emptying, associated with adequate relaxation of the sphincter complex. This process requires normal sensation and normal bladder outlet resistance. The neurophysiological mechanisms involved in normal bladder storage and evacuation include a complex integration of sympathetic, parasympathetic and somatic innervations which is ultimately controlled by a complex interaction between spinal cord, brain stem, midbrain and higher cortical structures [1].

Achievement of urinary control is equally complex and as yet not fully understood: various developmental stages have been observed [2].

In newborns the bladder has been traditionally described as "uninhibited", and it has been assumed that micturition occurs automatically by a simple spinal cord reflex, with little or no mediation by the higher neural centres. However, studies have indicated that even in full-term foetuses and newborns, micturition is modulated by higher centres and the previous notion that voiding is spontaneous and mediated by a simple spinal reflex is an oversimplification [3]. Foetal micturition seems to be a behavioural state-dependent event: intrauterine micturition is not randomly distributed between sleep and arousal, but occurs almost exclusively while the foetus is awake [3].

During the last trimester the intra-uterine urine production is much higher than in the postnatal period (30ml/hr) and the voiding frequency is approximately 30 times every 24 hours [4].

Immediately after birth voiding is very infrequent during the first few days of life. The first void may only take place after 12 to 24 hours. After the first week frequency increases rapidly and peaks at the age of 2 to 4 weeks to an average of once per hour. It then decreases and remains stable after 6 months to about 10 to 15 times per day. After the first year it decreases to 8 to 10 times per day, while voided volumes increase by three to fourfold.

During the postnatal period, micturition control mechanisms undergo further changes and extensive modulation. Using ambulatory bladder monitoring techniques in conjunction with polysomnographic recordings it has been shown that even in newborns the bladder is normally quiescent and micturition does not occur during sleep [5].

This inhibition (or lack of facilitation) of detrusor contractions during sleep is also observed in infants with neurogenic bladder dysfunction who have marked
detrusor overactivity while they are awake. In response to bladder distension during sleep, an infant nearly always exhibits clear electro-encephalographic evidence of cortical arousal, facial grimaces or limb movements, or actual awakening. Sleeping infants are always seen to wake up before the bladder contracts and voiding occurs. This arousal period may be transient and the infant may cry and move for a brief period before micturition and then shortly afterward go back to sleep. Because this waking response is already well established in newborns, it follows that the control of micturition probably involves more complicated neural pathways and higher centres than has been appreciated. There is also strong evidence that a pronounced reorganisation of pre-existing synaptic connections and neural pathways involved in bladder control occurs during the early postnatal period.

In newborns micturition occurs at frequent intervals and may have an intermittent pattern although bladder emptying efficiency is usually good. In over 80 percent of voids the bladder empties completely [6].

During infancy voiding pressures are much higher than in adults. It has also been noted that these pressures are higher in boys than in girls (mean pdet max of 118 vs. 75 cm H2O, respectively) [7,8]. These higher detrusor pressures decrease progressively with increasing age. In up to 70 percent of infants (up to the age of 3 years) with normal lower urinary tracts, intermittent patterns of voiding were observed. They tend to disappear with increasing age, and are thought to represent variations between individual infants in the maturation of detrusor and sphincteric co-ordination during the first 1 to 2 years of life. Videourodynamic studies have confirmed these findings [5,7,8,9,10].

Between the age of 1 and 2, conscious sensation of bladder filling develops. The ability to void or inhibit voiding voluntarily at any degree of bladder filling commonly develops in the second and third years of life. Central inhibition is crucial to obtain continence.

During the second and third year of life, there is progressive development towards a socially conscious continence and a more voluntary type of micturition control develops. The child becomes more aware of the sensation of bladder distension and the need to urinate, as well as social norms and embarrassment associated with urinary incontinence. Through an active learning process, the child acquires the ability to voluntarily inhibit and delay voiding until a socially convenient time, then actively initiate urination even when the bladder is not completely full, and allows urination to proceed to completion. During the first years of life, gradual development to an adult type of voluntary micturition control that conforms to the social norms depends on an intact nervous system, in addition to at least three other events occurring concomitantly:

- a progressive increase in functional storage capacity,
- maturation of function and control over the external urinary sphincter,
- and most importantly achievement of volitional control over the bladder-sphincteric unit so that the child can voluntarily initiate or inhibit a micturition reflex [11].

The final steps are usually achieved at the age of 3 to 4 years when most children have developed the adult pattern of urinary control and are dry both day and night. The child has learned to inhibit a micturition reflex and postpone voiding and voluntarily initiate micturition at socially acceptable and convenient times and places. This development is also dependent on behavioural learning and can be influenced by toilet training, which in turn depends on cognitive perception of the maturing urinary tract.

It is understandable that this series of complex events is highly susceptible to the development of various types of dysfunction. Various functional derangements of the bladder-sphincter-perineal complex may occur during this sophisticated course of early development of normal micturition control mechanisms. These acquired “functional” disorders overlap with other types of bladder functional disturbances that may have a more organic underlying pathophysiological basis.

II. NORMAL VALUES

1. NORMAL BLADDER CAPACITY

The bladder capacity increases during the first 8 years of life roughly with 30 ml per year, so with an average capacity of 30 ml in the neonatal period, a child’s bladder volume can be calculated as Y = 30 + 30 X, where Y = capacity in ml and X = age in years (Figure 1) [12].

Hjälmås described a linear correlation that could be used up to 12 years of age: in boys, Y = 24.8 X + 31.6, in girls Y = 22.6 X + 37.4, where Y is capacity in ml, and X is age in years [13].

It should be noted that these data were obtained during cystometric investigations. Cystometric capacity is generally less than normal bladder volumes. Obviously, the relation between age and bladder capacity is not linear for all ages, nor is the relation between body weight and bladder capacity [14].

Another formula to calculate bladder capacity in infants is: bladder capacity (ml) = 38 + (2.5 x age (mo)) [10].
Kaefer and co-workers demonstrated that a non-linear model was the most accurate for the relation between age and bladder capacity, and they determined two practical linear equations:

\[ Y = 2X + 2 \text{ for children less than 2 years old}, \]
\[ Y = \frac{X}{2} + 6 \text{ for those 2 years old or older}; \]

\( Y \) = capacity in ounces, \( X \) = age in years (Figure 2) [15].

None of these formulas have been acquired from a population-based study and do not reflect normal bladder capacity. Normal bladder capacity should be regarded as the maximum voided volume of urine and shows huge variation.

Girls were found to have a larger capacity than boys, but the rate of increase with age was not significantly different between them. Data on ‘normal’ bladder capacity have been obtained in continent children undergoing cystography, with retrograde filling of the bladder.

Data obtained from the International Reflux Study indicate that there is not a linear relation between age and capacity and that there is a huge variability (Figure 3).

2. NORMAL VOIDING

The micturition frequency of the foetus during the last trimester is approximately 30 per 24 hours. It decreases to 12 during the first year of life, and after that it is gradually reduced to an average of 5±1 voidings per day [10, 15].

The normal range for the micturition frequency at age seven is 3 to 7 [16].

By age 12, the daily pattern of voiding includes 4-6 voids per day [17].

Mattson and Lindström emphasize the enormous variability of voiding frequencies in children: also in individual children, the weight-corrected diuresis could vary up to 10-fold [18].

![Figure 1: Bladder capacity using the formula Y = 30 + 30X (Y = capacity in ml, X = age in years)](image1)

![Figure 2: Bladder capacity using the formula Y = (2X + 2) x 28.35 ml < 2 years Y = (X/2+6) x 28.35 ml > 2 years (Y = capacity in ml, X is age in years)](image2)

![Figure 3: Bladder capacities determined by VCUG in the International Reflux Study](image3)
3. NORMAL VOIDING PRESSURES

Bladder dynamics in children have demonstrated developmental changes with age. Detrusor pressures at voiding in children are similar to adults, with a mean maximum pressure of 66 cm H₂O in boys, and 57 cm H₂O in girls [19].

These pressures are lower than those reported in infancy by Yeung et al, who found boys having pressures of 118 cm H₂O and girls 75 cm H₂O [5].

4. NORMAL URINARY FLOW RATES

Urinary flow rates in normal children have been only minimally described. Szabo et al published nomograms for flow rates vs. age in normal children [20].

As in adults, flow rates are clearly dependent upon voided volume, and normal values can only be applied to flow rates that have been registered when voiding at a bladder volume approximating the normal capacity for age [18,21].

B. EVALUATION IN CHILDREN WHO WET

Even with clear definitions, the approach to history-taking and physical examination has to be structured. The child’s complaints at presentation are not synonymous with the signs and symptoms that have to be checked to arrive at a diagnosis. Also, sociocultural aspects and psychomotor development will distort the presentation. Validated questionnaires are very helpful in structuring the history-taking; they at least provide checklists [1].

With a structured approach the diagnosis of monosymptomatic nocturnal enuresis can be made with confidence.

When ultrasound imaging of kidneys and bladder, recording of urinary flow, and measurement of post-void residual are added to history and physical examination, the clinical entities caused by non-neurogenic detrusor and pelvic floor dysfunction can be diagnosed accurately in the majority of cases, and a high level of suspicion can be maintained towards incomplete bladder emptying in both neurogenic pelvic floor dysfunction and structurally caused incontinence. This is important in view of the potential these conditions have to cause irreversible loss of kidney function.

In a minority of incontinent children the non-invasive assessment yields equivocal results, or results suggesting gross deviations from normal function. Only in these situations is there an indication for invasive investigations, such as:

- Invasive urodynamics (cystometry, pressure/flow/EMG studies, videocystometry).
- Renal scans or intravenous urography.
- Cystourethroscopy.

I. HISTORY TAKING

For the paediatric age group, where the history is jointly obtained from parents and child, and where the failure to develop bladder control generates specific problems, a structured approach is recommended, with a questionnaire [1,2].

Level of evidence: 3. Grade of recommendation: B

Many signs and symptoms related to voiding and wetting are new to the parents, and they should be specifically asked for, using the questionnaire as checklist. If possible the child should be addressed as the patient and questioned directly, as the symptoms prompting the parents to seek consultation may be different from those are problematic for the child.

A voiding diary is mandatory to determine the child’s voiding frequency and voided volumes. Checklists and frequency volume chart can be filled out at home, and checked at the first visit to the clinics. History-taking should also include assessment of bowel function; a similar pro-active process using a questionnaire should be followed for defecation and faecal soiling [3].

The general history-taking should include questions relevant to familial disorders, neurological and congenital abnormalities, as well as information on previous urinary infections, relevant surgery and menstrual and sexual functions (in pubertal and older children). Information should be obtained on medication with known or possible effects on the lower urinary tract.

At times it is helpful to more formally evaluate the child’s psychosocial status and the family situation, e.g. using validated question forms such as CBCL (Achenbach) or the Butler forms [4,5].

Child abuse is very often signalled first by symptoms of vesico-urethral dysfunction [6].

At present there are no validated questionnaires to diagnose the cause of incontinence in children.

Level of evidence: 4. Grade of recommendation: C

II. PHYSICAL EXAMINATION

Apart from a general paediatric examination, the physical examination should include the assessment of perineal sensation, the perineal reflexes supplied by the sacral segments S1-S4 (standing on toes,
bulbocavernosus) and anal sphincter tone and control. Special attention should be paid to inspection of the male or female genital region, and of the urethral meatus. Asymmetry of buttocks, legs or feet, as well as other signs of occult neurospinal dysraphism in the lumbosacral area (subcutaneous lipoma, skin discoloration, hair growth and abnormal gait) should be looked for specifically [7].

In examining the abdomen for the presence of a full bladder, full sigmoid or descending colon which is a significant finding with a history of constipation.

Detailed questioning of the parents’ observation of the child’s voiding habits is essential as is direct observation of the voiding, if possible. Children may have their voiding dysfunction ameliorated or even eliminated by correcting anomalies of body position detected when observing the child’s micturition. Children may void in awkward positions, e.g. with their legs crossed or balancing on the toilet without proper support of the legs, thereby preventing the pelvic floor relaxation and obstructing the free flow of urine [8] (Figure 4).

Level of evidence: 4. Grade of recommendation: D

III. URINALYSIS

In order to be comprehensive, physical examination should include urinalysis to identify patients with urinary tract infection, diabetes mellitus, diabetes insipidus and hypercalciuria if indicated [9].

IV. NON-INVASIVE DIAGNOSTIC TECHNIQUES

1. FREQUENCY / VOLUME CHARTS: BLADDER DIARY

The frequency/volume chart is a detailed diary recording each void by time and urine output over 24-hour periods. The chart gives objective information on the number of voidings, the distribution of day and night voids, along with the voided volumes and episodes of urgency and leakage, or dribbling. In order to obtain a complete picture, defecation frequency and/or soiling are often also recorded. Then, this becomes termed as bladder-bowel diary due to its complexity.

From the frequency/volume chart the child’s “functional” bladder capacity may be assessed as the largest voided volume, with the exception of the morning micturition, which actually represents nighttime bladder capacity. Whenever possible, filling out the chart is the responsibility of the child: the parents provide assistance and support. Ideally the chart should cover 3 complete days, but in reality completion over a weekend restricts the record to 2 days.

The frequency volume chart is a reliable non-invasive measure of maximum bladder storage capacity and can be used as an outcome measure in children with bladder dysfunction if care is taken to minimise confounding factors and sources of error during chart completion [10].

The amount of urine voided by a non-supervised child during the day varies considerably since the child’s voidings are dictated more by social circumstances and/or bladder activity rather than by bladder capacity. Children with bladder symptoms void smaller volumes of urine than may be expected from traditional estimates [10]. This is unrelated to either gender, type of presenting incontinence or a positive family history of bladder dysfunction. The only significant influence upon voided volumes recorded on a frequency volume chart is the age effect, and voided volumes, even in incontinent children, increase incrementally with age. The frequency volume chart is useful when comparing the mean voided volume and standard deviation by a child’s age.

Figure 4: Improper position for voiding: the feet are not supported (unbalanced position) and the body is bent forward. Support of the feet will correct this and will allow the pelvic floor muscles to relax properly.
Validation and test/retest data on frequency/volume charts whilst scarce indicate that voiding interval is the most variable parameter. Data in normal children and in children with different categories of incontinence are available for comparison [10-12].

In order to obtain a complete picture it is better to ask for a bladder diary: fluid intake as well as voiding frequency, voided volumes, incontinence episodes and defecation frequency and/or soiling are recorded.

Test/retest evaluation is not available; trend analyses of frequency/volume charts can be extracted from currently available data.

Level of evidence: 3. Grade of recommendation: B

2. QUANTIFICATION OF URINE LOSS

Subjective grading of incontinence may not indicate reliably the degree of dysfunction. For objective grading, 12-hour pad test and frequency/volume charts are validated instruments [12-14].

In children, the 12-hour pad test should also give information about fluid intake. The pad test is complementary to the bladder diary, which denotes more the frequency of incontinence and the distribution of wetting episodes than the quantities of urine lost.

The amount of urine lost during sleep can be determined by weighing diapers or absorbent pads, before and after sleep. To obtain a measure of the total nocturnal urine output, the volume of the early-morning voiding should be added to the amount lost during sleep.

3. SCORING SYSTEMS

At present two scoring systems, based on validated questionnaires have been described. Specific scores correlated with lower urinary tract dysfunction with a specificity and sensitivity of about 90% [15,16].

The value of these scoring systems to determine the cause of incontinence seems to be of limited value to the individual patient, but can be very useful in studies to determine and compare treatment outcome.

Level of evidence: 3. Grade of recommendation: C

4. QUANTIFICATION OF CONSTIPATION

Scoring a plain X-ray of the abdomen (Barr score) yields inconsistent results in grading constipation. [17-19] Reproducibility seems to be best using the method described by Leech [20-22].

A better way to match clues from the medical history with signs and symptoms is the measurement of colonic transit time. As many children with non-neurogenic detrusor and pelvic floor dysfunction habitually use their pelvic floor as an “emergency brake”, anomalous defecation frequency and constipation have a high prevalence in this group.

A non-invasive way to determine fecal retention is the estimation of rectal diameter on ultrasound. In children without constipation the mean diameter was 2,4 and 2,1 cm in two different studies respectively [23-24]. In children with constipation the rectal diameter was on average 3,4 cm in one and 4,9 in the second study. Both studies do not mention specificity nor sensitivity. Finding a dilated and filled rectum on ultrasound while the child feels no need to defecate probably can replace a digital rectal examination.

Overt constipation should be dealt with before embarking on treatment of incontinence or detrusor and pelvic floor dysfunction [25,26].

Level of evidence 3. Grade of recommendation: B

5. URINARY FLOW

Voiding should be analysed in detail in all incontinent children with the exception of monosymptomatic bedwetting where voiding, as far as we know, is normal.

Graphic registration of the urinary flow rate during voiding is a standard office procedure. Flow patterns and rates should be repeated to allow for evaluation, and several recordings are needed to obtain consistency.

Approximately 1% of school children have a voiding that can be labelled abnormal with flattened or intermittent flow curves. The remaining 99% have a bell-shaped flow curve [27]. It should be noted that a normal flow does not exclude a voiding disturbance, nor does an abnormal flow pattern automatically means a bladder or voiding dysfunction, as in asymptomatic normal school children abnormal patterns were also found [28,29].

Flow recordings with a voided volume of less than 50% of the functional capacity are not consistent: they represent voiding on command, and many children will try to comply by using abdominal pressure. A helpful tool in this respect is the bladder scan: before micturition the bladder volume can be assessed [30,31]. If the bladder is still nearly empty the child should be asked to drink some water until the bladder is full enough for a reliable flow.

Urinary flow may be described in terms of rate and pattern and may be continuous, intermittent (in fractions), or fluctuating. An intermittent flow pattern shows a interrupted flow, whereas in fluctuating voiding the flow does not stop completely, but fluctuates due to incomplete relaxation of the sphincter.

Measurement of urinary flow is performed as a solitary procedure, with bladder filling by diuresis (spontaneous or forced), or as part of a pressure/flow study, with bladder filling by catheter. Patterns and rates should be consistent to allow for evaluation, and several recordings are needed to obtain consistency [32].
The same parameters used to characterise continuous flow may be applicable, if care is exercised, in children with intermittent, or fluctuating flow patterns (Figures 5 -7). In measuring flow time, the time intervals between flow episodes are disregarded. Voiding time is total duration of micturition, including interruptions.

Level of evidence: 3. Grade of recommendation: B

6. ULTRASOUND IMAGING OF UPPER AND LOWER URINARY TRACT

In most clinical settings, ultrasound-imaging techniques are routinely used in children with incontinence. Upper tract abnormalities such as duplex kidney, dilatation of the collecting system, and gross reflux nephropathy can be readily detected, but detection of the more subtle expressions of these abnormalities require urological expertise on the part of the ultrasound operator [33].

Lower urinary tract abnormalities are even more difficult to assess for the inexperienced, aside from bladder wall thickness: a bladder wall cross-section of more than 3-4 millimetres, measured at 50% of expected bladder capacity, is suspicious of detrusor overactivity [34,35]. Because only a few studies have been conducted to compare bladder wall thickness in normal children without complaints and in children with lower urinary tract dysfunction, more studies need to be performed to validate these non-invasive techniques [36, 37].

Another possibility is to assess bladder volume and bladder wall thickness to calculate the Bladder Volume / Bladder Wall Thickness index. In children with nocturnal enuresis this index correlated well with response to treatment [38].

a) Post-void residual volume

Except in small infants, the normal bladder will empty completely at every micturition [39].

The identification or exclusion of post-void residual is therefore an integral part of the study of micturition. However, an uneasy child voiding in unfamiliar
surroundings may yield unrepresentative results, as may voiding on command with a partially filled or overfilled bladder. When estimating residual urine, voided volume and the time interval between voiding and estimation of post-void residual should be recorded. This is of particular importance if the patient is in a diuretic phase. In patients with gross vesicoureteral reflux, urine from the ureters may enter the bladder immediately after micturition and may falsely be interpreted as residual urine. The absence of residual urine is an observation of clinical value, but does not exclude bladder outlet obstruction or detrusor pelvic floor dysfunction with absolute certainty. An isolated finding of residual urine requires confirmation before being considered significant, especially in infants and young children.

b) Ultrasound-flow-ultrasound

This combination of imaging and non-invasive urodynamics is a standardised procedure used to obtain representative data on flow rate and flow pattern, as well as post-void residual volumes. With ultrasound, bladder filling is assessed and when the bladder capacity is equal to the functional or expected bladder capacity for age, the child is asked to void into the flowmeter. After recording the flow, post-void residual is assessed again. This procedure avoids the registration of flow rates at unrealistic bladder volumes.

Alternatively children can be asked to use a flowmeter at home: a special flowmeter has been designed to use at home [40]. Because some children have difficulty voiding in a strange environment, this option can overcome this.

7. INVASIVE DIAGNOSTIC TECHNIQUES

The important question (for the incontinent child) “whether invasive diagnostic procedures are necessary” is decided by the results of the non-invasive procedures.

At present there are no studies indicating that a VCUG is useful in children with incontinence, but without urinary tract infections.

In general urodynamic studies will only be done if the outcome will alter the management, and this will also depend on whether the possible treatments being considered are invasive. The diagnostic information needed is that which is necessary to find the correct treatment. Indicators include, straining or manual expression during voiding, a weak urinary stream, previous febrile urinary tract infection, continuous dribbling incontinence or pronounced apparent stress incontinence, or previously identified dilating vesicoureteral reflux.

The finding of genitourinary abnormalities or signs of occult spinal dysraphism at physical examination also indicate the need for further diagnostics. Urinary flow registration will detect the plateau-shaped flow curve typical for structural bladder outlet obstruction, and an intermittent flow suggesting detrusor–sphincter-pelvic floor dys-coordination [32].

A clinically significant post-void residual on repeated occasions clearly points to incomplete bladder emptying. The pad test will detect the cases with obvious stress and urgency incontinence, or continuous dribbling. Ultrasound imaging will raise suspicion of an ectopic ureter.

In short, invasive diagnostics are indicated when the non-invasive testing raises suspicion of neurogenic detrusor-sphincter dysfunction (occult spinal dysraphism), obstruction (especially posterior urethral valves), genitourinary abnormalities (e.g. epispadias), advanced non-neurogenic detrusor-sphincter-pelvic floor dysfunction (as in children with vesicoureteral reflux and upper tract dilatation and/or febrile urinary tract infections), or significant post void residuals.

To diagnose the complex of non-neurogenic detrusor-sphincter dysfunction, recurrent urinary tract infections and vesicoureteral reflux, urodynamic studies are needed in only a minority of all incontinent children.

a) Voiding cystourethrogram (VCUG)

1. TECHNIQUE OF VCUG IN CHILDREN

Cleanse and rinse the external genitalia with lukewarm water: do not use detergents. Use a feeding tube with side holes and a rounded tip (Ch 06-08) or balloon catheter to catheterise the bladder; check the urine for infection. Empty the bladder completely before filling. Use a radio-opaque dye of maximum 30% concentration, at body temperature, and fill the bladder by slow-drip infusion, with a hydrostatic pressure of not more than 40 cm H₂O. Note the volume of the contrast medium instilled. Use fluoroscopy during filling at regular intervals.

Take spot-films (70mm or 90mm camera) with the child in supine position, with partial filling and at the end of filling, in AP projection, of the complete urinary tract. Upper tracts and lower tract should be visible.

When voiding is imminent, change the position of the child so that spot films of bladder and urethra in 3/4 projection can be taken during voiding. Also take a spot film of the upper urinary tract during voiding, as the degree of vesicoureteral reflux (VUR) may change with the pressure generated by the detrusor muscle during voiding. Post-void residual volumes vary very considerably with VCUG. The voiding phase is critically important to VCUG, both for reflux detection and for assessment of voiding dynamics. Without a voiding phase the VCUG is incomplete.
Prophylactic antibiotics are indicated in all children, to minimise the risk for post-VCUG urinary tract infection especially in children with an anatomic abnormality.

2. INDICATIONS FOR VCUG

A VCUG is an invasive procedure and should only be done if the outcome will influence the management. It is indicated in children with recurrent urinary tract infections in order to detect reflux and in children with an abnormal flow pattern to detect bladder outlet abnormalities (like valves, strictures or a syringocele). Presence of hydronephrosis on ultrasound investigation will certainly obviate the need for this investigation.

In children with incontinence the lateral projection during voiding is the most important part of the study. Especially in children with stress incontinence or a neurogenic bladder the position and configuration of the bladder neck during filling and voiding should be noted.

In children with non-neurogenic detrusor-sphincter-pelvic floor dysfunction as well as in children with neurogenic detrusor-sphincter dyssynergia, the proximal urethra may show the so-called ‘spinning top’ configuration, during filling and during voiding. With detrusor and pelvic floor muscles contracting at the same time, the force of the detrusor contraction will dilate the proximal urethra down to the level of the forcefully closed striated external sphincter.

The resulting ‘spinning top’ configuration used to be seen as a sure sign of distal urethral stenosis, a concept held responsible for recurrent urinary tract infections in girls, with urethral dilatation or blind urethrotomy as the obvious therapy. However, urodynamics made it clear that the ‘spinning top’ will only appear when detrusor and pelvic floor contract synchronously, which makes it a functional anomaly, not an anatomical one [41,42].

Women often recall their experience with VCUG as not an anatomical one [41,42].

In children urodynamic investigations should only be performed if the outcome will have consequences for treatment [43,44]. Furthermore like VCUG it may be considered when invasive or surgical interventions are planned. The main question is whether the urodynamic study will provide new information that cannot be obtained otherwise and will influence the further management. From the few studies that have addressed this issue it can be concluded that urodynamic studies in the majority of cases do not provide significant additional information to justify this type of investigation as a routine procedure in children [45-47].

Both children and parents need careful preparation and adequate information before the study is done. It is an invasive procedure and artefacts may occur. Because of the invasiveness of the investigations all children are anxious and this may be reflected in the outcome of the study. Especially during the first filling cycle, when the child does not know what to expect, detrusor overactivity may be seen and the voiding phase can be incomplete due to contraction or incomplete relaxation of the pelvic floor muscles during voiding.

Once the child knows that filling and voiding are not painful a subsequent filling and voiding cycle may show a completely different pattern. The study should be repeated at least 2 or 3 times. Only if during the first filling cycle, no detrusor contractions are seen and also the voiding phase is in accordance with history and uroflow, it is probably sufficient to do only one complete filling and voiding cycle [48].

Still the results may not always be reproducible and it should be stressed that the primary objective is to treat the child and not a “urodynamic abnormality” per se.

Special attention should be given to a pleasant surrounding for the child: one or both parents should be present and young children may be given a bottle. Older children may be distracted by watching a video movie. The child should be awake, unanaesthetised and neither sedated nor taking any drugs that affect bladder function.

During the study the investigator has the opportunity to observe the child and discuss various findings and correlate them to what the child feels and/or normally would do in such circumstances.

In children, the transition from filling phase to voiding phase is not as marked as in adults. To avoid missing this important transition, cystometry and pressure-flow/EMG measurements are performed as one continuous study in paediatric urodynamics.

Electromyography of the pelvic floor muscles is assumed to evaluate the activity of the striated urethral sphincter, in the filling phase and in the voiding phase. Surface skin electrodes are usually used to record the EMG. In children the pelvic floor EMG is probably of much more importance than in adults as it helps to differentiate the different voiding disorders.

Filling the bladder can be achieved by diuresis (natural
fill cystometry) or retrograde by catheter. For retrograde filling by catheter, saline 0.9% or contrast medium at body temperature is recommended in children. Especially in young children some urodynamic parameters, such as capacity and detrusor activity are influenced by the temperature of the filling fluid. Although the clinical relevance is as yet unknown, it is recommended to fill the bladder with fluid of body temperature [49].

When filling by catheter, slow fill cystometry (5 – 10 percent of expected bladder capacity per minute, or < 10ml/min) is recommended in children, as certain cystometric parameters, notably compliance, may be significantly altered by the speed of bladder filling.

Involuntary detrusor contractions may be provoked by rapid filling, alterations of posture, coughing, walking, jumping, and other triggering procedures.

The presence of these contractions does not necessarily imply a neurologic disorder. In infants, detrusor contractions often occur throughout the filling phase.

Bladder sensation is difficult to evaluate in children. Only in toilet-trained cooperative children is it a relevant parameter. Normal desire to void is not relevant in the infant, but can be used as a guideline in children of 4 years and older. Normal desire to void should be considered the volume at which some unrest is noted, e.g. wriggling the toes; this usually indicates voiding is imminent.

In the older child, the volume may be small with the first cystometry, for fear of discomfort. Also involuntary detrusor contractions occur more often during the first filling cycle (49). This is the reason that in paediatric urodynamics at least two cycles of filling are recommended.

Maximum cystometric capacity (MCC) is the volume in the bladder at which the infant or child starts voiding. The value for maximum cystometric capacity is derived from volume voided plus residual volume. Values for MCC should be interpreted in relation to normal values for age.

Compliance indicates the change in volume for a change in pressure. For children with neurogenic detrusor-sphincter dysfunction, data are available relating poor compliance to the risk of upper urinary tract damage [51].

The urethral closure mechanism during storage may be normal or incompetent. The normal urethral closure mechanism maintains a positive urethral closure pressure during filling, even in the presence of increased abdominal pressure or during detrusor overactivity (guarding reflex) [50].

Immediately prior to micturition the normal closure pressure decreases to allow flow.

Bladder outlet obstruction, recorded with a pressure / flow study, may be anatomical or functional in nature. An anatomical obstruction may be present at the bladder neck or in the urethra as a stricture or a stenosis and there is a small and fixed urethral diameter that does not dilate during voiding. As a result, the flow pattern is plateau shaped, with a low and constant maximum flow rate, despite high detrusor pressure and complete relaxation of the urethral sphincter. In a functional obstruction, it is the active contraction of the urethral sphincter or pelvic floor during passage of urine, that creates the narrow urethral segment as a constant or intermittent obstruction. To differentiate anatomical from functional obstruction, information is needed about the activity of the urethral sphincter during voiding.

This information can be obtained, and recorded together with pressure and flow, by monitoring the urethral pressure at the level of the urethral sphincter, or by recording a continuous electromyogram of the pelvic floor as in clinical practice the urethral sphincter is not readily accessible and the electromyogram of the external anal sphincter is often used to monitor activity of the striated urethral sphincter.

This corresponds to activity of the pelvic floor muscles. Also the use of video urodynamics can be very helpful in this respect, as contractions of the pelvic floor muscles can actually be seen during the voiding phase (Figure 8 and 9).

In infants and small children, pelvic floor muscle overactivity during voiding (with post-void residuals) is not uncommon: in all probability it is a normal developmental feature [52,53].

c) Cystoscopy

In by far the majority of children cystoscopy is not indicated. In boys with therapy resistant incontinence, an abnormal flow pattern, especially in combination with a history of (recurrent) urinary tract infection is suspicious of infra-vesical obstruction such as bladder neck obstruction, urethral valves, syringocele etc. A VCUG may not always show these abnormalities and pressure flow curves may be equivocal [55].

In girls the flow may be directed upward, indicating an abnormal meatal position or stenosis. A dorsal meatotomy generally solves this problem. It has been postulated that in girls the abnormal direction of the stream triggers the bulbocavernosus reflex resulting in dysfunctional voiding [56].
Figure 8: Urodynamic study illustrating involuntary detrusor contractions, counter action of pelvic floor muscles (guarding reflex) and incomplete pelvic floor relaxation during voiding resulting in post void residual urine (detrusor overactivity + dysfunctional voiding) [50].

Figure 9: Classification of urinary incontinence in children.

(Over)activity of the urethral sphincter-pelvic floor may occur during the voiding contraction of the detrusor in neurologically normal children; this set of events is termed dysfunctional voiding.

Grade of recommendation: for all diagnostic procedures level B
C. NOCTURNAL ENURESIS

I. DEFINITION

Nocturnal enuresis (NE) is involuntary voiding of urine during sleep, at least three times a week, in children over 5 years of age in the absence of congenital or acquired defects of the central nervous system [1]. Parental concern and child distress affect the clinical significance of the problem [2].

While most children who wet at night after age five are considered nocturnal enuretics, the child's development level is also important. The age criterion of five is arbitrary but reflects the natural course of achieving bladder control [4]. Verhulst et al argue for flexibility due to different age at which boys develop nighttime continence compared with girls [4]. Extrapolation from Verhulst's figures suggests that the prevalence of nighttime wetting for 8-year-old boys equals that for girls at 5 years [4].

Monosymptomatic NE is bedwetting without daytime symptoms. Non-monosymptomatic or polysymptomatic NE describes children with both day and nighttime wetting [5].

II. SEVERITY

Nocturnal enuretics vary in wetting frequency. Although fifteen percent wet each night, most children wet less frequently [4,6]. In a population survey of nearly 1,800 Irish children aged 4 –14 years, Devlin found the frequency of wetting as follows: less than once per week in 33 percent, once per week in 11 percent and 2 to 4 times per month in 25 percent [7]. Some children and parents are concerned about an occasional wet bed, while others accept regular wetting. Clinically severity can be defined as: infrequent (1-2 wetting episodes per week), moderately severe (3 – 5 wetting episodes per week) or severe (6 – 7 wetting episodes per week) [7].

III. PREVALENCE

Bedwetting is common. In the United Kingdom, estimates approximately 750,000 children and young people over 7 years regularly wet the bed. In the United States 5 to 7 million children regularly experience primary NE [8,9,10].

The prevalence of bedwetting varies regionally. In China, where parents take children out of diapers earlier, bedwetting seems to resolve more quickly. For example, in a large survey from Shandon, the proportion of children attaining nocturnal urinary control before age 2 was 7.7%; by age 3, this had increased to 53.1%, and by age 5 to 93%. The overall prevalence of NE was 4.3%, with a significantly higher prevalence in boys than girls. There was no additional decrease in the prevalence of enuresis between 6 and 16 years [11]. This suggests that structured awakening and toileting is effective treatment for monosymptomatic NE, even in small children.

Bedwetting becomes less common with advancing age. In the West, 15 per cent of children each year develop nocturnal bladder control (12). By adulthood, bedwetting is rare. Hirasing et al sampled over 13,000 adults [18-64 years] and found an overall prevalence rate of NE at 0.5% (13). Of these, 12 percent of men and 29 percent of women had daytime incontinence. Despite persistence of wetting into adulthood, 50 percent of men and 35 percent of the women never seek help for their problem. The enuresis prevalence of 0.5% in otherwise healthy adults in Hirasing's study refers to a largely untreated population. Fifty percent of the men had primary enuresis and had never been consistently dry at night. Assuming a prevalence of enuresis of 8 percent in 7-year-old boys, the risk for an enuretic boy to remain so for the rest of his life is 3 percent [12,14].

Many believe adult enuretics represent a “hard core” group with worse symptoms. These individuals are likely to have associated diurnal enuresis or voiding symptoms. One study included 18 males and 29 females with a mean age of 20 years with persistent NE. Of these patients 37 (79%) had moderate or severe symptoms and 17 (38%) also had daytime urinary symptoms. Thirty patients had urodynamics including 12 males and 16 females (93%) with detrusor overactivity. In addition, 73% of patients had urodynamic evidence of functional bladder outflow obstruction, including dysfunctional voiding and detrusor sphincter or detrusor pelvic floor discoordination. Two male patients (6.7%) had an obstructive pattern on urodynamics and subsequent cystoscopic examination confirmed the presence of congenital urethral stricture/values. Sixteen patients (53%) had significantly reduced bladder capacity of less than 300 ml [15-18]. These and other studies suggest that persistent NE after childhood is a serious adult problem requiring some investigation and considerable effort to treat.

IV. INHERITANCE

Bedwetting runs in the family of many children who suffer from bedwetting. In one study, a positive family history was found in 94 families (23%) of 411 probands with PNE, including 49% of fathers, 9% of mothers, 6% of both parents, 6% of the siblings and 30% of
proportion of children who developed secondary enuresis was 3.3 percent at 5 years, 4.7 percent at 6 years, 6.2 percent at 7 years, 7.0 percent at 8 years, 7.5 percent at 9 years and 7.9 percent at 10 years. Secondary NE is associated with a higher incidence of stressful events particularly parental separation, disharmony between parents, birth of a sibling, early separation of the child from parents and psychiatric disturbance in a parent [22, 30,31].

Von Gontard and colleagues found children with secondary enuresis had significantly more emotional difficulties compared to those with primary NE. Their evidence also suggests children with secondary enuresis, compared to those with primary enuresis, are more likely to have behavioural problems, a finding which corresponds to that of McGee et al [32].

Both Jarvelin and Fergusson et al argue that primary and secondary enuretics are similar [30,31]. They believe the two share a common etiological basis. The rate the child acquires primary control influences his or her risk of secondary enuresis. The primary form is the consequence of a delay in maturation of the physiological mechanisms. The child’s capacity to sustain and maintain nocturnal bladder control is manifest in the rate at which he or she acquires control. On the other hand, this capacity determines the child’s susceptibility to lapsing back to night wetting when exposed to stress.

Other sources of secondary enuresis must be excluded prior to proceeding with treatment for enuresis. These include sleep apnea from obstructive airway disease, obesity, constipation and infrequent or dysfunctional voiding. Treatment of sleep apnea from obstructive airway has been shown to improve or eliminate NE in some children following surgery or medical management [34,35]. Obesity has been associated with nocturnal enuresis both independently [36] and in the context of sleep apnea [37].

**Mono-symptomatic versus non-mono-symptomatic NE**

Mono-symptomatic NE refers to those children who report no bladder or voiding problems associated with wetting. Non-mono-symptomatic NE refers to bedwetting, that is associated with detrusor overactivity or voiding problems such as urgency and bladder holding during the day [5].

This classification becomes important when considering the most appropriate treatment intervention.

Many parents are unaware of daytime symptoms when seeking help for bedwetting and when identified these symptoms should be treated prior to intervention for the NE. Between 10-28% of children with NE have associated daytime wetting. If so, these children should be considered day and night incontinent. In these cases, night time incontinence is not any longer an
isolated phenomenon but part of the symptomatology of day and night time incontinence. These children are more resilient to treatment and more vulnerable to relapse [38]. These boys and girls are more appropriately managed in the context of the primary bladder problem.

VII. PATHOPHYSIOLOGY OF MONOSYMPTOMATIC NE

NE stems from a mismatch of bladder capacity, nocturnal urine output and the ability for the child to arouse during sleep. Night wetting is normal until age 5. Delayed maturation in one or more of the following systems results in NE: a lack of stability in bladder function, a lack of arginine vasopressin (AVP) release or response, or relative increased solute excretion during the night [39,40], or an inability to wake from sleep to full bladder sensations [41,42]. Combinations of all three problems may be present.

A unifying and simplistic concept with important clinical implications, is that NE is caused by a mismatch between nocturnal bladder capacity and the amount of urine produced during the night, combined with delayed or incomplete arousal response to the afferent neurological stimulus of the full bladder (Figure 10).

1. INCREASED NOCTURNAL URINE OUTPUT

In normal children, the circadian rhythm of urine production results in a nocturnal reduction in diuresis to approximately 50% of daytime levels [43,44]. In children this is the result of nocturnal release of hormones that regulate free water excretion (arginine vasopressin, AVP) or solute excretion (angiotensin II and aldosterone) and may result from circadian changes in glomerular filtration [45]. In the normal child, this results in increased urine concentration and reduced urine volume during sleep. This is why children who are not enuretic sleep through the night without being wet and do not need to rise to void.

Two thirds of patients with mono-symptomatic NE have been found to have a lack of circadian rhythm of vasopressin, resulting in high nocturnal urine production, which exceeds bladder capacity [46,47,48]. Rittig et al and Norgaard et al demonstrated abnormalities in the circadian rhythm of AVP secretion resulting in increased nocturnal urine output that exceeded bladder capacity in children with nocturnal enuresis [46,47]. These children make more urine at night, and often overcome their bladder capacity and wet early in the night. Abnormalities can also be intrinsic, related to reduced nocturnal circadian changes in glomerular filtration rate (GFR) [45] or in sodium and calcium excretion [49].

Detection of low plasma vasopressin levels, GFR assessments or specific sodium and calcium excretion are difficult to measure. Instead, we look for clinical signs of low vasopressin during the assessment interview. Weighing the diapers and adding the first morning void provides the total nocturnal urine output. if this total exceeds the child’s functional bladder capacity this may indicate nocturnal polyuria. Nocturnal urine output varies appreciably from night to night [50], but seems larger in children with NE who respond best to desmopressin (dDAVP).

Figure 10: Basic pathophysiology of NE or nocturia. When the bladder is full because of (relative) polyuria and/or a reduced bladder capacity, the child either wakes up to void (nocturia) or voids while sleeping (NE).
By the time the child becomes an adolescent, the circadian rhythm is less prominent. In adolescents and adults with nocturnal enuresis, there is no diurnal rhythm of plasma vasopressin concentration. The changes in urine production at night occur from a decrease in the urinary sodium excretion that is not due to differences in concentration of AVP but due to a lack of sensitivity to AVP [51] with resultant increased urine output [39]. There may be a small sub-group of children with impaired renal sensitivity to vasopressin or desmopressin [40,52]. Recent work by Devitt et al suggests that 18 percent of children have ‘normal’ levels of plasma vasopressin release but remain enuretic [48].

These children all failed to respond to a therapeutic dosage of desmopressin. This finding could indicate renal insensitivity to vasopressin but could also be indicative of detrusor overactivity or a small functional bladder capacity.

Total urine output during the night could be helpful in differentiating between the two conditions. The subgroup of patients with NE and increased nocturnal urine output generally has a normal functional bladder capacity and a favourable response to dDAVP [53].

2. DETRUSOR OVERACTIVITY DURING THE NIGHT

The detrusor, in order to function appropriately, needs to be relaxed during filling and allow an appropriate functional capacity. Detrusor overactivity usually causes small voided volumes resulting in a decreased functional bladder capacity [54].

Watanabe and his colleagues, employing EEG and cystometry recording during sleep, discovered that 32 percent of children with NE had involuntary detrusor contractions that resulted in enuresis [60-62]. These children had smaller functional bladder capacities at the point of wetting, than children with enuresis who did not have detrusor overactivity. Functional bladder capacity – defined as the largest daytime void on a frequency- volume (F/V) chart, after excluding the first morning void, may give a reasonably accurate assessment of daytime functional bladder capacity (FBC). Reduced functional bladder capacity, when below 70% of predicted FBC for age, is likely to result in poor response to dDAVP treatment [55]. Daytime bladder capacity is smaller than night time capacity in children without NE [56].

The pattern may be different at night. Yeung et al reported that 44 percent of treatment failures [with desmopressin or the enuresis alarm] have normal daytime bladder function but marked detrusor overactivity during sleep resulting in enuresis [63,64]. Almost none of these children had nocturnal polyuria. Ultrasound studies of the bladder furthermore revealed an increased bladder wall thickness in these children [57].

When further segregated prior to treatment, increased bladder wall thickness and bladder volume predicted the response to therapy in children with their primary nocturnal enuresis (more than three nights weekly). In one study, Yeung, et al [58] correlated ultrasound measured parameters and urodynamic findings. Of 35 children with frequent NE, bladder wall index was normal in only eight patients. It was less than 70% of predicted in 24, and more than 130% in three. When bladder volume and wall thickness index was correlated with ultrasound, 87% of the patients with a normal index exhibited a normal bladder pattern on imaging and 96% of patients with an index less than 70 exhibited detrusor over activity on ultrasound. All the children with a normal index either had a complete or good response to conventional treatment for nocturnal enuresis, whereas only 62% of those with an index less than 70 did not respond to treatment. With longer follow-up, bladder dysfunction had resolved in 38% of the children with an initial index of less than 30, all of whom had a good response to treatment. The bladder dysfunction persisted in the 63% of children who had partial or no response to treatment. What this means is that ultrasound measured bladder parameters may segregate children prior to management of primary nocturnal enuresis into groups that have a favorable outcome and those that do not, following conventional treatment. These studies will become more and more important in helping to predict response of various treatment regimens in the future.

This approach may be even more important in adults with refractory monosymptomatic nocturnal enuresis. Bower, et al. [15] found that in 56 consecutive adolescents and adults compared with 293 normal adults, there were significantly higher childhood scores of urgency, frequency, urge incontinence, infrequent voiding and small volume voids than their normal non-enuretic counterparts. This suggests that adolescents and adults with persistent nocturnal enuresis may have a more significant bladder component particularly since the majority of patients with adult type nocturnal enuresis do not seem to exhibit the nocturnal polyuria problem seen more commonly in the smaller children.

3. LACK OF AROUSAL FROM SLEEP/CNS FUNCTION

The fundamental mechanism resulting in nocturia or NE is that the bladder fills to its capacity during sleep and needs to empty (figure 10). Bladder fullness is due to nocturnal polyuria and/or a reduction of the bladder capacity due to detrusor over activity during sleep. These factors do not fully explain why the enuretic child does not wake up during the night to the sensation of a full or contracting bladder. Regardless of whether the child has detrusor overactivity or nocturnal polyuria, the enuresis event results from the child’s inability to awaken from sleep to empty prior to the wetting episode.
There is a widely held belief amongst parents and some clinicians that enuretics are deep sleepers. This is logical, since many of the children exposed to alarm therapy sleep through the alarm while family members awaken. Nevéus reviewed by questionnaire 1413 schoolchildren between the ages of six and ten and noted that enuresis was associated with subjectively high threshold arousal and significant confusion upon awakening from sleep [42]. Wolfish in a study of 15 enuretic and 18 control boys and girls found that enuretics wet most frequently during the first two-thirds of the night and that arousal attempts were less successful in enuretics than in normals [59]. This might explain why the most heavily endorsed view of both children and parents, regarding the aetiology of NE is a belief in deep sleep [60].

More recently Frietag, et al studied brainstem evoked potentials in 37 children with nocturnal enuresis and compared these aged 8 to 14 years, with 40 controls, mean age 10 years, and found that interpeak latencies of the brainstem evoked potentials were increased in children with nocturnal enuresis, suggesting that a maturational deficit of the brainstem was present in children with nocturnal enuresis. Differences in visually evoked potential latencies might point to a reason beyond functional cortical differences in children with family history of nocturnal enuresis [61].

Feittag’s study would suggest that a maturational effect is present; however, overnight studies in enuretic children with simultaneous sleep electroencephaloepihalographic and cystometry have revealed marked detrusor overactivity, only after sleep at night and not during wakeful periods during the day [62]. Because this pattern has not been observed in normal non-enuretic subjects even during the newborn period, one may hypothesize that this could be due to a small neurologic lesion affecting a tiny area in the vicinity of the Pontine micturition center, the posterior hypothalamus (responsible for secretion of antidiuretic hormone) or the locus coeruleus which may be the cortical arousal center [63].

Another interesting study by Baeyens et al. [64] showed a convincingly significant difference between children with enuresis and control groups, and the startled eye blink reflex which improved with maturation but did not seem to correlate with resolution of enuresis. Clearly there is considerable work that is required to further unravel the mechanisms behind perceived differences in arousal between enuretic and non-enuretic children.

However a raft of evidence counters such a belief. Sleep patterns of children with NE are no different from children who do not have NE [65].

Enuretic episodes occur during all stages of sleep in proportion to the amount of time spent in that stage and appear to occur independent of sleep stage but occur when the bladder is full [66].

Bedwetting children sleep normally but are unable to suppress nocturnal detrusor contractions or awaken in response to them or to bladder fullness. Waking becomes easier as the night progresses. However, several authors have found that children with NE are also more likely to wet in the first third of the night, often in the first two hours following sleep [59,66,67,70,71]. Thus the point of bladder fullness for most enuretic children coincides with a time of night where they find it most difficult to wake from sleep.

VIII. TREATMENT OF NOCTURNAL ENURESIS

The age at which the child and his or her parent begins to be concerned about bedwetting varies. In an important review article, Hjalmas, et al. noted that, “for successful treatment of nocturnal enuresis, the child must be brought to the physician by the parents who are concerned and the physician must have the necessary knowledge about the condition and be motivated to start treatment” [43]. In order to fulfill the requirements, parents, teachers, and nurses in primary care need to understand nocturnal enuresis and be ready to treat the child, regardless of age.

Nocturnal enuresis is thought of as a social problem and less of a medical problem; therefore, since the majority of children stop wetting as they mature and since no ill health follows bedwetting in most cases, there is a tendency for many practitioners to take a “wait and see” approach despite the fact that the family and the child in many cases are quite disturbed. In one study, 3803 French school children age five to ten years noted the prevalence of primary nocturnal enuresis to be 9.2%. The majority of the children noted that bedwetting bothered them and hoped that a doctor could help them. In this survey, a questionnaire was addressed to mothers of enuretic children, 100 school teachers and 100 school doctors. The mothers had a relatively tolerant attitude but two-thirds had consulted a doctor. Most of the doctors had proposed no solution or a “wait and see” attitude or treatment with a drug rather than an alarm. From this study, we may conclude that considerable work needs to be done to help educate not only parents but teachers and even physicians about the importance of treatment of nocturnal enuresis as well as supportive care [72].

The actual timing of treatment for nocturnal enuresis may vary depending on the needs of the child and the parent. Toilet training age may be different in different societies. For example, toileting in Asia may be earlier than in North America or other parts of the
Toilet training should be started when both the child and parents are ready. Most studies appear to show that children start training between 24 and 36 months of age with a current train toward later completion than in previous generations. This is markedly different than noted in some Asian cultures where training appears to begin much earlier. Toilet training should occur in an environment that is comfortable for the child. Unfortunately, toilets in most household bathrooms are adult sized, making it difficult for the child who needs to climb to the top of the toilet to relax. In these cases, a potty chair to toilet train the child, and once the child is old enough, he or she should be transitioned to an over-the-toilet seat with a footstool to allow optimal posture for voiding. Parents should encourage children to relax and take time to completely empty the bladder [43].

It is essential that both the child and his or her parents understand bedwetting pathophysiology and treatment philosophy. The clinician should give the child general advice such as what to eat and drink and to void regularly during the day, abstain from drinking too much during the late afternoon and evening and have relaxed routines at bedtime. The clinician should stress that NE is common and usually represents a delay in maturation without any psychopathological undertone. Up to 19 percent of children will become dry within the next 8 weeks without any further treatment besides good counselling [43,73,74].

1. EVALUATION

Hjalmas, et al. have recommended a careful history which we will summarize in these next few paragraphs. This approach, which has been recommended by the International Children’s Continence Society, provides an excellent guide toward the taking of a history for a child with nocturnal enuresis [43] (Figure 11).

a) The frequency volume chart (FVC)

Parents are asked to record a two-day three-night record. This includes recording the child’s fluid intake and urine output, frequency of micturition and the frequency and pattern of voiding. The largest single micturition is considered the functional bladder capacity. This chart can be performed beginning on a Friday evening and concluding on Sunday any weekend.

b) Symptoms of nocturnal enuresis

A careful history should include questions about the age of onset of nocturnal enuresis, length and circumstances of dry spells, number and time of episodes of nocturnal enuresis or nocturia, presence of daytime voiding symptoms or urinary tract infection, posture while voiding, daytime and evening fluid intake, sleep habits, frequency and consistency of bowel movements and psychosocial situation. One must establish whether or not symptoms represent primary

Figure 11: Schematic work-up in patients presenting with night-time wetting only.
or secondary nocturnal enuresis. It is critical to search for new psychological problems results in secondary nocturnal enuresis, particularly when the child presents with nocturnal enuresis after a prolonged period of dryness. The personality of the child, family situation, school environment, and presence of alternate caregivers might have an appreciable impact on voiding habits and will influence management options [43]. Children may drink large volumes of fluid in the hours before sleep and this may result in nocturnal enuresis or nocturia.

It is helpful to determine the number of hours of sleep and to compare this to standard charts of average duration of sleep by age. Morning fatigue may be the result of obstructive sleep apnea. Other symptoms of sleep apnea include mouth breathing, snoring, and restless sleep [43].

It is important to rule out symptoms of anatomical or physiologic urologic conditions that may lead to nocturnal enuresis. Many of these conditions are covered in other parts of this section, and include a failure to store urine or failure to empty urine. Storage symptoms include increased frequency, urgency, and urgency incontinence including squatting behavior, daytime incontinence and the sensation to need to void again. The clinician must carefully assess daytime wetting, particularly in older children. In many cases, the child may hide these symptoms from the clinician and the family.

Children void four to seven times a day or about every two to three hours [75]. If the child is voiding significantly more frequently than eight or more times a day, this may suggest incomplete emptying or overactive bladder symptoms. Urgency is present in many children and posturing, including squeezing or crossing the legs, squirming while standing or sitting, or physically compressing the genital area with a hand is all suggestive of overactive bladder due to detrusor overactivity which may or may not be associated with dysfunctional voiding. Other causes include urinary tract infection, polyuria from diabetes mellitus or diabetes insipidus which can also cause more frequent voiding [43]. Treatment for these symptoms is covered in other sections within this chapter.

Additional symptoms during the daytime include continuous dribbling between voids that can come from an ectopic ureter bypassing sphincter mechanisms or from failing to empty the bladder or sphincter incompetence. Also continuous leakage can result from neurologic causes or anatomical causes such as epispadias, or a closed bladder extrophy or urogenital sinus.

Lastly, children may have incomplete emptying from true dysfunctional voiding which results from the detrusor contraction at the same time that the sphincter or pelvis floor is contracting. In addition, a detrusor underactivity may result from neuropathy from diabetes mellitus and in some cases conditions such as the prune belly syndrome will result in detrusor underactivity. Lastly, urethral strictures may result in incontinence due to detrusor overactivity with poor bladder emptying. Boys with posterior urethral valves or Cobb's collar may also have incomplete emptying. Lastly, the clinician should be alert for symptoms of constipation and faecal incontinence. It is a common misconception that if a child is stooling once per day then he or she is not constipated. In fact, the best symptom of constipation includes infrequent or painful passage of hard small pellet-like stools. Faecal incontinence may also be present, the principal sign of this being faecal material in the underwear. Excessive stool retention may result in bladder dysfunction. In these cases [76] this may result in increased urethral sphincter and pelvic floor activity and explain the association of voiding dysfunction with incomplete voiding. Treatment of constipation may result in improvement in enuresis.

c) Physical examination

Anatomic and behavioral causes for enuresis may be identified through a careful physical examination. Evidence of improper gait, spinal deformities, and foot abnormalities including asymmetry, high-arched feet, or hammer toes are signs of sacral neuropathy. Physical signs of occult spinal abnormalities such as dimples, tufts of hair, skin discoloration, lipoma, asymmetrical buttocks and gluteal clefts are also important. A careful abdominal examination with particular emphasis on the left lower quadrant may identify the colon full of firm stool. In most cases, a rectal examination is not performed but in some cases this may also be indicated. Occult fecal impaction, poor perineal sensation and reduced anal sphincter tone can be indicative of neuropathy.

In boys, marked narrowing of the urethral meatus (when the meat lips are separated and no mucosa is seen), must be identified and carefully noted. If these signs are present, the boy should be asked to void so the clinician can witness and record the flow rate and residual urine. Narrowed or displaced urinary stream is suggestive of meatal stenosis.

In girls, the introitus should be identified for the position of the urethra. Evidence of wetting or irritation of the labia or vagina should be identified as this could be suggestive of post-void dribbling or incomplete emptying with and incontinence due to either detrusor overactivity or sphincter weakness [77].

d) Laboratory examination

There is very little laboratory examination that is required in patients with nocturnal enuresis other than a urinalysis to rule out UTI and evidence of glycosuria and a urine culture if the urinalysis is suggestive of infection.
Urodynamics and imaging are rarely important in the child with monosymptomatic nocturnal enuresis. If there is any suggestion, however, that daytime wetting is occurring, and then a full evaluation of the daytime problem should precede the evaluation for nocturnal enuresis.

The management of NE depends on:
- the child’s motivation to participate in treatment
- exclusion of confounding psychosocial factors
- providing information and instruction about daily habits, underlining the importance of having regular fluid intake, regular voidings, and relaxed routines at bedtime
- regular review of the new intervention

The therapist should convey a sense of understanding and compassion to both the child and the family. Education about the problem and a realistic discussion about the prognosis will help instil competence in the treatment offered which may improve both compliance and outcome [78]. What follows is taken in part from the excellent review article by Hjalmas, et al [43].

**EVIDENCE BASED RECOMMENDATIONS FOR TREATMENT OF NE**

First line treatment and preliminary steps: Primary and secondary forms of nocturnal enuresis are treated the same if faecal incontinence, constipation or daytime wetting is present, these should be treated first [76].

Initial management: Although treatment modalities like lifting, fluid restriction, dry-bed training, retention control training, psychotherapy, acupuncture, hypnosis all have been used, there is not sufficient data in the literature to strongly recommend any of these [93-100]. However, non invasive behavioural modifications such as resisting over hydration in the evening are appropriate recommendations at the initiation of therapy. The child must void before bed. Excessive calcium or sodium intake should be avoided as well [79].

During the day the child should be instructed to void regularly, not to hold urine until the last minute, and to relax and take time to completely empty. If deemed important by the parents, a letter should be sent to the school to explain this.

Timing of treatment for the child who wets is dependent on the family’s desire and the child’s desire. As a good rule of thumb, children should be six to eight years of age. Some children, however, may want to wait until later. Others may be ready closer to age six. We try very hard not to treat children that are much younger than six, however. It is important for the parents to know that relapses can occur and that the older the child is, the better chance they have the enuresis resolving. The successful treatment of children with nocturnal enuresis has a foundation of realistic expectations and a motivated family [43].

Before starting treatment, a “baseline” meeting with counselling, provision of information, positive reinforcement, reassurance that 15% of children resolve each year, and increasing motivation should occur first. Children are asked to fill out a calendar or chart depicting the wet and dry nights. Children became significantly drier in two non-randomized trials associated with fewer wet nights simply by focusing them more on record keeping and true reward charts [80].

1. PHARMAOCOLOGICAL TREATMENT

We have noted three main causes of enuresis. (1) Nocturnal polyuria, (2) detrusor overactivity, and (3) Disorder of arousal. Pharmacological treatment is designed to address these three areas.

a) Desmopressin

Arginine vasopressin (AVP) or antiuretic hormone (ADH) is normally produced in the hypothalamus and released in the pituitary in response to hyperosmolality or hypovolemic conditions. Vasopressin acts on the collecting ducts and distal tubules to enhance water absorption. AVP by virtue of an independent vasoconstrictor effect is also a potent vasopressor. Desmopressin (or dDAVP) is an analog of vasopressin created by deaminating the cystine residue at position 1 and substituted D-argenine for L-argenine at position 8. These changes result in significantly increased antidiuretic activity but loss of vasopressor activity. The half-life of Desmopressin is 1.5 to 3.5 hours. In a larger portion of children with monosymptomatic nocturnal enuresis, the normal circadian variation in urine production with nocturnal rise of vasopressin is absent. In these cases, dDAVP would seem to be particularly appropriate. Desmopressin is easy to administer and the clinical effects appear immediately. The usual dose is 0.2 to 0.4 mg orally, or 20-40 micrograms intranasally at bedtime. The intranasal form is no longer recommended for nocturnal enuresis in many places around the world. Some patients have a delayed response and a small group of children who do not respond to desmopressin in ordinary dosage will become dry when the dose is increased [81].

Desmopressin may be particularly beneficial in the child with limited numbers of wet episodes per month who wants added security on special nights such a sleepovers, etc.

Nocturnal polyuria is a characteristic of children that respond the best to desmopressin [82].

But detrusor dependent enuresis does not easily respond as well to desmopressin treatment. The presence of daytime urgency of daytime incontinence is common in this group and constipation or faecal
incontinence is a regular finding and these must be treated before offering dDAVP. In the short term, desmopressin is reported to produce more rapid improvement than alarm therapy. The results of various long-term studies which have followed children for six to 24 months after treatment cessation indicate an annual cure rate in children on long-term treatment of approximately 30% [83,84].

1. Tolerability and Safety

Large amounts of liquid should not be consumed the nights when the drug is taken. There have been several reports that note Desmopressin toxicity [85,86,87].

This data would suggest that a fairly rigid regimen of water restriction must be enforced for two hours prior to bedtime and to allow one eight-ounce glass of water at dinner and nothing for the two hours prior to bedtime.

The results of numerous clinical trials have shown that desmopressin is well tolerated even during long-term treatment and associated with a low risk of adverse events. In the SWEET study, only six of 242 children (2.5%) withdrew during the long-term treatment because of very mild adverse events following the administration of intranasal desmopressin. With the exception of water intoxication, which can be serious, this drug seems to be tolerated quite well.

In a survey on hyponatremia in patients with nocturnal enuresis by Robson and Norgard in 1996 was found in the majority of children water intoxication was due to considerable intake of water during the time the child was actually taking the desmopressin.

2. Predictors of Response

The SWEET study found that those who improved or became dry during desmopressin were older (greater than 8 years), had fewer wet nights during baseline, and had only one wet episode during the week and responded initially to the smallest dose of desmopressin used in the study [88,89].

The practical approach, however, is to offer the treatment to enuretic children since it is difficult to absolutely predict those that will respond.

There is considerable evidence that desmopressin works better than placebo. In one study, patients on desmopressin were 4.6 times more likely to achieve 14 consecutive dry nights compared with placebo [90].

However, relapse after short-term treatment is common. Sixty-one percent of 399 patients six to 12 years of age recruited from a primary care in one study responded to desmopressin initially [83]. Using intention to treat analysis 19% (77 of the 399) remained dry off medication and 18% were dry while still on desmopressin, thus not significantly better than the spontaneous cure rate. This suggests that desmopressin, by reducing the urine output over night, reduces nocturnal enuresis but does not significantly affect the resolution rate over time above the spontaneous rate.

Although several studies have shown that dDAVP is a well tolerated and safe drug, even during long-term usage, one has to be aware that dDAVP is a potent antidiuretic drug and that there have been reports on severe water retention with hyponatremia and convulsions, but these are infrequent [91-97].

Level of evidence: 1. Grade of recommendation: A

b) Antimuscarinic drugs

1. Oxybutynin

Oxybutynin should not theoretically be efficacious in children with monosymptomatic nocturnal enuresis. However, because there is considerable overlap in the diagnosis of monosymptomatic nocturnal enuresis, a number of children with few daytime symptoms of overactive bladder may have symptoms of overactive bladder at night. Moreover, it has been shown that on urodynamics 73% of adults with primary nocturnal enuresis have some form of functional bladder outlet outflow obstruction classified as (1) “primary bladder neck dyssynergia” or “detrusor sphincter dyssynergia” [18]. That would suggest then that Oxybutynin might be a useful alternative in some children who are unresponsive to DDAVP. The drug is also indicated in combined day and nighttime incontinence [52, 98,99].

In general, oxybutynin is well tolerated but there are some side effects, namely dryness of the mouth, constipation and vertigo (rare). Constipation can also result in increased residual volumes which may make it difficult for the child to empty prior to bedtime. Oxybutynin treatment in conjunction with desmopressin may have a role in cases with suspected day and night time detrusor overactivity.

Level of evidence : 2. Grade of recommendation: B.

In those children who have NE due to detrusor overactivity during the night, treatment with an antimuscarinic drug should be considered [100]. Because it is difficult to perform a night time cystometry in these children it may be tried in children who have more than 2 wetting episodes per night and who do not respond to dDAVP or be given in combination with alarm or dDAVP [101,99]. At present no studies have been performed to demonstrate its efficacy.

Level of evidence: 3. Grade of recommendation: C
c) Tricyclic antidepressants

Although tricyclic antidepressant drugs, imipramine in particular, have worked in a number of children, most of the studies that recommend this drug are relatively old. The major drawbacks to imipramine therapy are cardiotoxic side effects, in some cases even with therapeutic doses, and the possibility of death with overdose.

Because imipramine and other drugs of the same family have potential cardiotoxic side effects they cannot be generally recommended for treatment of this non-lethal disorder [102].

Although treatment with tricyclic drugs is associated with a decrease of one wet night per week, the lasting cure rate of only 17 percent restricts the use of these drugs [103].

Only in selected cases (like adolescent boys with Attention Deficit Hyperactivity Disorder and persistent NE) it should be considered [104].

Level of evidence: 1. Grade of recommendation: C (due to potential cardiotoxicity).

In addition to dDAVP and imipramine, other drugs, such as carbamazine and indomethacin have been investigated as well: based on study design as well as study outcomes, these drugs are not recommended at this stage [105-107].

d) Inhibitors of prostaglandin synthesis

Because nocturnal polyuria in children with NE may not be entirely attributed to a defect in free water excretion, but rather to an increase in nocturnal excretion of sodium, cyclo-oxygenase inhibitors (like diclofenac), which reduce urinary sodium excretion, have been tried and in a randomised double blind placebo controlled study proved to be effective [128]. Further studies need to be done to elucidate the role of these drugs.

2. ENURESIS ALARM

The enuresis alarm is the most effective means of facilitating arousal from sleep and remains the most effective way to treat mono-symptomatic NE(107,108). Intervention with an alarm is associated with nine times less likelihood of relapse than antidiuretic therapy. Relapse rates in the 6 months following treatment are in the order of 15 - 30 %. Alarm therapy has been shown in a meta-analysis to have a 43 percent lasting cure rate [109,110]. Alarm therapy should be considered in every patient. There is an average success rate of nearly 68% with efficacy increasing with the duration of therapy.

Better results occur with optimal motivation of the child and family and higher frequency of wet nights. Reduced efficacy associated with the lack of concern shown by the child, lack of supervision, inconsistent use, family stress, abnormal scores on behaviour system checklists, psychiatric disorder of the child, failure to awaken in response to the alarm, unsatisfactory housing conditions and more than one wetting episode per night. Enuresis alarms require several months of continuous use and are, therefore, unsuitable for some families [111-112].

For optimal results, alarm therapy requires a motivated family and child with significant commitment to time and effort. We sometimes recommend that this be done during the summer holiday if possible. The impact on other family members should be considered. In some families alarm therapy may wake other members of the family and may increase parental annoyance and place a child at increased risk for physical or emotional abuse. Close follow-up is important to sustain motivation, troubleshoot technical problems and otherwise monitor the therapy [43].

The exact mechanisms for alarm treatment are not known. The effects are not due to classical conditioning as stimulus awakening occurs after and not before wetting. Instead it is clearly an operant type of behavioural approach, i.e. a learning program with positive reinforcement that includes aversive elements. Dryness is reached either by waking up leading to “nocturia” in 35% of children or by sleeping through the night with a full bladder in 65%. Body worn alarms are as effective as bedside alarms (general assessment for alarm treatment [113].

The family should continue alarm therapy for at least 6 to 8 weeks before discarding it as ineffective. Compliance remains a problem: dropout rates are rarely disclosed in reported studies. Proper guidance and instructions are mandatory.

The key to success is not the stimulus intensity of the alarm triggering, but the child’s preparedness to awake and respond to the signal. Comparison of the different types of alarm did not show significant outcomes.

In general it can be stated that alarm treatment is more effective than other forms of treatment and the lasting cure rate about twice as high [114, 115].

Level of evidence 1. Grade of recommendation A

In some cases, alarm therapy can be enhanced using the alarm in addition to other behavioral components. Overlearning (giving extra fluids at bedtime after successfully becoming dry using an alarm) and avoiding penalties may further reduce the relapse rate (108).

3. DRY BED TRAINING

This is a package of behavioral procedures used in conjunction with the enuresis alarm first described by Azrin et al [116]. It incorporates:

• the enuresis alarm
• cleanliness training (encouraging the child to take
responsibility for removing of wet night clothes and sheets, re-making the bed and resetting the alarm),

- waking schedules – to ease arousability from sleep as described above and involving:
  1. for the first night, waking the child each hour, praising a dry bed, encouraging the child to decide at the toilet door whether he or she needs to void, and on returning to bed the child is encouraged to have a further drink.
  2. On the second night the child is awakened and taken to the toilet 3 hours after going to sleep. For each dry night, the clinician moves the waking time later by 30 minutes. If the child is wet on any night, the waking time stays at the time of the previous evening. The clinician discontinues the sense when the waking time reaches 30 minutes following sleep. The clinician restarts the waking schedule if the child begins wetting twice or more in any week, stating again 3 hours after sleep.

High success rates and low drop out have been reported although relapse rates are no different than enuresis alarm treatment alone. Modifications are advocated to remove some of the more punitive elements of the programme but at best, it is a complex, time consuming and demanding technique [113, 117,118].

Hirasing et al found 80 percent success with group administered dry bed training. Girls responded better than boys [119]. The majority of parents were satisfied with the programme but opinions of the children were divided. Factors not related to success were the child’s age, bedwetting frequency, secondary enuresis or family history.

In another study they found a positive effect on behavioural problems [120].

An important component analysis by Bollard & Nettelbeck found that the enuresis alarm accounted for most of the success achieved through dry bed training. They believe that a large proportion of the components of the procedure can be eliminated without sacrificing much of its overall effectiveness and that the waking schedule coupled with the enuresis alarm is as effective as the complete dry bed-training programme [121].

Level of evidence: 2. Grade of recommendation D (no more effective than alarm treatment alone)

4. AROUSAL TRAINING

Arousal training entails reinforcing appropriate behaviour [waking and toileting] in response to alarm triggering. The aim is to reinforce the child’s rapid response to the alarm triggering, not on ‘learning to keep the bed dry’.

The instructions involve:

- setting up the alarm before sleep
- when the alarm is triggered the child must respond by turning it off within 3 minutes
- the child completes voiding in the toilet, returns to bed and re-sets the alarm
- when the child reacts in this fashion he is rewarded with 2 stickers
- when the child fails to respond in this way the child pays back one sticker
- Van Londen et al first described this procedure with a group of 41 children, aged 6-12 years, with predominantly primary enuresis [122].

They reported 98 percent success [14 consecutive dry nights] compared to 73 percent success with alarm monotherapy.

The difference was significant [p<0.001]. Ninety two per cent remained dry after 2 years suggesting very low relapse rate. An extraordinary aspect of this study was the lack of contact between therapist and parents. All those included were parents who had ordered an alarm from a rental agency and were given the instructions with the alarm.

The authors conclude that arousal training is ‘definitely the treatment of choice for enuretic children between 6 and 12 years’. Compared with other studies and considering experience of daily practice one may question the very high success rate in this particular group of patients.

Level of evidence: 3. Recommendation: grade C

The enuresis alarm remains the most effective means of facilitating arousal from sleep. The key to success is not the stimulus intensity of the alarm triggering, but the child’s preparedness to awake and respond to the signal.

5. ACUPUNCTURE

In one randomised controlled trial that examined acupuncture, 40 children were allocated either to dDAVP or acupuncture, 75% of children were dry after 6 month of therapy (while still on medication), while 65% of patients were completely dry after a mean of 12 sessions.

From this study it is concluded that as an alternative, cost-effective and short-term therapy acupuncture should probably be counted among available treatment options. Another meta analysis provides some evidence for the efficacy of acupuncture for the treatment of childhood nocturnal enuresis [123].

Comparison of treatment outcome and cure rates is difficult because of the inconsistent use of definitions, the inclusion of children with daytime symptoms, and the variable follow-up periods in most studies. For a pragmatic approach, see Figure 11.

Level of evidence: 4. Recommendation: grade D
6. COMBINED TREATMENT WITH ALARM AND DESMOPRESSIN

Combined treatment may be superior to alarm alone especially for non-responders of each individual treatment. In this approach, treatments are started at the same time: the rapid action of dDAVP is believed to facilitate the child’s adaptation to the alarm [124, 125]. After 6 weeks the dDAVP is discontinued while the alarm treatment is continued until the child becomes completely dry. Compared with either therapy alone, the combination is particularly effective in children with high wetting frequencies and behavioural problems.

Combination with full-spectrum therapy may even yield higher success rates [126-127]. Van Kampen et al reported their results of ‘full-spectrum’ therapy in 60 patients: they were treated for 6 months with a combination of alarm, bladder training, motivational therapy and pelvic floor muscle training: 52 patients became dry [126].

Hjälmås et al have proposed the following (not validated) protocol [43].

1. careful screening to identify any functional or mechanical outlet obstruction and appropriate management,
2. monotherapy with either alarm or desmopressin for a minimum of 12 weeks,
3. combination of alarm and half-therapeutic or titrated dose of desmopressin that allows wetting up to 4 nights per week,
4. maintain both interventions for 8-10 weeks,
5. increase desmopressin to dose that allows only one wet episode per week,
6. withdraw alarm when dry for one month,
7. reduce desmopressin to half dose after a further 8 weeks,
8. withdraw desmopressin after a further 8 weeks.

7. NON RESPONDERS

About one third of children do not respond to treatment with alarm and/or dDAVP. The majority of these children are likely to have a small nocturnal bladder capacity and suffer from “detrusor dependent NE”. These children may void more frequently than their peers or have urgency and day-time incontinence. They are also often constipated. Prescription of dDAVP plus antimuscarinics should be considered, although evidence from the literature is lacking. Most likely the reduced urinary output during the night leads to a lower filling rate which may reduce the nocturnal involuntary detrusor contractions and enhance the action of antimuscarinic drugs. Treatment success is usually noted between 1-2 months. Treatment should be continued for 6 -12 months, but clinical evidence is lacking.

On the other hand some of these children may have day time incontinence, which was not discovered during the initial workup. They should be given a strict voiding regimen and a combination of dDAVP with the alarm [54].

Some children who remain non-responders to desmopressin in combination with alarm and / or anticholinergic drugs may have absorptive nocturnal hypercalciuria which may be responsible for the NE in some of these patients. With an appropriate (low calcium) diet these patients can become desmopressin responders [129].

NE is a symptom, not a homogeneous disorder. A really efficient treatment will never become possible until we have clarified all the different pathophysiological subgroups that go under the heading of NE.

- Gaining the confidence of the child and the family is paramount. The development of structure in the child’s life, early bedtime, careful calendaring, avoidance of fluids late in the day, are critical.
- Secondly, identifying compounding psychological or physiologic factors of the child such as constipation and diurnal enuresis are critical.
- Third, alarm treatment should probably be recommended as the first choice of treatment with the modifications listed above. Single parents have a difficult time with the effort that is required to awaken with the child for the alarm management and, in some cases when children are not frequently wet, dDAVP may provide effective therapy for the last few years that they are at risk. In general, those that do the best with the alarm therapy are those with frequent bedwetting, normal estimated bladder volume, parents who are willing to participate, and true monosymptomatic nocturnal enuresis.

- Desmopressin seems to work best in children
Urinary incontinence in children may be caused by a congenital anatomical or neurologic abnormality, such as ectopic ureter, bladder extrophy or myelomeningocele (MMC). In many children, however, there is no such obvious cause for the incontinence and they are referred to as having “functional incontinence.”

- If the initial treatment does not provide satisfactory results in two months, the child can switch to another. In some cases, using both the alarm and Desmopressin can be effective [124,130].
- Lastly, combinations of therapy including Desmopressin plus an antimuscarinic can be used in some cases as well if detrusor overactivity at night is suspected.

D. CHILDREN WITH BOTH DAY AND NIGHT TIME INCONTINENCE

Urinary incontinence in children may be caused by a congenital anatomical or neurologic abnormality, such as ectopic ureter, bladder extrophy or myelomeningocele (MMC). In many children, however, there is no such obvious cause for the incontinence and they are referred to as having “functional incontinence.”

Previously the bladder in infancy was considered overactive during filling with emptying being initiated by a detrusor overactivity contraction, however natural fill studies in infants demonstrated a stable detrusor during filling and dyscoordinated emptying[1,2,3].

Male infants void with significantly higher pressure than female infants and demonstrate a smaller bladder capacity than girls. However these dysfunctions are transitory as on follow-up detrusor overactivity has resolved, post void residual volumes have improved and voiding detrusor pressures are normalized. A continuous voiding pattern was seen consistently after 2 years of age.

Bladder control is believed to be under influence of the central nervous system. The pontine region is considered to be responsible for detrusor sphincter coordination while the cortical area is responsible for detrusor overactivity control. Formerly it was believed that bladder maturation followed maturation of cortical inhibition processes, However, recent work of CK Yeung suggests bi-directional maturation of both the coordinating influence on the bladder and the pons may be implicated. This implies that a condition such as detrusor overactivity would be the result of loss of cortical control or of deficiency in cortical control, while dysfunctional voiding would be the result of non maturation of the coordination.

With the emergence of functional MRI future studies will be able to illuminate this enigma.[4] This opens an era of corticocentric thinking on lower urinary tract dysfunction away from the current trend of vesicocentric thinking. Detrusor overactivity may be a symptom of a centrally located dysfunction affecting bladder, bowel, sexual function and even mood and behaviour.[2] Indeed many studies indicate that there exists a link between lower urinary tract dysfunction and ADHD (attention deficit and hyperkinesia) [5, 6].
The desire to void is a sensation which, in the developing child, is incorporated into daily life so that voiding takes place at an appropriate time and place. Problems with training or psychological difficulties can have a great impact on the results of training: some parents send their child to the toilet many times, though his/her bladder may be empty [7]. Voiding in these circumstances can only be achieved by abdominal straining. The positive reinforcement that the child receives by voiding even a small amount may lead to the development of an abnormal voiding pattern.

The same is true when children receive negative feedback related to voiding [8]. Urinary incontinence in children may be due to disturbances of the filling phase, the voiding phase or a combination of both. In the new ICCS terminology document these conditions are termed functional bladder disorders or Lower Urinary tract (LUT) conditions. They are divided into either detrusor overactivity (DO) or dysfunctional voiding as the studies tended to look primarily at daytime versus nighttime incontinence and made no effort to evaluate the type of daytime incontinence.

Daytime or combined daytime and nighttime incontinence at least once a week seems to occur in about 2-4 percent of 7-year-old children and is more common in girls than in boys [11]. Overall the rates of prevalence vary from 1 to 10 percent, but in general for 6 to 7 year old children the prevalence is somewhere between 2 and 4 percent, and rapidly decreases during the following years [12-17]. Sureshkumar et al in a population based survey of over 2000 new entrant primary school children [age 4-6 years] in Sydney Australia noted an overall prevalence of daytime wetting of 19.2% defined as at least one daytime wetting episode in the prior 6 months with 16.5% having experiencing more than one wetting episode and only 0.7% experienced wetting on a daily basis [18]. Multivariate analysis showed that recent stress, a history of daytime wetting along the paternal line, and a history of wetting among male sibs were independent risk factors for moderate to severe daytime wetting. Because this was a cross sectional study recall bias may have resulted in an overestimate of risk of daytime wetting being caused by such factors as emotional stress and family history. In addition, urine cultures were not obtained so occult UTIs could not be identified.

In a questionnaire based study supplemented by telephone calls Hellstrom assessed the prevalence of urinary incontinence in 7 year old Swedish school entrants [19]. Diurnal incontinence was more frequent in girls than boys, 6.7% vs 3.8%, respectively. Wetting every week was reported in 3.1% girls and 2.1% of boys. The majority of children with diurnal incontinence had concomitant symptoms: urgency was reported in 4.7% girls and 1.3% boys. Nocturnal incontinence combined with daytime wetting was equally common in males versus females, 2.2% versus 2%, respectively. At the age of 17 years daytime wetting, at least once a week, was found in 0.2 % of boys and 0.7% of girls. A limitation of this study is its dependency on recall. Children with daytime or mixed wetting were found to suffer from urgency in 50.7 percent of the cases, with 79.1 percent wetting themselves at least once in 10 days [20]. Urgency symptoms seem to peak at age 6–9 years and diminish towards puberty, with an assumed spontaneous cure rate for daytime wetting of about 14% per year [20, 21].

Most children are toilet-trained by the age of 3 years, although the mean age may range from 0.75 to 5.25 years, with girls being trained earlier [2.25 years] than boys (2.56 years) [22]. Although a recent study reported day dryness at a mean age of 17.4 months in the majority of countries the age of commencing toilet training has increased [23]. This is thought to be associated with higher education levels in parents and the popularity of the child-oriented approach.
rather than parent-initiated methods [24]. Children who exhibited elimination signals for voiding became dry sooner than those who did not show such signs. There is huge social and cultural variation in toilet training practices with some of the implicated issues being availability of inside toilet, washable versus disposable diapers, working or home-based mothers, rural or urban location and use or not of punishment methods [24].

Swithinbank et al have found a prevalence of day wetting [including also “occasional” wetting] in 12.5% in children age 10-11 years which decreases to 3.0% at age 15-16 years [25]. Based on these findings, it seems that the prevalence of all kinds of daytime incontinence diminishes by 1-2% per year from age 10-11 to age 15-16 years, while daytime incontinence, at least once a month, seems to diminish by 0.2% per year from age 7 to age 17 years. Because of treatment interventions the studies may not recount the true natural history.

A more recent cohort study of all school children in the first and fourth grades in the city of Eskilstuna (Sweden), daytime urinary incontinence (at least once a month) was reported in 6.3% of the first graders and 4.3% of the fourth graders, while bedwetting (at least once a month) was reported in 7.1% and 2.7% and faecal incontinence in 9.8% and 5.6%, respectively. This study demonstrates that soiling and daytime urinary incontinence often coexist.[26]

The natural history of detrusor overactivity in children is not well understood. It is no longer held that an detrusor overactivity in children is idiopathic or due to a maturational delay but more likely to be associated with feed forward loops from the generation of a high pressure system during voiding or filling. Both the interplay of neural drive with motor control and the dynamic nature of the growing bladder could be causative. This is in contrast to the adult population where detrusor overactivity is considered a chronic condition whose origin is unrelated to functional use. There is no long-term data to determine if childhood detrusor overactivity predicts detrusor overactivity as an adult.

By the age of 5 years, unless organic causes are present, the child is normally able to void at will and to postpone voiding in a socially acceptable manner. By this age, night-time and daytime involuntary wetting become a social problem and a cause for therapeutic intervention. In children who present with a change in voiding habits, such as a new onset of voiding dysfunction, one should consider the possibility of child sexual abuse [27].

This is difficult to prove but should be kept in mind, especially when invasive diagnostic and therapeutic procedures are contemplated. One may want to simply ask the parent or caregiver if there were any precipitating events or concerns that they feel may have led to the changes in the child’s voiding habits. The appropriate individuals should be contacted if there is a high index of suspicion. Of adult women with complex urinary symptoms, a significant proportion report sexual abuse as a child.

II. INTRODUCTION TO CLINICAL ASSESSMENT

The evaluation of daytime wetting is based on the medical and voiding history, a physical examination, a urinalysis, bladder diaries and uroflowmetry with postvoid residual. The upper urinary tract should be evaluated in children with recurrent infections and dysfunctional voiding. Uroflowmetry can be combined with pelvic floor electromyography to demonstrate overactivity of the pelvic floor muscles. Urodynamic studies are usually reserved for patients with therapy resistant dysfunctional voiding and those not responding to treatment who are being considered for invasive treatment [28-31].

Treatment is usually a combination of ‘standard therapy’ (see below), behaviour therapy, bladder training, physiotherapy and medical treatment. Surgery is rarely needed for the management of daytime wetting in the absence of a structural abnormality. The roles of neuromodulation, botulinum toxin and intravesical therapies in the management of pediatric urinary incontinence are less well-defined. Clean intermittent self-catheterization is sometimes necessary in children with poor bladder emptying, due to underactivity of the detrusor and subsequent large residuals, who do not respond to a more conservative approach.

The importance of treatment during childhood was pointed out in a general population study of 1333 adult women. Fifty percent reported symptoms of stress incontinence and 22 percent reported symptoms of urgency incontinence. Eight percent noted severe symptoms. Women who at age six years had wet episodes during the day or were wet several nights per week, were more likely to suffer from severe incontinence and report urgency symptoms: occasional bedwetting was not associated with an increased risk in adult life [31].

III. CONFOUNDING FACTORS: LOWER URINARY TRACT DYSFUNCTION, RECURRENT URINARY TRACT INFECTION AND VESICOURETERIC REFLUX (VUR)

The relationship between detrusor dysfunction and VUR associated with a urodynamic anomaly was first described by Allen and Koff and has been confirmed by several authors [32-35]. Koff demonstrated that
treatment of detrusor overactivity reduced the incidence of infection and resulted in a 3 fold increase in the rate of reflux resolution. In a study by Sillen of children with gross bilateral reflux, extreme detrusor overactivity without signs of bladder outlet obstruction was found in boys. Infant girls with gross bilateral reflux did not show the same degree of detrusor overactivity [36]. Other investigators assessing high grade VUR in newborns noted similar findings. Van Gool et al noted that 40% of 93 girls and boys evaluated for urgency incontinence and recurrent UTIs had reflux [37].

These studies in infants and the association of 'dysfunctional elimination syndromes' with reflux and infection in older children support the controversial suggestion that in some individuals vesicoureteral reflux is a secondary disorder related more to abnormal detrusor function than to a primary anatomic defect at the ureterovesical junction. It has recently been shown that increased intravesical pressure, without reflux may be detrimental for the upper tracts: renal scarring without reflux was described by Vega et al recently [38].

In support of this concept is the common finding of vesicoureteral reflux in children with neuropathic bladders and detrusor-sphincter dysynergia. In such children, the institution of clean intermittent catheterization and anticholinergic therapy leads to the resolution of VUR in a large number of cases. It is believed that the decrease of detrusor overactivity and restoration of functional capacity in combination with regular and complete emptying of the bladder are the responsible co-factors [39].

Koff et al evaluated the effects of antimuscarinic therapy in 62 children with a history of recurrent UTIs, VUR and detrusor overactivity, and compared these children with an age-matched control group with a normal urodynamic study [40]. The overall small sample size and the small number of compliant patients limit the study; however, it did demonstrate a statistically significant difference in the resolution rate of VUR between the treated group and the control group. The overall infection rate was lower in the treated group [16%] compared to the non-medically treated group [63%] and the age-matched control group [71%]. Several authors have documented the relationship between detrusor overactivity and dysfunctional voiding with recurrent UTIs.

Proposed etiologies for the increased incidence of UTIs in these patient populations include a milk back phenomenon whereby bacteria in the proximal urethra are “milked back” into the bladder during contraction of the pelvic floor muscles. Alternatively, decreased blood flow and relative hypoxia during periods of increased detrusor pressure such as during involuntary detrusor contractions and voiding against functional obstruction, may induce transient bladder mucosal injury. Constipation is prevalent among children with bladder symptoms, but often poorly identified by parents [41]. It is a risk factor for recurrent UTIs. Contrary to expectations, findings from the European Bladder Dysfunction Study suggested that symptoms of disordered defecation did not influence the cure rate of treatment for bladder symptoms [42]. In a prospective non-randomized clinical series of day wetting children a strong correlation was found between recurrent urinary tract infections, detrusor overactivity and detrusor-sphincter dysfunction [43, 44]. In a study by Hansson et al, symptoms of an detrusor overactivity, such as urgency and daytime incontinence were found in a high percentage of girls with asymptomatic bacteriuria [45].

In the majority of children with detrusor-sphincter-pelvic floor dysfunction the recurrent infections disappeared following successful treatment of the detrusor dysfunction. This finding confirms the hypothesis that detrusor-sphincter-pelvic floor dysfunction is the main factor responsible for the infections (and to a lesser extent vice versa) [46, 47]. Additionally, since such children typically have coexistent constipation, attempts at restoring normal bowel habits will also contribute to decreasing the risk of UTIs. At present, current opinion is that vesicoureteral reflux as such does not predispose to UTI: however it may facilitate renal involvement [causing pyelonephritis] once bacteriuria has been established in the bladder. This concept has not been scientifically validated and the incidence of renal scars as a consequence of pyelonephritis is reportedly the same, regardless of whether reflux has been documented or not [48]. Those children with VUR in association with detrusor overactivity and/or voiding dysfunction may be at increased risk for upper tract damage given their increased risk of developing UTIs. With this in mind, aggressive treatment of the underlying filling/voiding disorder, the addition of prophylactic antibiotics, and attention to their bowel habits should be given in an effort to decrease the risk of UTIs in this higher risk group [49-52].

In a recent study evaluating retrospectively a large group of children with LUT conditions it was shown that in patients who had urinary tract infection the presence of reflux increased the rate of renal cortical abnormalities.[53]

**IV. CLASSIFICATION**

Numerous classifications have been used for children who present with varying degrees of 'functional' urinary symptoms, unrelated to apparent disease, injury or congenital malformation. In 2006 the International Children's Continence Society (ICCS) released a standardized terminology to provide guidelines for the classification and communication about LUTS in
children [9]. Symptoms are classified according to their relation to the voiding and or storage phase of bladder function.

In addition to gaining a comprehensive history, observing micturition and examining a child form the basis of assessment, the information derived from a 48-72 hour bladder diary, stool record, voiding uroflowmetry and lower urinary tract ultrasonography is essential in making the initial diagnostic classification. Urodynamic investigations elucidate the basis of clinical findings but are first line evaluation techniques only in tertiary referral centers where children have not responded to previous treatment or have symptoms suggestive of neural involvement or anatomical anomalies.

The ICCS has classified daytime LUT conditions into groups that currently align with understanding of underlying pathophysiology. The groups commonly overlap and allocation is based on the 4 symptoms of urinary incontinence, frequency of volitional voiding, micturition volumes and fluid intake.

Over active bladder (OAB) including urgency
• Incontinence
• Dysfunctional voiding
• Underactive bladder

The symptom-specific conditions of
• Voiding postponement
• Vaginal reflux
• Giggle incontinence
• Extraordinary daytime urinary frequency
• Elimination syndrome

The term ‘non-neurogenic dysfunction’ is commonly encountered in the literature and describes the whole spectrum, from simple detrusor overactivity to severe cases with deterioration of the upper tracts. The fact that a neurologic deficit is not demonstrated at the time of evaluation, does not, however exclude the possibility that a neurologic abnormality was present at the onset of the problem.

It has been postulated that detrusor overactivity may eventually lead to poor bladder emptying due to underactivity of the detrusor or severe dys-coordination between detrusor, sphincter and pelvic floor. However, the natural history of many of these children does not confirm this hypothesis, nor the early onset of severe pathology in some of them. Hoebeke et al found no evidence for this dysfunctional voiding sequence: children with functional incontinence have different primary diseases, but all have a common risk of incontinence, UTI, VUR [15%] and constipation [17%] [54].

1. OVER ACTIVE BLADDER IN CHILDREN

The term detrusor overactivity is used to describe the symptom complex of urgency, which may or may not be associated with urgency incontinence and is not a direct result of known neurological damage. Recent suggestions describe DO as a symptom of cortico-central dysfunction that affects multiple systems rather than a dysfunction isolated to the urinary bladder [55]. Urge syndrome is characterized clinically by frequent episodes of an urgent need to void, countered by contraction of the pelvic floor muscles (guarding reflex) and holding manoeuvres, such as squatting and the Vincent curtsey sign. The term urgency refers to a sudden compelling desire to void that is often difficult to defer, unlike the need to void which is experienced by all individuals and may be intense if one holds one’s urine for a prolonged period of time. The symptoms arise from detrusor overactivity during the filling phase, causing urgency. These detrusor contractions are countered by voluntary contraction of the pelvic floor muscles to postpone voiding and minimize wetting. The detrusor contractions can be demonstrated urodynamically, as can the increased activity of the pelvic floor muscles during each contraction.

The voiding phase is essentially normal, but detrusor contraction during voiding may be extremely powerful. The flow rate reaches its maximum quickly and may level off (‘tower shape’). Such strong bladder and pelvic floor muscle contractions have been postulated to result in damage to the bladder mucosa increasing the risk of UTIs. In addition these children may note suprapubic or perineal pain. A cohort of patients presenting with nighttime pain syndromes based on pelvic floor spasms was described by Hoebeke et al. Good response to pelvic floor relaxation biofeedback is described in this study [56].

Over active bladder (OAB) should also be considered in “continent” children with recurrent UTI and vesicoureteral reflux. Depending on fluid intake and urine production, the complaints of incontinence become worse towards the end of the day, due to loss of concentration and fatigue and may also occur during the night. Children usually diminish their fluid intake to minimize wetting, and therefore incontinence may not be the main complaint or symptom.

Frequent voluntary contractions of the pelvic floor muscles may also lead to postponement of defaecation. Constipation and fecal soiling are often found in children with detrusor overactivity [57]. The constipation is aggravated by the decreased fluid intake. Constipation contributes to an increased risk of UTIs and may exacerbate the detrusor overactivity. An investigation of the natural history of combined emptying dysfunction of bladder and bowel using an elimination score in women and without urogy-
naecological problems demonstrated that childhood lower urinary tract dysfunction may have a negative impact on bladder and bowel function in later life [58].

A careful history, physical examination and scrutiny of the child’s bladder diary will identify symptoms of detrusor overactivity. Urine flow rate registration and post-void residual urine measurement help to identify co-existing dysfunctional voiding. Thus in the majority of children, invasive studies such as urodynamic studies are not indicated as part of the initial evaluation. Such studies are reserved for those children with a question of an underlying neurologic defect and those who fail to improve with medical and behavioral therapy, if invasive therapies are being considered. Those children with a history of recurrent UTIs should undergo assessment with a renal/bladder ultrasound and depending on the age of the child and the severity of the UTI(s) a voiding cystourethrogram (VCUG) to assess reflux is occasionally performed [59, 60]. By adopting a structured approach to history and physical examination, the diagnosis of urge syndrome can be made in the majority of children without the need for invasive diagnostic procedures.

**Treatment**

The treatment of urge syndrome involves a multimodal approach, involving strategies such as behavioral modification, antimuscarinic medication, adjunctive biofeedback and neuromodulation. Underlying and potentially complicating conditions such as constipation and UTIs are managed prior to intervention.

Level of evidence: 3. Grade of recommendation: C

### 2. DYSFUNCTIONAL VOIDING

Dysfunctional voiding refers to an inability to fully relax the urinary sphincter or pelvic floor muscles during voiding. There is no identified underlying neurologic abnormality. Children with dysfunctional voiding usually present with incontinence, urinary tract infections and constipation and demonstrate fluctuating or intermittent patterns during repeated uroflowmetry. A recent study report mild and severe obesity occurring in 51% and 31% respectively of children with daytime incontinence. These figures compare to population prevalence rates of 30% and 15% respectively and highlight a potential association between lower urinary tract dysfunction and obesity.

No clear data are available on the possible causes of dysfunctional voiding. It may be that an detrusor overactivity eventually leads to overactivity of the pelvic floor muscles, with subsequent insufficient relaxation during voiding [61]. Alternatively, poor relaxation of the pelvic floor muscles during voiding may be a learned condition during the toilet training years, adopted following episodes of dysuria or constipation or occur secondary to sexual abuse [62]. The child’s environment, in particular toilet conditions and privacy issues, can trigger or exacerbate voiding anomalies [63]. In some girls, anatomical anomalies of the external urethral meatus seem to be associated with a higher incidence of dysfunctional voiding. The urine stream may be deflected anteriorly and cause stimulation of the clitoris with subsequent reflex activity of the bulbocavernous muscle causing intermittent voiding [64]. Since no true structural obstruction can be identified the intermittent incomplete pelvic floor relaxation that occurs during abnormal voiding is termed a functional disorder.

Abnormal flow patterns seen in children with dysfunctional voiding:

- **Fluctuating (Staccato) voiding:** continuous urine flow with periodic reductions in flow rate precipitated by bursts of pelvic floor activity. Voids are commonly prolonged and incomplete.

- **Interrupted voiding:** characterized by unsustainable detrusor contractions resulting in infrequent and incomplete voiding, with micturition in separate fractions. Bladder volume is usually larger than age-expected capacity. Residual urine is often present. Detrusor overactivity may be seen but it may also be absent [43, 47, 59, 65].

Sustained alteration of voiding is associated with subsequent filling phase anomalies such as phasic detrusor overactivity and inappropriate urethral relaxation [66]. Urinary tract infections and kidney damage are common sequelae [67]. Over time, routine incomplete bladder emptying can progress to detrusor over-distension associated with chronic urinary retention. The child with this presentation is often classified as having poor bladder emptying due to detrusor underactivity.

Urinary symptoms associated with dysfunctional voiding range from urgency to complex incontinence patterns during the day and night [68]. Children with dysfunctional voiding have a higher rate of recurrent urinary tract infections than children with no voiding abnormality and also demonstrate increased incidence of higher grades of VUR [54, 69]. Symptoms are significantly more common in children with Attention Deficit Disorder than in ‘normal’ children [70].

Signs of dysfunctional voiding reflect initial “compensatory” overactivity of the detrusor along with poor emptying ability. They may include small bladder capacity, increased detrusor thickness, decreased detrusor contractility, impaired relaxation of the external urinary sphincter/pelvic floor during voiding, weak or interrupted urinary stream and large post-void residual volumes of urine. There may also be ultrasound abnormalities, secondary vesicoureteric reflux, fecal soiling or constipation [54, 71, 72].

**Treatment**

Symptoms are often refractory to standard therapy of
hydration, bowel management, timed voiding and basic relaxed voiding education. Effective intervention requires combination therapy, generally with a sizeable investment of time over a long period. Treatment is aimed at optimizing bladder emptying and inducing full relaxation of the urinary sphincter or pelvic floor prior to and during voiding.

Specific goals are:
- consistent relaxation of the pelvic floor throughout voiding,
- normal flow pattern,
- no residual urine and
- resolution of both storage and voiding symptoms.

Strategies to achieve these goals include pelvic floor muscle awareness and timing training, repeated sessions of biofeedback visualization of pelvic floor activity and relaxation, clean intermittent self-catheterization for large post-void residual volumes of urine, and antimuscarinic drug therapy if detrusor overactivity is present. If the bladder neck is implicated in increased resistance to voiding, alpha-blocker drugs may be introduced. Recurrent urinary infections and constipation should be treated and prevented during the treatment period.

Treatment efficacy can be evaluated by improvement in bladder emptying and resolution of associated symptoms [73]. Controlled studies of the various interventions are needed. As with detrusor overactivity, the natural history of untreated dysfunctional voiding is not well delineated and optimum duration of therapy is poorly described.

Level of evidence: 4. Grade of recommendation: C

3. UNDERACTIVE DETRUSOR

Children with underactive detrusor function may demonstrate low voiding frequency and an inability to void to completion using detrusor pressure alone. Voiding is of long duration, low pressure, intermittent and often augmented with abdominal straining.

Children with this condition usually present with urinary tract infections and incontinence. Urodynamically, the bladder has a larger than normal capacity, a normal compliance and reduced or no detrusor contraction during voiding. Abdominal pressure is the driving force for voiding. The previously used term ‘lazy bladder’ is incorrect and should no longer be used.

A correct diagnosis can only be made by urodynamic evaluation. Renal function studies, renal ultrasound and VCUG should be performed to assess the extent of renal damage and reflux. Long-standing overactivity of the pelvic floor may in some children be responsible for decompensation of the detrusor, leading to a non-contractile detrusor. However, no data are available to support this theory.

Treatment

Treatment is aimed at optimizing bladder emptying after each void. Clean intermittent (self) catheterization is the procedure of choice to promote complete bladder emptying, in combination with treatment of infections and constipation [which may be extreme in these patients]. Intravesical electrostimulation has been described, but at this time it is still not recommended as a routine procedure for children.

Level of evidence 4. Grade of recommendation C

4. VOIDING POSTPONEMENT

A new classification of voiding dysfunction in which children postpone imminent micturition until overwhelmed by urgency, resulting in urgency incontinence [74]. A recent study comparing children with typical OAB to those with voiding postponement revealed a significantly higher frequency of clinically relevant behavioral symptoms in postponers than in children with OAB, suggesting that voiding postponement is an acquired or behavioral disorder [74]. In the children with voiding postponement only 20% exhibiting a fluctuating voiding pattern. It remains to be determined whether or not voiding postponement can develop in the setting of a perfectly normal urinary tract or whether OAB is a necessary precursor.

Level of evidence 4. Grade of recommendation C

5. GIGGLE INCONTINENCE

In some children giggling can trigger partial to complete bladder emptying well into their teenage years, and intermittently into adulthood [75]. The condition occurs in girls and occasionally in boys and is generally self-limiting. The etiology of giggle incontinence is not defined. Urodynamic studies fail to demonstrate any abnormalities, there is no anatomic dysfunction, the upper tracts appear normal on ultrasound, the urinalysis is normal and there are no neurologic abnormalities [76, 77].

It is postulated that laughter induces a generalized hypotonic state with urethral relaxation, thus predisposing an individual to incontinence, however the effect has not been demonstrated on either smooth or skeletal muscle. It has also been suggested that giggle incontinence is due to laughter triggering the micturition reflex and overriding central inhibitory mechanisms. One small study hinted at an association with cataplexy (a state of excessive daytime sleepiness), suggesting involvement of central nervous structures, however with only 7 subjects further evidence is needed [78].

Since the etiology of giggle incontinence is not known it is difficult to determine the appropriate form of treatment. Positive results have been reported with conditioning training, methylphenidate and imipramine [76, 78-80]. Others have tried antimuscarinic agents and alpha-sympathomimetics. There is no acceptable
evidence that any form of treatment is superior to no intervention.
Level of evidence 3. Grade of recommendation D

6. VESICOVAGINAL ENTRAPMENT

Urinary leakage that occurs in girls a short time after voiding to completion, that is not associated with any strong desire to void, may be the result of vesicovaginal reflux

[81]. Urine may become entrapped in the vagina during voiding due to labial adhesions, a funnel shaped hymen, or an inappropriate position on the toilet. The classic presentation is that of a girl who does not spread her legs apart during voiding and who is not sitting all the way back on the toilet seat, but who is rather sitting near the end of the toilet seat tilting forward. Obesity may be an associated risk factor. Changes in voiding position and treatment of labial adhesions will lead usually to resolution of the urine leakage.

Level of evidence 4. Grade of recommendation C

7. ELIMINATION SYNDROME

This is a term used to describe dysfunctional emptying of bowel and/or bladder presenting with symptoms of detrusor overactivity, constipation and infrequent voiding.

The genitourinary tract and the gastrointestinal system are interdependent, sharing the same embryologic origin, pelvic region and sacral innervation. Although children with voiding disturbances often present with bowel dysfunction, until recently this co-existence was considered coincidental. However, it is now accepted that dysfunction of emptying of both systems, in the absence of anatomical abnormality or neurological disease, is inter-related. The common neural pathways, or the mutual passage through the pelvic floor musculature, may provide a theoretical basis for this relationship, as may the acquisition of environmental and developmental learning. The latter can be influenced by episodes of urinary tract infection, constipation, anal pain or trauma, childhood stressors, reluctance to toilet and poor toilet facilities [57, 63, 82].

There is also evidence to suggest that in severe cases symptoms may have a neurological basis.

The Elimination Syndrome [ES] is seen more frequently in girls than boys and is significantly associated with the presence of both VUR and UTI [83]. VUR is slower to resolve and breakthrough urinary tract infections are significantly more common in children with ES when compared to those without the diagnosis. Infections do not ameliorate with antibacterial prophylaxis. Age of first febrile UTI does not appear to be an etiological factor [84], however, recurrence of UTI in children older than 5 years is associated with the presence of ES [84, 85].

Abnormal recruitment of the external anal sphincter during defecation or at call to stool is considered causative, in that it elicits concomitant urethral sphincter and pelvic floor co-contractions. Thus in both systems a functional obstruction to emptying is generated. In the case of the urinary system, high pressures generated by the detrusor muscle to overcome a decrease in urethral diameter can stimulate detrusor hypertrophy, detrusor overactivity, and lead to incompetence of the vesicoureteric junctions. In the early stages of defecation disorders, bowel emptying is incomplete, infrequent and poorly executed. As the dysfunction progresses stool quality becomes abnormal, the child develops distension of the rectum and descending colon, seems to lose normal sensation and develops fecal retentive soiling. If constipation was not present as a predisposing factor, it rapidly develops [82].

Children with elimination syndrome commonly complain of urinary incontinence, non-monosymptomatic nocturnal enuresis, recurrent urinary tract infections, imperative urgency to void (OAB) exceptional urinary frequency and on investigation are often noted to have poor voiding efficiency, vesicoureteric reflux, constipation, soiling, no regular bowel routine and infrequent toileting. The incidence of children with elimination syndrome and sub-clinical signs and symptoms is unknown.

Assessment follows the same process as for other aspects of pediatric bladder dysfunction, with the addition of a 2 week bowel diary and relevant symptom score. The inclusion of an ultrasound rectal diameter measure, either via the perineum or when assessing the bladder, has been shown to be discriminative for children with elimination syndrome. Urinary flow curve, perineal EMG and post void residual urine estimate, when considered in isolation, are not conclusive for the diagnosis of elimination syndrome. There is no evidence to suggest that anorectal manometry is warranted as a first line investigation in these children. Recently a symptom scale for DES has been developed providing objective assessment for diagnosis and quantification of severity [86].

Treatment

Treatment aims at assisting a child to become clean and dry in the short term, by retraining appropriate bladder and bowel awareness and teaching dynamic elimination skills. As bowel dysfunction is more socially isolating than urinary incontinence, and in the light of evidence that amelioration of underlying constipation can relieve bladder symptoms, most clinicians begin with treatment of the bowel. Strategies include disimpaction [if needed], prevention of stool reaccumulation, and post-prandial efforts to empty the bowel while maintaining optimal defecation dynamics. Once stools are being passed regularly, treatment focuses on teaching awareness of age
appropriate fullness in the bladder and training unopposed emptying (without straining or pelvic floor muscle recruitment), at pre-scheduled times. Pelvic floor awareness training and biofeedback therapy are integral.

There are currently no known studies of the efficacy of treatment in children with elimination syndrome. Several authors have evaluated the outcome of constipation management on bladder symptoms, however until last year the baseline characteristics of subjects were not described adequately enough to allow clear diagnosis of elimination syndromes [57, 87].

Level of evidence 4. Grade of recommendation C

V. PRINCIPLES OF NON PHARMACOLOGICAL TREATMENT FOR ALL DIFFERENT STATES

Treatment of the overactive bladder focuses on both the involuntary detrusor contractions and the child’s response to these. The initial treatment of daytime urinary incontinence involves a behavioral and cognitive approach. The child and parent(s)/caregiver(s) are educated about normal bladder function and responses to urgency. Voiding regimens are instituted and UTIs and any constipation are managed. Additional treatment involves pharmacotherapy, pelvic floor muscle relaxation techniques and biofeedback, either alone or in combination.

Although there are many studies reported in the literature assessing the effects of various forms of therapy on daytime incontinence and urinary symptoms, many of these are case series rather than being randomized or controlled trials. The paucity of studies evaluating basic standard therapy initiatives has precluded double-blinded trials of novel and multimodal interventions. Whilst clinically important benefits are commonly described, patient numbers, objective outcome measures and length of follow-up are sub-optimal.

The main objectives of treatment are to normalise the micturition pattern, normalise bladder and pelvic floor overactivity and cure the incontinence, infections and constipation. Traditional therapy for day-wetting children is cognitive and behavioural. Children learn to recognize the desire to void and to suppress this by normal central inhibition instead of resorting to holding manoeuvres [i.e. immediate voiding without postponement] to generate urethral compression. Children with dysfunctional voiding learn to initiate voiding with a completely relaxed pelvic floor and to pass urine in association with a detrusor contraction rather than via generation of abdominal pressure. Dietary changes and bowel regimens are used to treat the constipation [87]. Antibiotic prophylaxis may prevent recurrent UTIs, however, data to support this is limited.

“Bladder training” is used widely, but the evidence that it works is variable [50, 88]. Some authors contend that in less severely affected children a thorough explanation of the underlying causes and the expected progress of resolution is sufficient treatment in itself [37]. More active conventional management involves a combination of cognitive, behavioral, physical and pharmacological therapy methods. Common modes of treatment include parent and child reassurance, bladder retraining (including timed toileting), pharmacotherapy, pelvic floor muscle relaxation and the use of biofeedback to inhibit rises in detrusor pressure associated with urinary incontinence [25, 89-91]. Further treatment options include suggestive or hypnotic therapy and acupuncture. A combination of bladder training programs and pharmacological treatment, aimed specifically at reducing detrusor contractions, is often useful and sometimes necessary.

1. BLADDER REHABILITATION AND UROTHERAPY

Initial intervention for OAB and dysfunctional voiding uses a non-pharmacologic approach. This is often termed Urotherapy. Despite its use for many years there is no set format for urotherapy and many clinical studies utilize differing combinations of therapies, which makes it difficult to evaluate the results [25, 51, 90]. The aim of urotherapy is to normalize the micturition pattern and to prevent further functional disturbances. This is achieved through a combination of patient education, cognitive, behavioral and physical therapy methods.

A Danish report of the outcome of standard urotherapy in 240 children with daytime incontinence noted achievement of dryness in 126 children (55%). Alarm therapy has traditionally been used for the treatment of nocturnal enuresis and was recently used in management of daytime wetting. When a time watch was utilized as a reminder to void at regular intervals 70% of children became dry. An earlier study of a contingent alarm [which sounded when the child wets] versus a noncontingent alarm system (which sounded at intermittent intervals to remind the child to void) over 3 months in 45 children [92] was equally successful for the achievement of continence. Predictors for dryness included a low voiding frequency, larger volumes voided in relation to age-expected storage and fewer incontinent episodes per week [93].

Following a 3 month training programme, 42.8% of daywetting children were cured at 1 month, 61.9% by 6 months, and 71.4% by 1 year [94]. Allen et al [95] reported that urotherapy patients with good compliance with timed voiding were significantly more likely to improve their continence than those with poor
compliance. It has recently been highlighted however, that there is frequently conflict between school rules, routines and toilet facilities and the urotherapy programme components. Adaptive coping techniques added to urotherapy training may enhanced gains in dryness.

In children with OAB and dysfunctional voiding the pelvic floor muscles relaxation is impaired during voiding. Physiotherapy is concerned with re-training of specific muscle groups. Adjunctive physiotherapeutic input offers children different strategies to achieve pelvic floor relaxation during micturition.

Level of evidence 3. Grade of recommendation C

2. ADJUNCTIVE BIOFEEDBACK

Biofeedback is a technique in which physiological activity is monitored, amplified and conveyed to the patient as visual or acoustic signals, thereby providing the patient with information about unconscious physiological processes. Biofeedback may be utilized for the management of both filling phase (detrusor overactivity) and voiding phase (dysfunctional voiding due to pelvic floor muscle overactivity) abnormalities.

Biofeedback can help children to identify how to relax their pelvic floor muscles or recognize involuntary detrusor contractions.

Training with biofeedback can be used as a single treatment [96, 97], or in conjunction with a comprehensive rehabilitation program [98, 99]. It may be performed by a cystometrogram during which the child is taught to recognize and inhibit involuntary detrusor contractions by watching the pressure curve during cystometry. This is invasive and a time consuming process with limited use as a routine treatment.

More commonly pelvic floor muscle relaxation is taught through the use of EMG biofeedback and real-time uroflow. The child sits on a toilet with a flow transducer, watching both the flow curve and EMG on a computer display, and attempts to empty completely in one relaxed void. Ultrasound may be used to determine the post void residual and demonstrate complete emptying. Interactive computer games are commonly used to make biofeedback training more attractive to children [100, 101], however care should be taken that posture and muscle recruitment approximates that of the voiding position.

The results of biofeedback are commonly reported as case series rather than RCTs. Results are generally positive but overall may not be superior to high quality standard urotherapy. The group receiving adjunctive biofeedback in the Vasconcelos study [94] did not achieve greater continence rates at the study end point, although a greater proportion of subjects achieved earlier dryness. Furthermore, the post void residual volumes were significantly reduced in the biofeedback group compared to the standard therapy only group.

Long duration follow-up, whilst desirable, confounds results of intervention in children who are continually growing and maturing. Hellstrom et al report results of a 6 week bladder rehabilitation program inclusive of biofeedback and [90] and note that at 3 years 71% of the children with detrusor overactivity, 70% of those with dysfunctional voiding and 73% of those with a combined disturbance had a normal micturition pattern. The potential for bias from intercurrent events and interventions precludes statements about the efficacy of biofeedback alone.

Level of evidence: 3. Grade of recommendation C

3. CLEAN INTERMITTENT (SELF) CATHETERISATION

In children with an underactive detrusor, bladder emptying can be achieved with timed and double voiding. If this does not adequately empty the bladder clean intermittent self-catheterization (CISC) may be tried [102-104]. This requires careful guidance for both the child and the parents. Sometimes it is necessary to give the child a suprapubic catheter for a while and gradually prepare him/her to accept CISC. Once the infections have cleared and the child is continent it will become easier for both the parents and the child to accept. The frequency of CISC depends on the severity of the problem and may vary between four times a day and once a day before going to bed.

Level of evidence 4 Grade of recommendation C

4. NEUROMODULATION

Neuromodulation has been used in adults for a variety of lower urinary tract symptoms and has recently been applied in children. The use of transcutaneous stimulation with surface electrodes stimulating the sacral root (S3) has shown promising results, especially when tested as part of a randomized controlled trial [105]. Transcutaneous and percutaneous neuromodulation delivered over either the sacral outflow or peroneal region of the ankle at a frequency between 10-25 Hz, has proven a useful adjunctive treatment in children with an detrusor overactivity [22, 24, 25]. Intravesically stimulation can impact function of an underactive detrusor and potentially improve detrusor contractility and enhance bladder emptying [106, 107]).

Electrical current directly affects the central nervous system by artificially activating neural structures; facilitating both neural plasticity and normative afferent and efferent activity of the lower urinary tract. For children with structural abnormalities, for example imperforate anus, electrostimulation is one method of facilitating strength gains in the skeletal muscle and its fascial attachments. Treatment is particularly useful in patients with very little pelvic floor awareness
to stimulate muscle recruitment. Once neural efficiency has improved, training is augmented by active pelvic floor contractions.

A literature search revealed 10 reports of the use of neuromodulation in children with non-neurogenic bladder dysfunction. Only one of these studies was randomized and controlled, whilst the rest were case series. Use of neuromodulation in children with neurogenic LUT dysfunction has been reported in 6 studies, 2 of which were randomized controlled trials. From Table 2 it is clear that different modes of application have been trialed in mostly small series of children. There is minimal standardization of populations, application parameters or outcome measures. Thus evidence is largely drawn from low quality studies. Clearly neuromodulation in children warrants larger, controlled and randomized studies.

Reported changes with neuromodulation include: significantly increased bladder capacity, decreased severity of urgency, improved continence, and decreased frequency of urinary tract infection. Significant improvement in urodynamic parameters of bladder compliance, number of involuntary contractions, and bladder volume at first detrusor contraction have also been noted.

More recently the first reports on sacral nerve stimulation with implantable electrodes have been published. In a group of 20 patients between 8 and 17 years old followed prospectively, urinary incontinence, urgency and frequency, nocturnal enuresis and constipation were improved or resolved in 88% (14 of 16), 69% (9 of 13), 89% (8 of 9), 69% (11 of 16) and 71% (12 of 17) of subjects, respectively. Complications were seen in 20% of patients. [108] Due to the uncontrolled design the level of evidence is low. Experience from adults offered this treatment modality suggests future positive development in children to be likely.

Level of evidence: 4. Grade of recommendation D

5. ALARM TREATMENT

Alarm therapy has traditionally been used for the treatment of nocturnal enuresis and has rarely been used for daytime wetting. Only one randomised clinical trial has been published to establish the efficacy of this form of treatment. Halliday et al compared a contingent alarm which sounded when the child wets] with a noncontingent alarm system (which sounded at intermittent intervals to remind the child to void) [92]. Forty-four children participated in the study, 50% were assigned to each form of therapy for a 3 month period. Success was measured as 6 consecutive weeks without daytime wetting. Nine children in the non-contingent group and 6 children in the contingent group had persistent wetting. Although the risk of persistent wetting with the contingent alarm was 67%

6. CONCLUSION

Most clinical studies describe combinations of therapies rather than single interventions, which makes it difficult to evaluate the results. Physiotherapy and biofeedback both focus on the pelvic floor. Relaxation of the pelvic floor during voiding is essential for normal voiding and most of which patients are unable to relax their pelvic floor muscles. Biofeedback is important for showing the children the effect of their efforts. Most studies only state the clinical responses, and do not provide information on urodynamic parameters before and after treatment.

A ‘normal’ flow curve may not mean normal voiding if no information is provided on post-void residual urine. In most papers the inclusion and exclusion criteria are not clearly documented, and it may very well be that the more difficult patients with both storage and voiding dysfunction were included in the study population. Furthermore, different series may describe different groups of patients due to poor definitions and an inadequate classification system. In children with a suspected bladder outlet obstruction, endos-copic investigations should be performed. Most often the anatomic abnormality causing obstruction can be treated at the same time. In girls, a meatal web may cause a deflection of the stream upwards [causing stimulation of the clitoris and bulbocavernous reflex]. A meatotomy may cure this problem, though no information on the long-term effects is available [64].

VI. PHARMACOLOGICAL TREATMENT

Antimuscarinic therapy remains one of the common forms of therapy for the detrusor overactivity. Its use is predicated on the concept that parasympathetic mediated stimulation of muscarinic receptors in the bladder causes detrusor overactivity, which is responsible for the symptoms of detrusor overactivity. Antimuscarinic agents have been demonstrated to increase bladder capacity, increase bladder compliance and decrease detrusor contractions in neurogenic detrusor overactivity. Detrusor overactivity is believed to play a role in many children with functional incontinence, vesicoureteral reflux and

Tolterodine, a nonselective antimuscarinic, is currently being used for the treatment of detrusor overactivity in children with moderate to severe daytime incontinence [51].

Despite the frequent use of anticholinergic therapy, often in conjunction with a behavioral therapy regimen, the outcome of pharmacologic therapy for daytime urinary incontinence is “unpredictable and inconsistent” and there are few randomized studies available to assess drug safety and efficacy. Currently the pharmacologic therapy most widely used in children with detrusor overactivity is oxybutynin [111]. More recently, a long-acting formulation, Oxbutynin- XL, has been approved by the FDA for use in children [112]. Historically, oxybutynin use has been limited by its adverse effect profile with such side effects as dry mouth, constipation, facial flushing and CNS effects. The incidence of side effects seems to be dose-related, both for oral and intravesical administration [113].

The CNS effects are related to the ability for oxybutynin to cross the blood brain barrier. Oxybutynin- XL utilizes a novel delivery system, which results in absorption in the large intestine, thereby bypassing the first pass metabolism in the liver. This leads to a decrease in the amount of active metabolite [produced in the liver]: resulting in a more favorable tolerability profile. The delivery system requires an intact tablet and thus it cannot be cut or crushed to facilitate swallowing. Another method of delivery of oxybutynin is intravesical therapy. This method of delivery also avoids the first pass effect and leads to increased amounts of oxybutynin available compared to immediate release oxybutynin. Its use in the neurologically intact patient is limited by the need for catheterization [114].

There are only a few studies, none randomized and double blinded, assessing the efficacy of oxybutynin in detrusor overactivity in children. Curran et al, in a retrospective review assessed the efficacy of several agents, primarily oxybutynin in children with non-neurogenic detrusor overactivity, confirmed by urodynamic who were refractory to behavioral therapy. Some children were treated with combination therapy. Eighty percent had complete resolution or a significant improvement in their urinary symptoms. The authors noted an average time to resolution of symptoms of 2.7 years [range 0.2 to 6.6], however patients were not followed frequently [115]. In a recent study by Van Hoeck et al, holding exercises with and without oxybutynin showed no beneficial effect of adding oxybutynin [116].

Level of evidence: 3. Grade of recommendation C

Tolterodine, a nonselective antimuscarinic is currently being used for the treatment of detrusor overactivity in adults. It is the first antimuscarinic agent designed specifically for use in detrusor overactivity and is felt to be “bladder selective”. It’s affinity for the bladder compared to other organ systems leads to an improved tolerability profile. The chemical nature of tolterodine makes it less likely to penetrate the blood brain barrier, which is supported by EEG studies [117]. The delivery system of the long acting preparation is such that the capsule may be cracked and “sprinkled” on food. Tolterodine has not been approved for use in children but there are several studies, which evaluate its safety and efficacy in children with detrusor overactivity. Hjälmas reported the results of an open label, dose escalation study using immediate release tolterodine in 33 children [118]. Doses ranged from 0.5 mg po BID to 2 mg po BID for 14 days. The results demonstrated a 21% (23% with 2 mg po BID) mean decrease from baseline in micturition frequency and a 44% mean decrease from baseline for the number of incontinence episodes in children treated with 1 mg and 2 mg po BID. Bolduc et al reported on a prospective crossover study of 34 children followed for > 1 year who were crossed over from oxybutynin to tolterodine because of adverse effects with oxybutynin [119]. Detrusor overactivity was confirmed in 19/20 who had urodynamic studies performed prior to therapy. Children received either 1 mg or 2 mg po BID and the median treatment period was 11.5 months. Efficacy was assessed by a questionnaire and was comparable for oxybutynin and tolterodine. Sixty-eight percent noted a > 90% reduction in wetting episodes at 1 year and an additional 15% noted a > 50% reduction in wetting episodes. Fifty nine percent reported no side effects with tolterodine and 18% reported the same side effect as with oxybutynin, but felt it was less severe. Eight patients [24%] discontinued tolterodine.

Munding et al reported on the use of tolterodine in children with “dysfunctional voiding” manifested as daytime wetting, frequency or urgency [120]. There was no documentation of uroflow studies to make the diagnosis of “dysfunctional voiding” and from the symptoms these children appeared to have detrusor overactivity. Children were started on behavioral modification for 4-6 weeks and pharmacologic therapy was instituted if they failed or had only slight improvement with behavioral therapy. A minimum of 1 month’s follow-up was needed for inclusion, but the mean follow-up was only 5.2 months. Doses ranged from 1 mg po BID to 4 mg po BID. Assessment of results was made by telephone survey. Thirty three percent had > 90% reduction in daytime and nighttime wetting episodes and 60% had > 50% reduction. Four patients [13.3%] had side effects, constipation in 2, dry mouth in 1 and diarrhea in 1.

Reinberg et al performed an open label parallel group retrospective study of the efficacy and safety of immediate release and long acting tolterodine and extended release oxybutynin [121]. Children started
out with the lowest possible dose, 2 mg tolerodine and 5 mg oxybutynin and titrated up according to response and side effects. Children were arbitrarily assigned to therapy based on the formulary restrictions of the health plan and there was an uneven distribution of patients in the treatment groups. Final dose and duration of treatment were not noted. Study nurses asked about side effects and a voiding diary was used to assess efficacy. The authors concluded that extended release tolerodine \( [p < 0.05] \) and oxybutynin \( [p < 0.01] \) were more effective than immediate release tolerodine in improving urinary incontinence symptoms and that extended release oxybutynin was more effective than extended release tolerodine in resolving diurnal incontinence \( (p < 0.05) \). Long term tolerability of tolerodine extended release in a large pediatric population has been shown. [122]

Level of evidence: 3. Grade of recommendation C

One of the drugs which has been investigated in a randomized placebo controlled trial was tolerodine [123, 124]. Because of serious cardiac side effects tolerodine has been withdrawn from the market. Trospium chloride is another agent, which has been used in small series in children. It is currently available in a twice a day dosing formulation. In the adult population, there is a 16% intra-individual variability in bioavailability and 36% inter-individual variability. Absorption is affected by food intake. Trospium's chemical structure make it unlikely to penetrate the blood brain barrier as supported by EEG studies [117]. Lopez Periera et al evaluated the use of trospium in 62 children with documented detrusor overactivity and absence of 'detrusor sphincter dyssynergia' [125]. Children were randomly assigned to 10, 15, 20 or 25 mg of trospium administered in 2 divided doses or placebo. Fifty-eight children were evaluated. Response rates were assessed by incontinence episodes and urodynamic parameters. Overall, 32% had an excellent response, 42% a good response and 8% a fair response. Detrusor overactivity completely resolved in 35%. Four children had medication related adverse effects including headache, dizziness, abdominal cramps and dry mouth.

Level of evidence: 3. Grade of recommendation C

Like trospium, propiverine has been used in children, but results are variable and inclusion and outcome criteria were not in accordance with ICCS definitions making comparison with other studies difficult [19]. Recently a randomized, double-blind, placebo-controlled phase 3 trial with propiverine in children aged 5-10 yr was performed. Of 171 randomized children, 87 were treated with propiverine and 84 with placebo. The primary efficacy parameter showed a decrease in voiding frequency (-2.0 episodes for propiverine versus -1.2 for placebo; \( p = 0.0007 \)). Superiority could also be demonstrated for voided volume (31.4 vs. 5.1 ml; \( p < 0.0001 \)) and reduction in incontinence episodes (-0.5 vs. -0.2 episodes per d; \( p = 0.0005 \). This clinical trial showed superior efficacy of propiverine over placebo and good tolerability for the treatment of children suffering from DO and urinary incontinence. [126] This is the first study with level of evidence 1 that shows beneficial effect of anticholinergic therapy.

Level of evidence: 1. Grade of recommendation B/C (only single study)

**Botulinum toxin** is currently being used in children, mainly with neurogenic detrusor overactivity. Initial results seem promising, but more studies need to be done. In children, 300 Units on average, are injected in 30-40 spots [127]. The trigone should not be injected, as there is an increased risk of reflux developing. The results last about 6-9 months. Botulinum toxin is not registered for injection in the detrusor or the sphincter in children. It is off label used and further prospective studies are needed before general recommendation.

One prospective uncontrolled study by Hoebeke et al shows beneficial effects of botulinum toxin in 70% of children with therapy resistant detrusor overactivity. [128]. Injection of botulinum toxin is also possible into the external sphincter, but the results are more variable and last only 3-4 months [129]. Radotic et al describe excellent results in the treatment of dysfunctional voiding. In 20 children good results are described for 17 patients. [130] In a retrospective study by Franco et al, similar results are described in 16 children, however using a higher dosage [130, 131].

Level of evidence: 3. Grade of recommendation C

**Treatment of the overactive pelvic floor and sphincter** is much more difficult. Treatment with *alpha*-adrenergic blockade seems promising, but from the presented studies it is difficult to draw firm conclusions: as most series are small, not randomized and describe a mixed patient population [132-134].

In a more recent uncontrolled study by Donohoe et al a total of 26 patients with Primary Bladder Neck Dysfunction (20 males, 6 females, mean age 12.8 years) were treated with alpha-blockers. Mean average and maximum uroflow rates improved from 5.5 to 12.6 cc per second and from 10.3 to 19.7 cc per second, respectively, while mean EMG lag time decreased from 24.4 to 5.7 seconds and post-void residual urine volume from 98.9 to 8.9 cc [all \( p < 0.001 \)]. Mean follow-up was 31 months and no major adverse side effects were observed. [135] Further randomized controlled studies are needed to define the place of alpha-blockers.

Level of evidence: 3. Grade of recommendation C

Because there is much variability in presenting symptoms as well as the underlying pathology an individual approach is advisable: a step by step algorithm has been developed by Marschall-Kehrel,
E. NEUROGENIC DETRUSOR-SPHINCTER DYSFUNCTION

I. INTRODUCTION

Neurogenic detrusor-sphincter dysfunction (NDSD) can develop as a result of a lesion at any level in the nervous system. This condition contributes to various forms of lower urinary tract dysfunction which may lead to incontinence, urinary tract infections (UTIs), vesicoureteral reflux (VUR), and renal scarring. Surgery may be required to establish adequate bladder drainage, and potentially, if not managed properly, NDSD can cause renal failure, requiring dialysis or transplantation. Management of neurogenic detrusor sphincter dysfunction in children has undergone major changes over the years. While the use of diapers, permanent catheters, external appliances and various forms of urinary diversion were acceptable treatment modalities; these are now reserved for only a small number of resistant patients [1]. Initially long term renal preservation was the only aim of therapy and early diversion had the best long term results for preserving renal function. Despite some of the complications of ileal conduits and cutaneous urostomies requiring secondary surgery, this form of treatment offered the best outcome for renal preservation with socially acceptable continence [2].

Introduction of clean (self) intermittent catheterization revolutionized the management of children with NDSD. It, not only made conservative management a very successful treatment option, but also made surgical creation of continent reservoirs a very effective alternative with a good quality of life [3].

The most common cause of NDSD in children is neurospinal dysraphism and this condition presents with various patterns of detrusor-sphincter dysfunction within a wide range of severity. About 15 % of neonates with myelodysplasia have no signs of lower urinary tract dysfunction (LUTD) when initially studied [4]. However there is a high chance of progressive changes in the dynamics of the neurological lesion in time and even babies with normal LUT function at birth have a 1 in 3 risk of developing either detrusor sphincter dyssynergia or areflexia by the time they reach puberty [5]. Nearly 60 % of the neonates with neurospinal dysraphism may develop upper tract deterioration due to increased detrusor filling pressures and infections, with or without reflux [6,7].

As our understanding of urodynamic studies has evolved it allowed us to understand the nature and severity of the problems and administer management in a more rational manner differing according to the functional characteristics of each detrusor sphincter unit. Although the last quarter century has witnessed a remarkable progress in understanding pathophysiology, pathogenesis and the management of these children, the main goals of treatment remained the same i.e. the prevention of urinary tract deterioration and the achievement of continence at an appropriate age.

II. PRESENTATION OF NEUROGENIC DETRUSOR SPHINCTER DYSFUNCTION IN CHILDREN

Neurogenic detrusor sphincter dysfunction can develop as a result of a lesion at any level in the nervous system, including the cerebral cortex, spinal cord or the peripheral nervous system. The type and degree of detrusor sphincter dysfunction is poorly correlated with the type and spinal level of the neurologic lesion.
The closure of spinal canal in utero takes place in the caudal direction from the cephalic end and is completed at around 35 days of gestation. The failure of mesodermal in-growth over the developing spinal canal results in an open lesion most commonly seen in the lumbosacral area. The degree of this closure deficiency contributes to a variable presentation of neural injury with varying degrees of LUTD and lower extremity problems. Developmental anomalies that result from defects in neural tube closure are termed as myelodysplasia. This term includes a group of lesions like spina bifida occulta, meningocele, lipomyelomeningocele, or myelomeningocele.

Myelomeningocele is by far the most common defect seen and the most detrimental. Traumatic and neoplastic spinal lesions of the cord are less frequent in children [8].

The neurologic lesions produced by myelodysplasia are variable contingent on the neural elements that protrude within the meningocele sac. The bony vertebral level correlates poorly with the neurologic lesions produced. Additionally, different growth rates between the vertebral bodies and the elongating spinal cord can introduce a dynamic factor to the lesion and scar tissue surrounding the cord at the site of meningocele closure can tether the cord during growth [9-10].

In occult myelodysplasia the lesions are not overt and often with no obvious signs of neurologic lesion. The diagnosis of this condition has increased since the advent of spinal ultrasonography and magnetic resonance imaging. Yet, in nearly 90% of patients, a cutaneous abnormality overlies the lower spine and this condition can easily be suspected by simple inspection of the lower back. These cutaneous lesions can vary from a dimple or a skin tag to a tuft of hair, a dermal vascular malformation, or an obvious subdermal lipoma [8]. Alterations may be found in the arrangement or configuration of the toes, along with discrepancies in lower extremity muscle size and strength with weakness or abnormal gait. Back pain and an absence of perineal sensation are common symptoms in older children.

Incidence of abnormal lower urinary tract function in patients with spina bifida occulta is as high as 40%. Occult lesions may also become manifest with tethering of the cord later in life. This can lead to changes in bowel, bladder, sexual and lower extremity function.

Sacral agenesis is a rare congenital anomaly that involves absence of part or all of one or more sacral vertebrae. Perineal sensation is usually intact and lower extremity function is usually normal and the diagnosis is made when a flattened buttock and a short gluteal cleft is seen on physical examination. This lesion may produce variable degrees and patterns of LUTD.

Cerebral palsy patients may also present with varying degrees of LUTD usually in the form of overactive detrusor and wetting.

Imperforate anus is a rare anomaly and presents with a closed rectum that does not open onto anal skin verge. These children may present with accompanying spinal cord pathology. This is more common when the rectum ends above the pelvic floor muscles and they should undergo a MR imaging for detection. Early detection of this problem in imperforate anus patients is important to improve the child’s chance of maintaining healthy kidneys and becoming continent.

III. CLASSIFICATION: PATTERN RECOGNITION

The purpose of any classification system is to facilitate the understanding and management of the underlying pathology. There are various systems of classification of the neurogenic bladder.

Most systems of classification were formulated primarily to describe those types of dysfunction secondary to neurologic disease or injury. Such systems are based on the localization of the neurologic lesion and findings of the neuro-urologic examination. These classifications have been of more value in adults as neurogenic lesions are usually due to trauma and more readily identified.

In children the spinal level and extent of congenital lesion is poorly correlated with the clinical outcome. Indeed, severe detrusor sphincter dysfunction has been associated with minimal bony defects. Various possible neuropathologic lesions of the spinal cord including syringomyelia, hydromyelia, tethering of the cord and dysplasia of the spinal cord are the causes of these disparities and they may actually extend several segments above and below the actual site of the myelomeningocele. Therefore urodynamic and functional classifications have been more practical for defining the extent of the pathology and planning treatment in children.

The detrusor and sphincter are two units working in harmony to make a single functional unit. The initial approach should be to evaluate the state of each unit and define the pattern of bladder dysfunction. Determined by the nature of the neurologic deficit, they may be either in an overactive or in an inactive state. The detrusor may be overactive with increased contractions, with a diminished bladder capacity and compliance or be inactive with no effective contractions; the bladder outlet (urethra and sphincter) may be independently overactive causing functional obstruction or paralyzed with no resistance to urinary flow leading stress incontinence.

These conditions may exist in any combination [9-14].
Urodynamic evaluation (preferably in combination with fluoroscopy) makes pattern recognition possible. Four major types are usually used to describe the detrusor-sphincter dysfunction:

1. Detrusor overactivity with overactivity of the sphincter (mostly dyssynergia),
2. Detrusor overactivity with normal or underactivity of the sphincter,
3. Detrusor underactivity with sphincter overactivity
4. Detrusor underactivity with sphincter underactivity.

Besides these 4 patterns, one can use the ICS classification: overactive detrusor, underactive detrusor, overactive sphincter and underactive sphincter. Sometimes this is more helpful, as the detrusor may be overactive during filling, but underactive during ‘voiding’.

The urodynamic investigation is considered normal when there is suitable age matched capacity, good compliant bladder with no overactivity and normal innervation of the sphincter with normal sacral reflexes and an increase in pelvic floor activity during filling and no activity during voiding. Presence of overactivity during filling with or without decreased capacity and compliance is usually seen when there is upper motor neuron lesion and this is usually accompanied by overactivity of the sphincter and failure to relax during voiding. A lower motor neuron lesion is considered when the detrusor contractions are weak or lost and the sphincter is underactive. Urodynamic investigations make it possible to establish a management plan for each individual patient.

Evidence level 3. Grade of recommendation B

For the very young child the combination of an overactive detrusor and sphincter is potentially dangerous because of the high intravesical pressures, which will put the upper tract at risk (vesicoureteral reflux and hydronephrosis), whereas an underactive detrusor and paralysed sphincter is relatively safe, providing a low-pressure reservoir [15-17].

Level of evidence: 2

IV. MANAGEMENT

The main aim in management of NDSD in children is to ensure and maintain a reservoir with normal age-matched capacity and good compliance that can be emptied completely at low pressures and at regular intervals.

In the first years of life the kidneys are highly susceptible to backpressure and infection. In this period emphasis will be on documenting the pattern of neurogenic detrusor- sphincter dysfunction and assessing the potential for functional obstruction and whether or not there is vesicoureteral reflux [17,18]. Ultrasound studies and a VCUG or video-urodynamics to exclude reflux have to be performed soon after birth. Measurement of residual urine during both ultrasound and cystography should also be done. These studies provide a baseline for the appearance of the upper and lower urinary tracts, can facilitate the diagnosis of hydrourephrosis or vesicoureteral reflux, and can help identify children at risk for upper urinary tract deterioration and impairment of renal function.

A urodynamic evaluation can be done after some weeks and needs to be repeated at regular intervals, in combination with evaluation of the upper tracts [19].

Level of evidence 3. Grade of recommendation: B

Overwhelming experience gained over the years with early management of neurogenic bladder in infants has lead to a consensus that children do not develop upper tract deterioration when managed early with CIC and antimuscarinic medication [19-22]. Therefore initial treatment should consist of oral or intravesical antimuscarinic drugs in combination with clean intermittent catheterisation, to start soon after birth in all babies and especially in those with signs of possible outlet obstruction [23-27].

Level of evidence 2. Grade of recommendation: B

The early initiation of intermittent catheterization in the newborn period, makes it easier for parents to master it and for children to accept it as they grow older [28,29].

With early management not only are upper tract changes less, but also bladders are better protected and incontinence rates are much lower.

It has been suggested that increased bladder pressures due to detrusor sphincter dyssynergia cause secondary changes of the bladder wall. These fibroproliferative changes in the bladder wall may cause further loss of elasticity and compliance: resulting in a small non-compliant bladder with progressively elevated pressures. It is believed that early institution of intermittent catheterization and anticholinergic drugs may prevent this in some patients [30-32].

Level of evidence 3

Retrospective evaluation of patients has also shown that significantly fewer augmentations were required in patients with early start of CIC [23,24].

Level of evidence 4

The main disadvantage of CIC is bacteriuria which is found in 60% of the patients, but symptomatic UTIs are less common (20%) with CIC when compared to the group without CIC (40%). Since the risk of reflux is similarly lower with CIC the renal scar rates are
lower. CIC alone when begun in infancy can achieve continence at a rate of 60%. When combined with newer and more potent antimuscarinic drugs continence rates approach 75-80% [33-36].

At present oxybutynin, tolterodine, trospium and propiverine are the most frequently used anti-cholinergic drugs to treat detrusor overactivity in children. Some clinical studies are available, but no randomised placebo controlled studies have been performed [31,37-41].

A prospective controlled trial evaluating trospium in children reports that trospium is effective and safe in correcting detrusor overactivity in children but this study does not include patients with a neurogenic bladder [42].

Two different forms of tolterodine have been investigated in children with neurogenic bladder and extended release formulation of tolterodine is found to be as efficient as the instant release form with the advantages of being single dosage and less expensive [43].

Level of evidence 3. Grade of recommendation: B

Use of medication in children with neurogenic bladder to facilitate emptying has not been studied well in the literature. Few studies investigating the use of alpha-adrenergic blockade in children with neurogenic bladder report good response rates but they are non-controlled studies and long-term follow-up is lacking [44-46].

Level of evidence 4

Use of intravesical oxybutynin in children with poorly compliant neurogenic bladder has been investigated in some studies and incontinence has been shown to be improved significantly in most studies, with "dry and improved" rates ranging from 61% to 83% [47]. Use of lidocain intravesically also has been shown to be effective to improve bladder capacity and compliance and decrease overactivity in children with neurogenic bladder [48]. None of these studies are randomized controlled trials and evidence available is insufficient to strongly recommend this therapy. There are no data available on long term use.

Level of evidence 3. Grade of recommendation: C

In neurogenic bladders that are refractory to antimuscarinics and still remain to be in a small capacity and high-pressure state, injection of botulinum toxin into the detrusor has been introduced to be a new treatment alternative [49-50]. Initial promising results in adults have also initiated its use in children. So far pediatric studies have been open-label studies and prospective controlled trials are lacking [51-53]. Injection of botulinum toxin in therapy resistant bladders seems to be an effective and safe treatment alternative. This treatment seems to be more effective in bladders with evidence of detrusor overactivity, while non-compliant bladders without obvious detrusor contractions are unlikely to respond to this treatment. Dosage in children should be determined by body weight, with caution regarding total dose if also being used for treatment of spasticity, and minimum age [54-57].

Level of evidence 3. Grade of recommendation C

In a single study urethral sphincter botulinum-A toxin injection has been shown to be effective in decreasing urethral resistance and improve voiding. The evidence is still too low to recommend its routine use in decreasing outlet resistance, but it could be considered as an alternative in refractory cases [58].

Intravesical electrical stimulation of the bladder has been introduced more than four decades ago and it has been tested in some open clinical trials in children since 1984. Its practice is limited to a few centres who have reported varying results. The nature of this type of treatment (time consuming and very dedicated personal) does not make it attractive for the majority of treatment centres [59].

Intravesical electrical stimulation of the bladder

Level of evidence 3. Grade of recommendation C

Children with neurogenic bladder also have disturbances of bowel function. Fecal incontinence in these children is frequently unpredictable; it is related to the loss of lower bowel sensation and function, altered reflex activity of the external sphincter and the consequent failure to fully empty the rectum [60].

The majority of children with a neurogenic bladder also have constipation and this is managed most commonly with laxatives, such as mineral oil, combined with enemas to facilitate removal of bowel contents. A regular and efficient bowel emptying regimen is often necessary to maintain fecal continence and this may have to be started even at a very young age. With antegrade or retrograde enemas, the majority of these children's constipation can be managed and they may attain some degree of fecal continence [61-65].

Level of evidence 3. Grade of recommendation C

Biofeedback training programs to strengthen the external anal sphincter have not been shown to be more effective than a conventional bowel management program in achieving fecal continence [66]. Electro-stimulation of the bowel may also offer a variable improvement in some patients [67].

Level of evidence 3. Grade of recommendation D

Biofeedback training programs

Urinary tract infections are common in children with neurogenic bladders. In the absence of reflux, patients with urinary tract infections should be treated if symptomatic. There is strong evidence not to prescribe antibiotics to patients with bacteriuria without clinical symptoms [68-71]. Bacteriuria is seen in more than
half of the children on clean intermittent catheterization (CIC), but patients who are asymptomatic do not need treatment.

Level of evidence 3. Grade of recommendation B

Patients with vesicoureteral reflux and urinary tract infection often should be placed on prophylactic antibiotics to reduce the incidence of pyelonephritis, which can potentially lead to renal damage [72].

Sexuality, while not an issue in childhood, becomes progressively more important as the patient gets older. This issue has historically been overlooked in individuals with myelodysplasia. Patients with myelodysplasia have sexual encounters, and studies indicate that at least 15-20% of males are capable of fathering children and 70% of females can conceive and carry a pregnancy to term. Therefore counseling patients regarding sexual development is important in early adolescence.

Children with a good response to antimuscarinic treatment and an overactive sphincter may be continent in between catheterizations. Bladder pressure and (normal) development of the upper tracts will determine whether additional treatment is necessary.

Children with therapy resistant overactivity of the detrusor, or small capacity and poor compliance will usually need additional surgical treatment such as bladder augmentation.

Children with detrusor overactivity but with underactive sphincters will be in a better shape in terms of protecting their upper tracts, but they may be severely handicapped because of their incontinence. Initial treatment will be intermittent catheterization (as it may reduce the degree of incontinence and offers a much better control over urinary infections) in combination with antimuscarinic drugs. At a later age the outlet resistance has to be increased in order to render them continent [73]. There is no medical treatment of proven efficacy that increases bladder outlet resistance. Alpha-receptor stimulation of the bladder neck has not been very effective. Surgical procedures need to be considered for maintaining continence [75-77].

It is important to establish adequate bowel emptying before attempting to correct bladder dysfunction surgically or medically.

Patients with a neurogenic bladder require lifelong supervision and monitoring of renal function is extremely important. Periodic investigation for upper tract changes, renal function and bladder status is mandatory. Therefore repeat urodynamic studies are needed more frequently at younger ages and less frequently at later ages. A repeat urodynamic study is warranted when the patient has a change in symptoms or undergoes any neurosurgical procedure.

In case of any apparent changes both in the upper and lower urinary tract or any changes of neurological symptoms, a more detailed examination including urodynamics and MRI of the spine is indicated. Renal failure usually progresses slowly but may occur with startling rapidity in these children.

F. SURGICAL MANAGEMENT OF URINARY INCONTINENCE IN CHILDREN

Intermittent catheterization and drug therapy are usually sufficient in the majority of cases for maintaining continence and preserving upper tracts. Surgical procedures should be considered if conservative measures fail to achieve continence between catheterizations or preserve upper tracts.

Surgical intervention is required for congenital and acquired diseases interfering with the function of the storage function of the bladder, the sphincter mechanisms or which bypass normal sphincter mechanisms. A plethora of different surgical procedures has been proposed to maintain continence by using different mechanisms. Various procedures using different mechanisms for maintaining continence may be used in the same patient.

In many cases measures such as intermittent catheterization and drug therapy are needed in addition to surgery since most of the surgical procedures can achieve ‘dry-ness’, but rarely restore normal voiding.

Patients with bladder neck incompetence pose a real challenge and require a different approach. All surgical procedures to “reconstruct” the bladder neck have one thing in common; an obstruction is created to enhance bladder outlet resistance. Even if successful, normal spontaneous voiding with low pressures without external help is not possible in most patients. Considering the long-term outcome, it may be better not to void spontaneously when bladder outlet resistance is increased because longstanding outlet resistance may cause secondary changes of the bladder wall.

The rarity and complexity of the conditions associated with congenital incontinence in children precludes the establishment of higher levels of evidence because of the rarity and spectrum of the pathology. Results are highly dependent on the skills of the individual surgeon. Therefore graded recommendations for specific procedures cannot be provided. There are no randomized controlled trials (level 1 and 2 evidence). Based on the available literature most studies have a level of evidence 3-4 and grade of recommendation C or D.
I. ABNORMALITIES OF STORAGE

1. BLADDER EXSTROPHY

The incidence of bladder exstrophy is 1 per 30,000 live births. (male to female ratio 2:3.1-6.1). Closure of the bladder is generally performed within the first days of life; pelvic osteotomies facilitate reconstruction of the abdominal wall and may improve ultimate continence [1,2,3]. Some children will develop more or less normal capacities. Even after successful closure there will be some children who end up with a poorly compliant small bladder requiring later bladder enlargement or urinary diversion (ureterosigmoidostomy) [4,5,6,7]. Patients with a good bladder template who develop sufficient bladder capacity after successful primary closure and epispadias repair can achieve acceptable continence without bladder augmentation and intermittent catheterization [8,9,10].

Reconstruction of the bladder neck can either be done at the time of bladder closure or at a later stage. Early reconstruction may facilitate normal bladder function, but should be attempted only at centers experienced with such surgery [11,12]. Continence rates vary from center to center and may range between 43 to 87% [13,14].

2. CLOACAL EXSTROPHY

The incidence of cloacal exstrophy is 1 per 200,000 live births. This is a much more complex deformity that requires an individual approach. Most of these children have anomalies of the nervous system, upper urinary tract and gastrointestinal tract that can adversely affect urinary tract reconstruction. Before reconstructive procedures are considered, an extensive evaluation has to be carried out.

3. AGENESIS AND DUPlication of THE BLADDER are both extremely rare. Agenesis is rarely compatible with life. In bladder duplication other associated congenital anomalies are often observed such as duplication of external genitalia or lower gastrointestinal tract.

4. ABNORMAL STORAGE FUNCTION in combination with other anomalies is usually caused by a neurologic deficit or is secondary to bladder outlet obstruction. Sacral anomalies are frequently seen with cloacal malformations and imperforate anus [15, 16, 17,18].

Posterior urethral valves may cause severe hypertrophy of the detrusor with a small poorly compliant bladder [19,20].

Unfortunately, following valve ablation, these bladders may not return to normal function [21,22].

II. ABNORMALITIES OF SPHINCTERIC FUNCTION

1. EPISPADIAS (without exstrophy): incidence 1 in 60,000 live births, male to female ratio: 3-5:1. All patients with bladder exstrophy also have complete epispadias.

In male patients with complete epispadias and all females the sphincteric mechanism is deficient and the child has complete incontinence. Reconstruction of the bladder neck is either performed at the time of epispadias repair or at a later stage. The bladder function may or may not be normal in these patients [23,24].

2. MALFORMATION OF THE UROGENITAL SINUS occurs exclusively in phenotypic females. The incidence is 1 in 50,000 live births. In patients with classical urogenital sinus or cloaca, the sphincteric mechanism is insufficient and due to associated neurological abnormalities the bladder function may be abnormal.

3. ECTOPIC URETEROCELES protruding into the urethra may be responsible for a partial defect of the bladder neck. In these rare cases, sphincteric incontinence may be the result.

4. SPHINCTER ABNORMALITIES secondary to spina bifida and other neurologic disorders are of particular importance. The sphincter may be overactive (like in detrusor sphincter dyssynergia) or underactive. Overactivity of the sphincter causes secondary changes of the bladder wall (increased collagen type III with decreased elasticity and compliance). Continence is usually achieved with antimuscarinic drug treatment or bladder augmentation (using the overactivity of the sphincter for continence). In cases of incompetence of the sphincter, different types of surgical intervention are possible to enhance the sphincteric mechanism. In general all patients with a neurogenic bladder need Clean Intermittent Catherization (CIC). In patients bound to a wheelchair a suprapubic channel can be created (Mitrofanoff) to facilitate CIC.

5. BYPASS OF SPHINCTERIC MECHANISM

a) Ectopic Ureter is an abnormally located terminal portion of the ureter. Instead of the ureter opening in the bladder, it opens in the urethra, vagina, or uterus. Ectopic ureters occur more frequently in girls and are commonly part of a duplex system: in girls the ectopic orifice of the upper pole moiety drains into the urethra below sphincteric level or vaginal vestibule, thus causing incontinence [25].

When the ectopic ureter represents a single system, the trigone is usually asymmetrical and not well developed. These children may suffer from continuous
incontinence as well as a deficient sphincteric mechanism: this is particularly true in bilateral ectopia of single systems. In these patients the trigone and bladder neck are functionally abnormal and treatment includes surgical reconstruction of the bladder neck. When the upper pole ureter opens in the mid or distal female urethra or outside the urinary tract (i.e. vulva or vagina) incontinence results. Upper pole nephrectomy or ipsilateral uretero-ureterostomy solves the problem.

A rare and a challenging condition is when there are bilateral ectopic ureters. Since bladder is hypoplastic in these children achieving normal bladder capacity and function may require additional procedures to ureteric reimplantation [26,27,28].

b) Urethral duplications

Most patients with urethral duplication will leak urine from the abnormal meatus during voiding. In rare cases, when the urethra bypasses the sphincteric mechanisms, continuous leakage may be present [29].

c) Vesicovaginal fistulas

Acquired fistulas may be traumatic or iatrogenic, following procedures on the bladder neck.

III. EVALUATION AND DIAGNOSIS

A detailed history and physical examination in combination with imaging studies and urodynamic evaluation are the corner stones for successful management. Imaging studies are essential to define the anatomical abnormalities responsible for and associated with incontinence. Ultrasonography of bladder and kidneys as well as a voiding cystourethrogram are the basic studies. In infants and small children sacral ultrasonography can demonstrate normal position and mobility of the spinal cord. The scout film of the contrast voiding cystourethrogram (VCUG) assesses the lower spine and sacrum, intersymphyseal distance, and fecal retention. The contrast films will show bladder configuration, presence of vesicoureteral reflux, incomplete voiding, bladder neck competence, urethral anatomy, and vaginal reflux. Occasionally, an intravenous urogram will provide the clearest assessment of the urinary tract. MRI and CT scanning can be helpful in defining spinal abnormalities as well as congenital abnormalities in the urinary tract.

In addition to imaging studies, urodynamic studies (cystometrography and when needed electromyography of the sphincters and urinary flow studies) are useful for all patients with neurogenic incontinence, and after surgery in some cases of bladder exstrophy and after posterior urethral valves resection to help define the mechanism of any continued incontinence. However in many patients much useful information on the function of the lower urinary tract can be obtained with very basic studies including ultrasound and cystometry.

IV. INDICATIONS FOR SURGICAL PROCEDURES TO CORRECT URINARY INCONTINENCE

1. STORAGE FUNCTION

Reduced bladder capacity is the main indication for simple bladder augmentation. Reduced capacity can be congenital (bilateral single ectopic ureters, bladder exstrophy) or caused by previous surgery e.g. bladder neck reconstruction in exstrophy patients, where a part of the bladder is used to create an outlet resistance. Other indications are low functional bladder capacity as it may be present in neurogenic bladder (meningomyelocele) or bladder scarring from previous surgery or obstruction. Bladder scarring from bilharzia remains common in endemic areas and is increasingly common with immigration to the developed world. In all such cases surgery is indicated when conservative treatment has failed.

Several studies suggest that aggressive early intervention with CIC and anticholinergic therapy improves bladder compliance and may protect children from augmentation surgery [30,31].

Yet in a recent survey has reported that there has been no change in augmentation rates during the last 5 years: they demonstrated significant interinstitutional variability [32].

2. SPHINCTER FUNCTION DURING STORAGE

Most of the diseases in childhood requiring surgical repair for incontinence not only have an influence on bladder capacity but also on sphincter function. Conservative measures to improve sphincter function have limited value and surgery is required in many cases. There are different surgical options; either to increase outlet resistance or to create or implant a new sphincter mechanism. In neurologically normal patients such as classic exstrophy patients, early anatomic reconstruction may allow ‘normal’ bladder and sphincter function. Sling procedures are indicated when the residual sphincter function is not sufficient to avoid incontinence. This may be the case in patients with neurogenic bladder disturbances and urethral incontinence. If there is no residual sphincter function or outlet resistance, an artificial sphincter may be required. Primary urinary diversion (rectal reservoir/continent stoma) offers an alternative solution to this problem.

3. PROCEDURES TO BYPASS THE SPHINCTER

If bladder outlet surgery fails or urethral catheterization is not possible, a continent stoma may be constructed.
Some patients prefer catheterizing through a continent stoma rather than through the sensate urethra. The continent stoma (Mitrofanoff principle) may be combined with bladder augmentation and/or bladder neck reconstruction or closure. An alternative to such procedures would be the use of the anal sphincter for urinary continence with the use of colon as the storage reservoir.

**V. BLADDER RESERVOIR CONSTRUCTION**

1. **URETEROSIGMOIDOSTOMY**

This type of continent urinary reconstruction may be utilized in reconstruction for bladder extrophy, an incontinent urogenital sinus or the traumatic loss of the urethral sphincter. As this reconstruction is totally dependent on the normal function of the anal sphincter, contraindications include incompetence of the anal sphincter, anal prolapse, previous anal surgery, and irradiation. Because of the potential for electrolyte resorption, renal insufficiency is also a contraindication.

Low pressure rectal reservoirs are superior to simple ureterosigmoidostomy because the augmented or reconfigured rectal bladder achieves lower pressure storage and accordingly, enhances continence.

There are two techniques which have been utilized:

- **a) The augmented rectal bladder** in which the rectosigmoid is opened on its antimesenteric border and augmented by an ileal segment. The sigmoid may be invaginated to form a nipple valve to avoid reflux of urine into the descending colon and thus to minimize metabolic complications.

- **b) The sigma-rectum pouch** (Mainz pouch II) in which there is an antimesenteric opening of the rectosigmoid and a side to side detubularization anastomosis. Ureteral reimplantation of normal sized ureters is by a standard submucosal tunnel (Goodwin, Leadbetter). If the ureter is dilated the technique utilizing a serosa lined extramural tunnel may be more appropriate [33,34].

As reported by D’elia et al, the results of these low-pressure rectal reservoirs are excellent with day and night continence better than 95% and complications related to the surgical procedure range from 0 -10% with the sigma-rectum pouch to 34% for the augmented rectal bladder [35]. Late complications for the sigma-rectum pouch range from 6-12.5% and the late complications for the augmented rectal bladder are 17%. Early complications include pouch leakage while late complications are mainly related to the ureteral implantation into the bowel and pyelonephritis. Metabolic acidosis also occurs (69% of the patients had a capillary base excess of −2.5 mmol/L and used oral alkalinizing drugs to prevent hyperchloreaemic acidosis).

Periodic follow-up studies are important to check the upper urinary tract and prevent metabolic acidosis. Due to the risk of malignancy at the ureterointestinal anastomosis, colonoscopy should be performed annually beginning at postoperative year 10 [30, 36,37,38,39].

Level of evidence : 3. Grade of recommendation: B

2. **BLADDER AUGMENTATION, BLADDER REPLACEMENT AND CONTINENT URINARY DIVERSION, USING Intestine**

The indication for bladder augmentation, replacement of the bladder, or the creation of a continent urinary diversion, is either the morphological or functional loss of normal bladder function. The main goal of this surgery is to relieve high pressure and low capacity of the urinary bladder and create a new reservoir with low storage pressures that can be emptied periodically. It is particularly important that the patients understand that spontaneous voiding will not be possible after such surgery and life long intermittent catheterization will be required.

Before deciding on what type of procedure can be performed some significant factors must be addressed. These are:

1. Physical and mental capacity of the patient to do intermittent catheterization.
2. Previous surgery (on urinary tract and bowel)
3. Renal function status (including acid base state)
4. Absence or presence of reflux
5. Outlet resistance
6. The need for a catheterizable channel

The different technical approaches to bladder augmentation or replacement are dependent on the clinical presentation of the patient:

- a simple bladder augmentation using intestine may be carried out if there is any bladder tissue, a competent sphincter and/or bladder neck, and a catheterizable urethra,
- an augmentation with additional bladder outlet procedures such as bladder neck reconstruction or other forms of urethral reconstruction are required when both the bladder and outlet are deficient. This occurs most commonly in spina bifida or bladder extrophy. It must be appreciated that bladder outlet procedures may complicate transurethral catheterization.
- augmentation with surgical closure of the bladder neck may be required primarily, or as a secondary procedure in certain rare clinical situations. In this situation a continent stoma will be required. Most urologists however prefer to leave the bladder neck and urethra patent as a safety precaution:
when the bladder is very full leakage will occur and it allows transurethral manipulations such as catheterization if the continent reservoir cannot be emptied through the suprapubic catheterizable channel.

• an augmentation with additional continent stoma is utilized primarily following failure of previous bladder outlet surgery. It is advisable also when it can be anticipated that there will be an inability to catheterize transurethrally. An abdominal wall continent stoma may be particularly beneficial to the wheelchair bound spina bifida patient who often can have difficulty with urethral catheterization or who is dependent on others to catheterize the bladder. For continence with augmentation and an abdominal wall stoma, it is essential that there be an adequate bladder outlet mechanism to maintain continence.

• total bladder replacement in anticipation of normal voiding in children is very rare, as there are infrequent indications for a total cystectomy, with preservation of the bladder outlet and a competent urethral sphincter. This type of bladder replacement is much more common in adult urologic reconstruction.

The main contraindications are the inability of the patient to be catheterized, or perform CIC him or herself and the anticipation of poor patient compliance. When there is reduced renal function generally with a creatinine above 2 mg/dl or a creatinine clearance below 40 ml/min/1.73 m², there is a relative contraindication to the use of ileum or colon because of metabolic acidosis secondary to reabsorption. The stomach with its excretion of acid may be used with a low creatinine clearance possibly in preparation for transplantation. It is, however, not wise to use stomach in any voiding patient or one with any questions of an incompetent bladder outlet because of the severe skin irritation that the acid urine may produce (hematuria-dysuria syndrome).

**a) Which intestinal segment should be utilized?**

1. **STOMACH**

Stomach has limited indications primarily because of the complications that have been seen. It is the only intestinal segment suitable in patients with significantly reduced renal function [40,41,42].

Additionally, when no other bowel may be available, as after irradiation or there exists the physiology of a short bowel syndrome, as in cloacal extrophy, this may be the only alternative remaining.

2. **ILEUM / COLON**

Clinically these two intestinal segments appear to be equally useful. In children, sigmoid colon is widely used except in those who have been treated for imperforate anus. Use of the ileocecal region can be associated with transient and sometimes prolonged diarrhea. This segment should be avoided in patients with a neurogenic bowel such as in myelomeningocele or who have been subject to previous pelvic irradiation. If the ileocecal valve must be used, it can easily be reconstructed at the time of performing the ileo-colonic anastomosis. The ileum can be satisfactorily used for bladder augmentation: however because of its smaller diameter a longer segment of ileum is required to create a comparable reservoir to that created from colon. Colon has greater flexibility for ureteral implantation and construction of a continent catheterizable channel.

3. **GENERAL PRINCIPLES**

There are several important principles for bladder augmentation and replacement that should be respected:

• use the minimal amount of bowel and if available use hindgut segments or conduits from previous surgical procedures,

• a low-pressure large capacity reservoir is essential. This requires detubularization of any intestinal segment used.

• for colonic reservoirs a sigmoid segment of 20-30 cm is generally satisfactory. A slightly longer segment of ileum is generally used. The length of the segments can be scaled down in smaller children. Care should be taken not to use more than 50 to 60 cm of ileum in adolescents and comparable lengths in younger children because of reduction of the intestinal resorptive surface.

• the jejunum is contraindicated in intestinal reconstruction of the urinary tract because of its metabolic consequences (hyponatremia, hypercalciemia, and acidosis).

• it is wise to strive to achieve an anti-reflux ureteral anastomosis into the reservoir to avoid the potential for reflux and consequently ascending infection: in high pressure bladders with reflux the reflux usually disappears spontaneously following augmentation [43,44].

• a reliable continence mechanism (continent urinary outlet) must be assured.

• because of the risk of stone formation only resorbable sutures and staples should be used in bladder augmentation and reservoir construction.

4. **BLADDER AUGMENTATION TECHNIQUES**

i. In **gastric augmentation** a 10-15 cm wedge-shaped segment of stomach is resected. Most commonly this is based on the right gastroepiploic artery but can be based on the left one as an alternative. The segment is brought down to the bladder easily in the retroperitoneal space along the great vessels.

ii. When using large or small bowel the segment to
be utilized is opened on the antimesenteric border and detubularized prior to anastomosis to the bladder remnant. The anastomosis of the intestinal segment to the bladder remnant and to itself is usually carried out in one running layer of inverting absorbable sutures.

iii. The techniques for urinary diversion with continent stoma (Mainz pouch, Indiana pouch, Kock pouch) are covered in the chapter on urinary diversion in adults [45,46,47].

Currently, augmentation cystoplasty is the standard treatment for low capacity and/or low compliance bladders secondary to neurogenic, congenital and inflammatory disorders. Due to the relatively high morbidity of conventional augmentation there is renewed interest in alternative methods [48, 49, 50,51,52,53]. These alternative techniques try to avoid the contact between urine and intestinal mucosa and include gastrocystoplasty, bladder auto-augmentation, seromuscular augmentation, alloplastic or biodegradable scaffolds graft with autologous urothelium developed in cell culture, and ureterocystoplasty.

5. SEROMUSCULAR PATCH

To overcome one of the major disadvantages of a conventional augmentation that is mucus formation several techniques have been developed to use intestinal segments free of mucosa. The first attempts at using intestinal segments free of mucosa to improve bladder capacity resulted in viable seromuscular segments covered with urothelial mucosa [67,68]. The intense inflammatory response and shrinkage observed in the intestinal segment discouraged its use in humans [69]. Further attempts consisted of using the association between demucosalized intestinal segments and auto-augmentation. In the initial model using sheep, the animals tolerated the demucosalization procedure poorly, reflected by inflamed, hemorrhagic colonic segments in the animals sacrificed within one month. In addition, colonic mucosa regrowth occurred in one third of the animals [70]. Follow-up studies in a dog model with previously reduced bladder capacity suggested that the contraction of the intestinal patch in seromuscular enterocystoplasty can be avoided by the preservation of both the bladder urothelium and lamina propria, together with the submucosa and muscularis mucosa of the intestinal patch [71,72]. This form of bladder augmentation was shown to prevent absorption of toxic substances like ammonium chloride [73]. Other authors using the same technique to line de-epithelialized gastric patches in the mini-pig model found it useless due to the fibrotic changes and decreased surface of the patch [74].

The initial experience in treating humans with colocystoplasty lined with urothelium were reported by Gonzales and Lima who developed a slightly different technique independently [75,76]. Bladder capacity increased significantly while bladder pressures decreased. Biopsies demonstrated urothelium covering the augmented portion of the bladder in the majority of cases.

Longer term follow-up is now available and although the results are very encouraging, the results seem to be highly operator dependent and the way the mucosa is removed seems to be a crucial factor. Lima et al do no longer preserve the bladder urothelium and use a silicone balloon to prevent the augmented segment from contracting (they remove the balloon after 2 weeks: urine is diverted using ureteral stents): in 123 patients no ruptures were found and only 10% were regarded as failures [77].

Gonzalez et al found seromuscular colocystoplasty in combination with an artificial urinary sphincter successful in 89% of their patients and that it effectively achieves continence with no upper tract deterioration, and concludes that this is their preferred method of augmentation when adverse bladder changes occur after implanting the AUS [78].

Although more authors have now reported their results it still remains a more complex form of augmenting the bladder. This procedure has not receive a general acceptance among the paediatric urological community but is being done in some designated centres [79, 80, 81,82]. A recent comparison of the long term outcome of this technique with standard intestino-cystoplasty has indicated that most of the risks and benefits of augmentation cystoplasty performed using intestine and seromuscular patch appear similar.

Level of evidence 3. Grade of recommendation C

6. AUTO-AUGMENTATION

The principle of auto-augmentation of the bladder is the excision of a great portion of the detrusor while leaving the urothelium intact, creating a large diverticulum for the storage of urine at lower pressures. This urine stored at a low pressure can be drained by intermittent catheterization. The theoretical advantages of this procedure are the low complication rates of the surgery, reduced operative morbidity with shorter stay in the hospital, absence of urine salt resorption, less mucous production in the urine and possibly absence of carcinogenic potential. Although some series showed good results with this procedure [54,55,56,57], most authors have been unable to achieve previously reported success [58].

Long-term results have been rather disappointing. MacNeily et al concluded that of 17 patients with neurogenic bladder following auto-augmentation, 71% were clinical failures and 14 out of 15 were urodynamic failures [59]. Similar findings have been reported by others (60,61). The inability of this procedure to achieve long-term good results may be due to the regeneration of nerve fibers divided during the surgery as well as the ischemic atrophy of the mucosa.
Although there are many potential advantages to this approach to a small poorly compliant bladder the inconsistency of success make it a less favorable option at this time. It is generally felt that pressures can be lowered but that capacity remains unchanged.

More recently, some authors have proposed the laparoscopic auto-augmentation as a minimally invasive procedure for the treatment of low capacity/low compliance bladder [62,63]. Despite the indifferent results some still suggest its consideration before a standard augmentation because of the reasons listed above [64,65,66].

Level of evidence 4. Grade of recommendation C

7. URETERAL BLADDER AUGMENTATION

Another alternative to avoid the morbidity of intestinal bladder augmentation is the use of ureteral segments to improve bladder capacity and/or compliance. Megaureters associated with poorly or nonfunctioning kidneys provide an excellent augmentation material with urothelium and muscular backing, free of potential electrolyte and acid base disturbance, and mucus production [83,84].

Another alternative in patients with ureteral dilation and good ipsilateral renal function, is to combine transureteroureterostomy with ureterocystoplasty [85]. Another alternative in bilateral dilated ureters with preserved renal function is bilateral reimplantation and the use of bilateral distal ends for detubularized bladder augmentation [86,87].

Bladder augmentation with ureter may be effective in a small sub group of patients with ureteral dilatation and poor bladder capacity. Overall long-term results are good and remain so over a longer period of time [88,89,90,91,92,93].

In a recent evaluation of the long term functional outcome of this technique it is reported that ureterocystoplasty provides durable functional urodynamic improvement, yet some patients (4 out of 17 in this series) would eventually need a standard intestinal cystoplasty [94].

Level of evidence 3. Grade of recommendation B

It has been shown that this type of augmentation can also be employed in children who require a kidney transplantation [95,96,97].

8. EXPERIMENTAL METHODS

The artificial bladder has been the topic of speculation and experiment that remains still outside the bounds of clinical application. Somewhat nearer to clinical application may be the concept of tissue engineering using autologous urothelium and bladder muscle cells. These cells may be grown on biodegradable scaffolds—both naturally derived and synthetic—for the temporary support of growing tissues and then can be used for augmenting the bladder. A number of synthetic materials and natural matrices have been used in experimental and clinical settings and major improvement have been gained in techniques of cell harvest, culture, and expansion as well as polymer design.

A range of applications of engineered bladder tissues are at different stages of development. There have been a few in preclinical trials, recent progress suggests that engineered bladder tissues may have an expanded clinical applicability in the future.

Clinical trials with these methods are not far away [98-110].

Although this field of research may represent the future of bladder reconstructive surgery, currently only few experimental studies are available and it may be some time before all this knowledge can be used clinically. We strongly encourage further research in this field.

VI. BLADDER OUTLET SURGERY

1. URETHRAL ENHANCEMENT

In those children where sphincteric incompetence is the only cause of incontinence or plays a mayor role in association with decreased bladder capacity or compliance, surgical procedures to enhance outlet resistance should be considered. In many cases bladder outlet surgery needs to be combined with other procedures aimed at creating a large low pressure storage reservoir.

2. BULKING AGENTS

The injection of bulking substances in the tissues around the urethra and bladder neck to increase outlet resistance in children dates back to at least 1985. However, concern about distant migration of the injected substance and risk of granuloma formation prevented this technique from gaining widespread acceptance [111,112].

The search for safer, biocompatible substances to create periurethral compression has first led to the use of cross-linked bovine collagen, with initially reported success in about 20-50% of children [113,114,115].

Collagen injection appeared to effectively improve urethral resistance, but this did not always translate into satisfactory dryness, besides, the effect of the injection is of short duration and repeated injections were often necessary [116,117]. Because of this collagen is no longer recommended for this indication.

At present the following substances are available and have been tested in children with incontinence: dextranomer / hyaluronic acid copolymer (a nontoxic, nonimmunogenic, non-migrant synthetic substance) and polydimethylsiloxane.
Usually the substance is injected endoscopically in the bladder neck area (finding the best spot is often the most difficult part of the procedure): more than one procedure may be necessary. On average 2.8 – 3.9 ml is injected. More than 50% of patients need more than one injection. Initial results of 75% success have been reported, but after 7 years there is a gradual decrease and only 40% remained dry [118,119,120]. Others have reported success rates of 0 - 70% [121-128].

Despite limited success it remains an option for all patients who are poor surgical candidates and those who want to avoid extensive BN reconstruction.

An alternate route may be the injection around the urethra using laparoscopy [129].

Level of evidence : 3. Grade of recommendation C

3. ARTIFICIAL URINARY SPHINCTER

Since its introduction in 1973 the AUS has undergone major transformations over the years. Different devices are currently in use: one of the most frequently used devices is the AS800-T that has been in use for almost 20 years [130]. It consists of an inflatable cuff, a pressure regulating balloon and a unit containing a pump and control mechanisms. The inflatable cuff can only be implanted around the bladder neck in females and pre-pubertal males. In post-pubertal males the bulbous urethral placement is possible but not recommended for wheelchair patients or those who perform intermittent catheterization [131]. In patients who have had extensive urethral surgery (extrophy and epispadias) it may also not be technically feasible.

Implantation of an AUS requires special training and difficulties may be encountered in the dissection of the space around the bladder neck in obese, post-pubertal males or in patients with a history of previous bladder neck procedures. A 61-70 cm H2O pressure balloon is used exclusively when the cuff is around the bladder neck and a lower pressure balloon when it is around the bulbous urethra. Although high in cost, the artificial sphincter remains the most effective means or increasing urethral resistance and preserving the potential for voiding.

The ideal candidate for AUS implantation is a patient with pure sphincteric incompetence who voids spontaneously and has good bladder capacity and compliance. Unfortunately only a small proportion of children with sphincteric incontinence meet the criteria. The AUS may also be used in patients dependent on clean intermittent catheterization. The compatibility of the AUS with intermittent catheterization and enterocystoplasty is well documented [132,133,134].

The ability to empty the bladder spontaneously or by Valsalva maneuver may be preserved after AUS implantation. In series reporting children with AUS, the majority having neurogenic incontinence, 25% void spontaneously [135]. When the AUS is implanted before puberty, the ability to void spontaneously may be lost after puberty.

Overall, 40 to 50% of neurogenic patients require a bladder augmentation concomitantly or subsequently to the AUS implantation [133,136,137,138].

The continence rate ranges from 63 to 97% [139-146].

Herndon et al reported a success rate of 86% (of 134 patients): 22% voided, 11% had to perform CIC after voiding, 48% only performed CIC through the urethra, 16% performed CIC through a continent channel and 3% used diversion [147]. Mechanical problems occurred in 30% of patients who had an 800 model implanted (versus 64% in the old model). Revisions (in 16%) were significantly less in the 800 model. Erosion occurred in both groups (16%). A major complication was perforation of the augmented bladder in this group (it occurred in 10 patients). In 28% a secondary bladder augmentation was necessary.

Another interesting aspect of the AUS is that in some children the device is either deactivated or no longer functions but they remain dry: others have reported that placing a cuff only without activation is all that is required to make them dry [148].

The complications most commonly encountered in patients with AUS are mechanical failures. The longevity of the present devices is expected to exceed 10 years, although Spiess et al reported a mean lifetime of only 4.7 years [149].

The second most common problem is the development of reduced bladder compliance with time. This may result from an error in the preoperative evaluation or the reaction of the detrusor to obstruction (a reaction noted in some patients with spina bifida). These changes can be seen after many years of follow-up. The results of decreased capacity and compliance may be incontinence, upper tract deterioration, or the development of vesicoureteral reflux. Therefore long term follow-up with ultrasound, renal scintigraphy and if indicated urodynamics is mandatory in all patients with an AUS.

Infection of the prosthesis should occur in no more than 15% of all cases. Erosions of the tissues in contact with the prosthesis are rather infrequent. Bladder neck erosions are practically non-existent when the sphincter is implanted around a “virgin” bladder neck. When the AUS is used as a salvage procedure following bladder neck reconstruction, the erosion rate may be as high as 30% [137]. Despite the high complication and revision rate, AUS results show that acceptable continence rates can be achieved in the long-term. For this reason AUS implantation may be better considered as the initial treatment in selected cases [150].
4. FASCIAL SLINGS

Fascial slings constructed with the fascia of the anterior rectus muscle have been used to increase outlet resistance in incontinent children, particularly those with neurogenic dysfunction since 1982 [151]. The sling is used to elevate and compress the bladder neck and proximal urethra. The dissection around the urethra may be facilitated by a combined vaginal and abdominal approach, however, this option is limited to post-pubertal females [152].

Several technical variations of the sling have been reported. The fascial strip may be a graft or a flap based on the rectus sheath on one side. The fascial strip can be crossed anteriorly or wrapped around the bladder neck to enhance urethral compression.

Although the short-term success rate reported by most authors is encouraging, there are no series reporting detailed results at 5 years [153-154]. Most authors report a greater success when fascial slings are used in conjunction with bladder augmentation and success seems more likely in females than in males [155-158]. In patients with neurogenic incontinence postoperative CIC is recommended.

The pubovaginal sling in girls may also be placed through the vagina: in 24 girls with spina bifida this procedure was successful in 19, while another 3 became dry following additional injections with bulking agent around the bladder neck via a suprapubic needle introduction. CIC was possible in all patients. One patient developed a vesicovaginal fistula [159].

Complications of sling procedures include difficulties with intermittent transurethral catheterization, erosion of the urethra and persistent incontinence. Overall, the increase in outlet resistance provided by slings seems less than that provided by the artificial sphincter. Experience with these procedures suggests an overall success between 50 and 80% in females.

Numerous alternatives are being used nowadays: small intestinal submucosa has been used in 20 children and showed equivalent rates of continence. The advantage being that it is available off-the-shelf. Results were better in girls than in boys (85 vs 43% being dry) [160,161,162].

When combining bladder augmentation with a Gore-tex sling in 19 children the results were bad: because of erosion the sling had to be removed in 14 patients, all except one also had a bladder stone. In this respect this type of sling should not be used [163].

From the data published it presently seems that the AUS provides more consistent results in boys and for girls capable of spontaneous voiding who have not had previous bladder neck surgery. Bladder neck slings may be used for the enhancement of bladder outlet resistance in the majority of patients with neurogenic bladder who need augmentation cystoplasty and whom we do not expect will be capable of voiding spontaneously. Sling procedures are probably equally effective for girls dependant on intermittent catheterization and in conjunction with bladder augmentation. At present, given the cost and lack of effectiveness of injection procedures, their use does not appear justified in incontinent children. The cost of the AUS may restrict its use.

Level of evidence 2. Grade of recommendation B

It is important that one should be aware of the fact that these patients who undergo bladder outlet surgery need long-term follow-up not only because of the complications but also because their bladder behavior may undergo unexpected clinically asymptomatic changes that could negatively affect their upper tracts if augmentation procedure are not performed at the same time [164].

5. BLADDER NECK CLOSURE

In ‘desperate’ cases the bladder neck may be closed, the indication being persistent leakage despite several attempts to enhance outlet resistance by bulking agents or other surgical procedures. Although initial results are acceptable, long-term results are usually disappointing: persistent urinary leakage, stomal stenosis and leakage or stone formation (in up to 40%) [165,166]. One of the most important factors seems to be compliance with intermittent catheterization and bladder irrigation.

6. BLADDER OUTLET RECONSTRUCTION

Surgical procedures to achieve urinary continence are dictated by functional and anatomic deficiencies and by the ultimate goal of either continence (with normal voiding) or dryness (dependent on intermittent catheterization).

Construction of a functional urethra for continence usually implies an anatomic defect without a neurogenic component (epispadias / exstrophy) and includes urethral and bladder neck narrowing and urethral lengthening [167-172].

Such procedures may initially require intermittent catheterization or occasional post voiding catheterization, but bladder empying by voiding is anticipated.

Urethral reconstruction for dryness, however, mandates intermittent catheterization. The goal in surgery to achieve dryness is to create a urethra suited to catheterization, which has closure such that intra-luminal pressures always exceed intravesical pressure. The most dependable procedures for dryness utilize a flap valve or tunnel to achieve urethral closure, although urethral slings, wraps and injections have also been used [173].

Level of evidence 3. Grade of recommendation C

Reconstruction to achieve continence is based on the principle that proximal reduction of the caliber of the
urethra supports the inherent proximal sphincteric mechanism of the bladder neck and proximal urethra. The narrowing must be dynamic to permit closure for continence and yet permit opening with funneling during voiding. Several techniques have been described to achieve this goal [3, 166-176]. Young (1922) performed a “double sphincter technique” that involved the excision of a wedge of tissue at the anterior bladder neck, as well as removal of a wedge of tissue just proximal to the epispidias meatus (external sphincter). Dees (1949) added the concept of lengthening the urethral tube to that of narrowing. In his procedure parallel incisions were made through the existing bladder neck area which created a posterior urethral plate from what had previously been the trigone of the bladder. This is tubularized to give added length to the proximal urethra. The added length provides increased potential for urethral closure and moves the bladder neck and proximal urethra into the abdominal cavity. Leadbetter (1964) modified the Young-Dees procedure by creating muscular flaps from the area of the bladder neck and proximal urethra which were used to wrap the newly created proximal tube. This procedure was popularized by Jeffs (1983) who applied it to a staged repair of extrophy. He supported a lengthened urethra by a suspension. They report their long term continence rate with this procedure as greater than 80%, without the need for CIC or augmentation [177].

Presently, this represents the gold standard for reconstruction for continence, however, modifications of the technique have reported similar or improved results. Most urethral lengthening procedures utilizing the posterior urethra and bladder neck require ureteral reimplantation and preservation of the posterior urethral plate. Because part of the bladder is used to create the functional lengthening of the urethra bladder capacity decreases following the procedure. It also remains to be seen whether the created urethra is actually a functioning urethra: in many patients fibrosis around the urethra prevent it from being really “functional”: in these patients it may act as an anatomic obstruction and long-term follow-up is necessary to follow not only the bladder but also the upper tract.

Surgery for dryness is dependent on the effectiveness of intermittent catheterization and is usually reserved for patients with neurogenic dysfunction or multiple previous surgeries. Procedures to achieve dryness usually create a urethral closure pressure that exceeds bladder pressure.

A flap valve can be constructed by using an anterior or posterior bladder flap (full thickness) to construct a tube that is placed in a submucosal tunnel [171,175,176].

The major disadvantage of these procedures (flap valves) is that the valve will not allow leakage with high intravesical pressures, potentiating renal damage. Therefore, these procedures can be dangerous to the patient who is not totally committed to follow catheterization recommendations.

Unfortunately, the ideal procedure for surgical reconstruction of the bladder neck does not exist. The surgical approach to urinary incontinence in the child must be multifaceted because of the inherent complex and varied nature of the problem.

Recent data would support the concept that very early reconstruction in the exstrophy / epispidias group may result in physiologic bladder cycling which facilitates normal bladder and urethral development. This results in higher potential for continence without the need for bladder augmentation and bladder neck reconstruction (Level 3). More work and clinical experience in this area is strongly recommended (Grade A).

7. ALTERNATIVE CONTINENCE CHANNELS

In the surgical treatment of incontinence in children every effort must be made to preserve the natural upper and lower urinary tract. The bladder is the best urinary reservoir, the urethra the best outlet and the urethral sphincters the best control mechanism. If the bladder is partly or wholly unusable it may be augmented or replaced by a variety of techniques. Urthral failure may occur either because the sphincters are incompetent or because it is overactive and does not allow spontaneous voiding. It would be preferable for the former to be treated by one of the techniques described above and the latter by intermittent catheterization (CIC). If all of these fail, continent supra pubic diversion is indicated.

a) The Mitrofanoff principle

Mitrofanoff’s name is given to the principle of burying a narrow tube within the wall of the bladder or urinary reservoir whose distal end is brought to the abdominal wall to form a catheterizable stoma suitable for intermittent catheterization [178]. The technique is simple and familiar to all urologists who are accustomed to re-implanting ureters. Several narrow tubes are available for the Mitrofanoff conduit [179,180]. In the original description, the appendix was used. However, even if the appendix is still present, it may be unusable in 31% of patients [181].

If no suitable tube is found, a good tube can be formed by tailoring ileum transversely so that only 2-3cm of ileum can be made into a 7-8 cm conduit. This modification was originally described by Yang in humans and by Monti in experimental animals [182,183]. It is increasingly used though great care must be taken in its construction to avoid an internal fistula [184].

The ureter may be used but there may be some difficulty in achieving sufficient calibre with a previously normal ureter. Earlier reports that the Fallopian tube could be used have not stood the test of time.
The Mitrofanoff system achieves reliable continence which is maintained in long term follow-up, for a high proportion of patients. Long-term follow-up data shows that in the original series of Paul Mitrofanoff of 23 patients after a mean follow-up of 20 years, 1 patient had died, but in the other 22 patients no metabolic changes were noted. The bladder neck was closed in 21 patients. Secondary bladder augmentation had to be performed in 8, while in 4 children a non-continental diversion was created. With time the need for additional surgery decreased and after 20 years 16 patients had a good and stable continent diversion [185].

The pressure generated within the lumen of the conduit is 2 to 3 times higher than that within the reservoir so that continence is preserved even when the intra abdominal pressure is raised by straining. Conversely, the pressure in the lumen of a Kock nipple is only slightly higher than that in the reservoir so that continence is less reliable [186,187].

The conduit may be buried either between the mucosal and muscle layers of the reservoir, or may be completely imbrocated in the full thickness of the reservoir wall. Any well supported tunnel of about 2-4 cm will suffice. The choice depends both on the nature of the reservoir and on the conduit [188].

Continence rates of 90-100% with the Mitrofanoff Principle are reported, regardless of diagnosis, reservoir or conduit type [188,189]. Follow-up for at least ten years has shown that the system is resilient [190,191,192].

A modified technique of vesicostomy is described using a gastrostomy button, which could be used as a continent urinary stoma in children with incomplete voiding. Button vesicostomy is a useful addition to the options available for a catheterizable continent urinary stoma in children in the short or medium term(193).

Although perfect continence seems attractive, it may not be in the child's best interests. A 'pop-off' valve may be in the interest of the child if catheterization is impossible or forgotten.

b) The Ileo-cecal valve

The ileo-cecal valve is an obvious sphincter to combine with cecum and ascending colon as the reservoir and the terminal ileum as the conduit. The early continence rate of 94% was not sustained because of high pressures in the tubular reservoir and weakness of the valve [194,195,196].

The Indiana system is based on the competence of the ileo-caecal valve but with a detubularized reservoir [197]. The valve itself is reinforced with non-absorbable plicating sutures and the terminal ileum which forms the conduit is tailored. The best reported continence rate is 96% with a 2% rate of catheterization difficulties.

In the complete Mainz I pouch a length of terminal ileum is intussuscepted through the ileo-cecal valve as a Kock nipple [198]. It is impossible to say whether the nipple or the ileocecal valve (or both) produce the continence which is reported in 96% of patients.

Both these systems work well as complete reconstructions and are widely used as bladder replacements in children. The sacrifice of the ileocecal valve may cause gastro-intestinal complications.

c) Kock pouch

The first workable continent diversion was the Kock pouch [42]. The reservoir is made from 40cm ileum reconfigured to reduce the intrinsic pressure. The continence mechanism is formed by intussusception of 12cm of ileum. In a complete form it requires 72cm of ileum which may be more than can be spared from the gastro-intestinal tract.

Although first described as a mechanism for a continent ileostomy in children the Kock pouch is now not commonly used in children because of the problem with large amount of bowel needed, stone formation and mediocre success with dryness of the catheterizable stoma [199,200].

d) Artificial Sphincter

As a last resort, the AUS may be considered to give continence to a reconstructed outlet. Experimental evidence suggests that AUS cuffs can be placed safely around intestine providing the cuff pressure is low [201]. The AUS has been used successfully around large bowel, in three of four children with follow-up to 11 years [202].

e) Where to place the cutaneous stoma

In patients with spina bifida, particularly non-walkers, the site must be chosen with particular care. The natural tendency is for the spine to collapse with time so that the lower half of the abdomen becomes more pendulous and beyond the range of vision. A low site may seem appropriate in the child, but will become unusable in the adult. It is best to use a high, midline site, preferably hidden in the umbilicus. The site should be determined in a sitting position and marked before surgery because in the supine position the position will change dramatically. In some patients the best position may not be in the midline at all: special care must be taken that the patient can manage bladder emptying and irrigation him/herself.

For most other patients, the site of the stoma should be chosen by cosmetic criteria. The umbilicus can be made into a very discrete stoma; the risk of stenosis is low and it is a readily identifiable landmark. Otherwise, the stoma should be as low on the abdominal wall as possible and certainly below the top of the underpants. However, many surgeons find the best results by placing the catheterizable stoma in the umbilicus.

The problem of stomal stenosis remains ever present.
It can occur at any time so that only follow up of many years could determine whether any system of anastomosis to the skin is better than any other. The published rate of stomal stenosis is between 10 and 20%. The multi-flap V.Q.Z. stoma is claimed to have the lowest rate but follow up is short and it may well not pass the test of time [203].

II. COMPLICATIONS OF CONTINENCE SURGERY IN CHILDREN

1. STORAGE AND EMPTYING COMPLICATIONS

In the short term, it has been shown that the continent diversions can store urine and can be emptied by clean intermittent catheterization (CIC). It is apparent that there is a constant need for review and surgical revision. This observation mirrors the late complications of augmentation cystoplasty for neuropathic bladder where the median time to revision surgery is as long as ten years [204,205].

In general, once continent, they remain continent, although there are occasional reports of late development of incontinence. The problem lies more in difficulties with catheterization, particularly stenosis and false passages which may occur in up to 34% of patients [188]. In a recent retrospective evaluation of 500 augmentations over 25 years with a median follow-up of 13.3 years, the cumulative risk of further surgery at the bladder level was 0.04 operations per patient per year of augmentation and 34 % of the patients needed further surgery for complications. Bladder perforation occurred in 43 patients (8.6%) with a total of 53 events and 125 surgeries done for bladder stones in 75 cases [206].

The principal complications arise because the reservoir is usually made from intestine. Ideally, urothelium should be used and preservation of the bladder epithelium gives fewer complications than enterocystoplasty [207].

Combinations of detrusor myectomy and augmentation with de-mucosalised colon have given promising results in the short term. The surgery is difficult as the bladder epithelium must not be damaged and the intestinal mucosa must be removed completely. When achieved there are no metabolic problems and many patients can void [207].

When augmentation can be done with a dilated ureter, the results are good and the complication rate low even in children with compromised renal function or transplantation [208].

All intestinal reservoirs produce mucus. The amount is difficult to measure and most estimates are subjective. No regime has been shown to dependably reduce mucus production [209].

2. RESERVOIR RUPTURE

The incidence of spontaneous rupture varies between different units. There may be delay in diagnosis although the history of sudden abdominal pain and diminished or absent urine drainage should make it obvious. The patient rapidly becomes very ill with symptoms of generalized peritonitis [210,211]. A ‘pouchogram’ may not be sensitive enough to demonstrate a leak. Diagnosis is best made by history, physical examination, ultrasonography and a CT cystogram. If diagnosed early, catheterization and broad spectrum antibiotics may sometimes lead to recovery. If the patient fails to respond within 12 hours on this regime or if the patient is ill, laparotomy should be performed at once. If there is any instability of the patient laparotomy should be considered as an immediate necessity as bladder rupture in this clinical situation can be lethal.

Level of evidence 2. Grade of recommendation A

Figures are not available on the incidence of this complication in reservoirs made only of bowel but come from patients with intestinal segments in the urinary tract. Most papers report small numbers. In a multicentre review from Scandinavia an incidence of 1.5% was noted. There were eight patients with neurogenic bladder which was said to be disproportionately high [210]. In a series of 264 children with any sort of bowel reservoir or enterocystoplasty, 23 perforations occurred in 18 patients with one death [211]. Therefore, as this complication is more common in children it becomes a very important consideration [212]. A review of 500 bladder augmentation procedures performed during the preceding 25 years, spontaneous perforations occurred in 43 patients (8.6%), for a total of 54 events. The calculated risk was 0.0066 perforations per augmentation-year [213].

Patients and their families should be warned of this possible complication and advised to return to hospital at once for any symptoms of acute abdomen, especially if the reservoir stops draining its usual volume of urine. All young patients with urinary reconstructions including intestinocystoplasty should carry suitable information to warn attending physicians of their urinary diversion in case of emergency.

3. METABOLIC COMPLICATIONS

Metabolic changes are common when urine is stored in intestinal reservoirs and must be carefully monitored. It is uncertain whether they are commoner in children or whether they just live longer and are more closely monitored.

Nurse et al found that all patients absorbed sodium and potassium from the reservoirs but the extent was variable [214]. A third of all patients (but 50% of those with an ileocecal reservoir) had hyperchloremia. All patients had abnormal blood gases, the majority
having metabolic acidosis with respiratory compensation. The findings were unrelated to renal function or the time since the reservoir was constructed.

In 183 patients of all ages at St Peter’s Hospitals who had any form of enterocystoplasty, hyperchloroaeamic acidosis was found in 25 (14%) and borderline hyperchloroaeamic acidosis in an additional 40 (22%) patients. The incidence was lower in reservoirs with ileum as the only bowel segment compared to those containing some colon (9% v 16%). When arterial blood gases were measured in 29 of these children a consistent pattern was not found [215].

In a series of 23 patients, Ditonno et al found that 52% of patients with a reservoir of right colon had hyperchloroaeamic acidosis [216]. In ileal reservoirs, Poulsen et al found mild acidosis but no patients with bicarbonate results outside the reference range [217].

Many authors do not distinguish between patients with normal and abnormal renal function. All of 12 patients in one series with a pre-operative serum creatinine above 2.0 mg% developed hyperchloroaeamic acidosis within 6 months of enterocystoplasty [218]. It is prudent to monitor patients for metabolic abnormalities, especially hyperchloroaeamic acidosis, and to treat them when found [219].

With increasing experience, it has become clear that there is a risk of developing vitamin B12 deficiency, sometimes after many years of follow up. It is likely that resection of ileum in children leads to an incomplete absorption defect. Stores of B12 may last for several years before the serum level becomes abnormal. At a mean follow up of six years, low levels of B12 have been found in 14% of children. There was a corresponding rise in the serum methyl malonic acid which is a metabolite that accumulates in B12 deficiency suggesting that the finding was clinically significant. Similarly, in adults, 18.7% have B12 deficiency at five years. In the adults the mean B12 level was significantly lower when the ileocæcal segment as opposed to ileum alone had been used (413 ng/ml compared to 257 ng/ml) [220,221]. In order to avoid the serious neurological complications, regular monitoring of B12 levels is essential.

In a review of 500 augmentations Starting at 7 years postoperatively, 6 of 29 patients (21%) had low B12 values, while 12 of 29 (41%) had low-normal values [222].

Pediatric patients who have undergone ileal enterocystoplasty are at risk for development of vitamin B12 deficiency. These patients are at the highest risk beginning at 7 years postoperatively, and the risk increases with time. An annual serum B12 value in children beginning at 5 years following bladder augmentation is recommended.

Level of evidence 2. Grade of recommendation B

The stomach has had a checkered career as a urinary reservoir. Its non-absorptive role in the gastro intestinal tract has made it particularly useful in reconstruction of children with inadequate intestine, such as those with cloacal exstrophy. There is little effect on gastro intestinal function. Metabolically, the acid production leading to hypochloroaeamic alkalosis may be positively beneficial in children with renal failure. It produces no mucus and the acidic urine is less easily infected and seldom grows stones. However about a third of children have had serious long term complications, often multiple. The quite severe dysuria / haematuria and the skin complications from the acid urine, particularly, have limited its use [223,224].

4. EFFECTS ON THE GASTROINTESTINAL TRACT

Little attention has been paid to the effects on gastro intestinal motility of removing segments of ileum or cæcum for urinary reconstruction in children. In adults, disturbance of intestinal function has been found to be more frequent and more debilitating than might be expected.

Disturbance of bowel habit does not mean diarrhoea alone. It also includes urgency, leakage and nocturnal bowel actions. It is clear that quality of life may be seriously undermined by changes in bowel habit [225].

It is known that the bowel has a considerable ability to adapt, especially in young animals, when parts are removed. Nonetheless, reconstruction should be undertaken with the smallest length of bowel possible. Particular care should be taken in children with neurologic abnormality in whom rectal control is already poor. Poorly controlled fecal incontinence may occur in a third of patients [226,227].

5. RENAL FUNCTION

Obstruction and high pressures in the bladder during storage have devastating effects on the upper urinary tract. Bladder augmentation eliminates these high pressures. Urinary diversion with recurrent urinary tract infections and stone formation also may have deleterious effects on renal function. It is therefore of utmost importance to evaluate renal function in young children who have undergone undiversion or continent diversion. In the follow-up so far available these procedures do not seem to affect renal function. When function has improved after such surgery it is likely to be the result of eliminating obstruction or high bladder storage pressure.

In rats with near complete nephrectomy the rate of progression of renal failure is no worse in those with ileocystoplasty compared to those with normal bladder [228]. This suggests, experimentally, that storage of urine in small intestine is not, on its own, harmful to renal function.

Clinically, in the longer term, renal deterioration has
been related to obstruction, reflux and stone formation. In one long-term study of Kock pouch patients, these complications occurred at the same rate as that found in patients with ileal conduits: 29% at five to 11 years [229]. Similarly, in a prospective follow-up to a minimum of 10 years, it was found that the deterioration in glomerular filtration rate (GFR), that was found in 10 of 53 patients, was due to a ‘surgical’ cause in all but one [230].

Although a more complicated procedure, a renal transplant can be anastomosed in an intestinal reservoir with similar long-term results as those using an ileal conduit [231,232].

**6. INFECTIONS AND STONES**

The incidence of bladder reservoir stones varies between 12 and 25%. This is higher in children compared to adults. Palmer et al reported an incidence of 52.5% during a follow-up of four years [233]. Renal stones are uncommon, occurring in about 1.6% of patients, an incidence which would be expected in a group with congenital urinary tract anomalies.

In a series comparing the Kock pouch with the Indiana pouch (which does not have staples), 43.1% of 72 Kock reservoirs formed stones compared to 12.9% of 54 Indiana reservoirs [234]. Furthermore, no patient with an Indiana pouch formed a stone after 4 years, but patients with Kock pouches continued to do so at a steady rate up to eight years.

Apart from the presence of a foreign body, several factors have been blamed for the high stone risk. Almost all reservoir stones are triple phosphate on analysis, though Terai et al found carbonate apatite, urate and calcium oxalate in up to 50% of stones from patients with an Indiana pouch [235]. This suggests that infection rendering the urine alkaline is a key factor. Micro-organisms that produce urease and split urea to form ammonia are the main culprits. The incidence of infection in reservoirs is high, 95% in one series, and yet the majority of patients do not form stones, suggesting that there are predisposing factors other than infection and the anatomical abnormality of the urine reservoirs [236].

It has been suggested that the immobility associated with spina bifida may be responsible, but this seems to have been in series with a predominance of such patients and was not confirmed in other studies [237].

The production of excess mucus has also been blamed. The problem is that the measurement of mucus is difficult.

The finding of a spectrum of stone formation from mucus, through calcification to frank stone lends some support to this aetiology. However, it could be a secondary event, with mucus becoming adherent to a stone that has already formed. Many surgeons encourage patients to wash out their reservoirs vigorously with water two or three times a week. There seem to be fewer stones in those that claim to practice regular washing. In a prospective study a regime of weekly washouts did not improve the incidence of stones in 30 children compared to historical controls [238].

Mathoera et al found an incidence of 16% during a follow-up of 4.9 years in 90 patients: girls were more frequently affected than boys and concomitant bladder neck reconstruction, recurrent infections and difficulties with CIC were other risk factors identified, while the frequency of irrigation did not appear to be a risk factor [239].

Mucins are an important component of the epithelial barrier and protect the epithelium from mechanical and chemical erosion. Mucins are known to act as important adhesion molecules for bacteria. Mucins may also enhance the formation of crystals [240]. Mucin expression changes after incorporating the intestinal segment in the bladder. Upregulation of MUC1 and MUC4 expression occurs in transposed ileal segments resembling normal epithelium, whereas ileal segments in enterocystoplasty showed an upregulation of MUC2,3,4 and 5AC expression towards the site of anastomosis with the ileal segment. These changes which may be due to exposure to urine coincide with a change from ileal sialomucins to colonic sulfomucins by a change in glycosylation. The mucins bind calcium and may form a template resembling the crystal structure on which crystals are formed and grow. From these studies it is concluded that inhibition of bacterial adhesion (by using different irrigation fluids based on sugars) could be of eminent importance in the prevention of certain types of infection stones.

An interesting comparison has been made between children with a native bladder alone and those with an augmentation, all of whom were emptying by self catheterization. There was no significant difference in the incidence of stones with or without an augmentation [241].

Stones are associated with inadequate drainage in the sense that CIC through the urethra, the most dependent possible drainage, has the lowest stone rate. Patients with the most ‘up hill’ drainage, that is with a Mitrofanoff channel entering the upper part of an orthotopic reservoir have a higher incidence of stones [239].

Kronner et al made the observation, that the incidence of stones was statistically associated with abdominal wall stomas and a bladder outlet tightening procedure (21.1% compared to 6% in patients with augmentation alone) [236].

Once a bladder stone has been diagnosed it has to be removed: several methods are available, but ESWL should be avoided as it is difficult to remove all
fragments (and small particles may get trapped in mucus and the pouch wall), which may form the focus of a new calculus. Because of the recurrent nature of these stones the least invasive method should be recommended [242,243].

Because of the high incidence of stones following enterocystoplasty several measures should be recommended to the patients and their parents. Regular CIC under hygienic circumstances with adequate fluid intake and irrigation seem to be the most important [244]. It is unclear whether prophylactic antibiotics are useful, but a clinical infection should be treated adequately. Maybe in the future different types of irrigation fluid may prove helpful.

7. GROWTH

The suggestion that enterocystoplasty delayed growth in height seems to have been ill founded. In a group of 60 children reported in 1992 it was stated that 20% had delayed growth [245]. Current follow up of the same group has shown that all have caught up and achieved their final predicted height. Furthermore, measurements in a group of 123 children from the same unit have shown no significant delay in linear growth [246].

Enterocystoplasty may have an effect on bone metabolism even if growth is not impaired. At least in rats with enterocystoplasty there is significant loss of bone mineral density especially in the cortical compartment where there is endosteal resorption. These changes are not associated with HCA and are lessened by continuous antibiotic administration [247,248].

More recent follow-up data shows either no effect on growth or a decreased linear growth [249-252].

8. PREGNANCY

When reconstructing girls it is essential to have a future pregnancy in mind. The reservoir and pedicles should be fixed on one side to allow enlargement of the uterus on the other.

Pregnancy may be complicated and requires the joint care of obstetrician and urologist [253]. Particular problems include upper tract obstruction and changes in continence as the uterus enlarges.

Pregnancy with an orthotopic reconstruction appears to have a good outcome but chronic urinary infection is almost inevitable and occasionally an indwelling catheter is needed in the third trimester [254]. With a suprapubic diversion, catheter drainage for incontinence or retention may be needed in the third trimester [255].

Except in patients with an artificial urethral sphincter and extensive bladder outlet reconstruction, vaginal delivery is usual and caesarean section should generally be reserved for purely obstetric indications (distorted pelvis in spina bifida patients). During the delivery the bladder reservoir should be empty and an artificial sphincter deactivated. The urologist should be present during Caesarean section to ensure protection for the reservoir, the continent channel and its pedicles.

9. MALIGNANCY

The possibility of cancer occurring as a complication of enterocystoplasty is a constant source of worry. Currently cancer following augmentation cystoplasty is a recognized risk factor. It is known to be a frequent complication of ureterosigmoidostomy after 20 to 30 years of follow up. Animal evidence suggests that faecal and urinary streams must be mixed in bowel for neoplasia to occur. However, if it is chronic mixed bacterial infection, rather than the faeces per se, then all bowel urinary reservoirs are at risk.

In patients with colonic and ileal cystoplasties high levels of nitrosamines have been found in the urine of most patients examined [256]. Clinically significant levels probably only occur in chronically infected reservoirs [257]. Biopsies of the ileal and colonic segments showed changes similar to those that have been found in ileal and colonic conduits and in ureterosigmoidostomies. More severe histological changes and higher levels of nitrosamines correlated with heavy mixed bacterial growth on urine culture [258].

In a review by Filmer et al, 14 cases of pouch neoplasm were identified (259). Special features could be found in nearly all the cases. Ten patients had been reconstructed for tuberculosis; four tumors were not adenocarcinomas; one patient had a pre-existing carcinoma; six patients were over 50 years old. Cancer was found in bowel reservoirs at a mean of 18 years from formation. This is a few years earlier than the mean time at which malignant neoplasms are seen in ureterosigmoidostomies.

In a review of 260 patients with a follow-up of more than 10 years, Soergel et al found 3 malignancies (all transitional cell carcinoma): 2 following ileocecal and 1 after cecal augmentation. The age at augmentation was 8, 20 and 24 years respectively: the tumors were found when they were 29, 37 and 44 years old. All had metastatic disease and died. The incidence of malignancy in this group was 1.2%; considering that the development of tumors usually takes 20-25 years the probable incidence of malignancy following enterocystoplasty may be as high as 3.8% [260].

Patients who undergo bladder augmentation with a gastric remnant are at increased risk for malignancy, probably similar to that in patients with enterocystoplasty. In a review of 119 patients underwent augmentation cystoplasty with stomach in 2 institutions, three patients had gastric adenocarcinoma, while the
other had poorly differentiated transitional cell carcinoma. Each case progressed to malignancy more than 10 years after augmentation [261,262,263].

If cancer is going to be a common problem, there will be some difficulty in monitoring the patients at risk [264]. Endoscopy with a small instrument through a stoma may not be sufficient. Ultrasound may not be able to distinguish between tumors and folds of mucosa. Three dimensional reconstruction of computerised tomography may be helpful, though the equipment is expensive and not widely available at present [265]. At present it is advised to perform an annual endoscopic evaluation in all patients following enterocystoplasty starting 10 years after surgery.

10. PSYCHOLOGICAL CONSEQUENCES AND QUALITY OF LIFE

The main justification for performing a bladder reconstruction or continent diversion is to improve the individual’s Quality of Life (QoL).

It would seem logical that continent urinary diversion would be better than a bag. This is not always the case. In adults the only sure advantage is cosmetic. Validated QoL surveys in children have not been reported, primarily because of the lack of suitable instruments [266]. Our prejudice is that reconstruction does, indeed, improve the lives of children. Supporting evidence is very thin and based on experience in adults.

The ileal conduit has been a standard part of urological surgery for over 50 years. It has well known complications but few would seriously suggest that they were more troublesome than those of the complex operations for bladder replacement. In an early investigation into quality of life issues, Boyd et al investigated 200 patients, half with an ileal conduit and half with a Kock pouch: there was little difference between the groups except that those with a Kock pouch engaged in more physical and sexual contact. The only patients that were consistently ‘happier’ were those who had been converted to a Kock pouch [267].

In a recent QoL survey in adults, a wide range of complications were considered to be acceptable, although an ordinary urological clinic would be full of patients trying to get rid of such symptoms: mild incontinence (50%), nocturia (37%), bladder stones (12%), urinary infections (9%), hydronephrosis (5%). Nonetheless, their QoL was judged to be good, primarily because 70% had experienced no adverse effect on their normal daily lives [268].

Quality of life does not mean absence of disease or a level of complications acceptable to the reviewing clinician. It is a difficult concept to measure because lack of validated instruments, difficulties in translating from one culture or language to another, of the difficulties in selecting control groups and variations in clinical situations. Gerharz et al have constructed their own 102 item instrument and compared 61 patients with a continent diversion and 131 with an ileal conduit. Patients with a continent diversion did better in all stoma related items indicating that containment of urine within the body and voluntary emptying is of major importance.

In addition they had better physical strength, mental capacity, social competence and used their leisure time more actively. There was little difference in satisfaction with professional life, financial circumstances and in all interactions within the family including sexual activity [269].
G. PSYCHOLOGICAL ASPECTS OF URINARY INCONTINENCE, ENURESESIS AND FAECAL INCONTINENCE

Since the publication of the ICI report in 2005 [1] an increasing body of studies have been published on psychological factors of incontinence in children including some comprehensive reviews [2-7]. This part makes an update based on the recent literature.

**I. INTRODUCTION**

Children with urinary incontinence, enuresis and faecal incontinence carry a higher risk for manifest behavioral disorders, as well as for subclinical emotional and behavioral symptoms. It is important to assess and integrate psychological factors in treatment for two reasons:

1. As can be seen in the next table 3, the rate of comorbid behavioural and emotional disorders is much higher than possible organic causes [7]. The same care used to exclude organic causes should be applied to the assessment of behavioral aspects. Therefore, even paediatricians and urologists should have a basic understanding of psychological principles in order to treat their young patients adequately.

2. In functional elimination disorders, provision of information, cognitive therapy and behavioural modification are the most effective, first-line approaches to treatment. Medication can be helpful in many cases, but are usually not the mainstay of treatment. Surgery is rarely indicated. As most of the techniques used in “urotherapy” are based on cognitive-behavioural psychotherapy, it is, again, essential be acquainted with the basic psychological principles.

The aim of this chapter is to provide information on comorbid manifest clinical disorders, as well as symptoms which might be emotionally distressing for children and parents, but do fulfil the criteria for a disorder. Often, these will resolve upon attaining continence, while manifest disorders usually do not. In addition, children with psychological disorders are less compliant, so that the failure rate of the incontinence treatment is much higher. Therefore it is recommended that both incontinence and any comorbid psychological disorder need to be treated separately to ensure effective therapy.

Also, the relevance of psychological factors for the different subtypes of incontinence will be considered. The terminology of the ICCS for enuresis and urinary incontinence (8) as well as of the Rome-III classification (9) for faecal incontinence will be used.

**II. CLINICAL BEHAVIOURAL DISORDERS**

The rate of clinically relevant behavioural disorders in children and adolescents lies between 12.0% (ICD-10 criteria) [10] and 14.3% (DSM-IV) [11,12]. The rate of comorbid behavioural disorders is definitely increased in children with all types of incontinence. Comorbidity denotes the co-occurrence of two or more disorders at the same time (concurrent comorbidity) or in sequence (sequential comorbidity). The focus on comorbidity allows a descriptive approach without making reference to possible causal associations. Basically, four combinations are possible:

- A behavioural disorder can be a consequence of the wetting problem
- A behavioural disorder can precede and induce a relapse when a genetic disposition for enuresis is present, for example in secondary nocturnal enuresis
- Wetting and a behavioural disorder can both be due to a common neurobiological dysfunction (such as in nocturnal enuresis and ADHD)
- and finally, with such common disorders, no causal relationship can be present and the two may co-exist by chance.

Psychological disorders (synonyms: psychiatric, psychic, mental disturbances) indicate that there is “a clinically significant behavioural or psychological syndrome or pattern (not a variant of normal behaviour) that occurs in an individual, that it is associated with present distress, disability or impairment and carries a risk for the future development of the individual” (DSM-IV) [11].

* Comparable norms: 10%
Clinically relevant disorders can be assessed by two basic methods: the categorical and the dimensional approach. The categorical method is based on a detailed diagnostic process (including: history, observation, exploration, mental state examination, questionnaires, testing, physical examination and other procedures) and are professional diagnosis according to standardised classification schemes: ICD-10 [10] or DSM-IV [11]. Dimensional assessment is based on symptom scores by questionnaires, but do not represent diagnoses. Cut-offs are defined to delineate a clinical (and sub-clinical) range.

One can differentiate externalising or behavioural disorders with outwardly-directed, visible behaviour (examples: conduct disorders, ADHD, etc.); internalising, i.e. inwardly-directed, intrapsychic disorders such as emotional disorders (examples: separation anxiety, social anxiety, phobias, sibling rivalry, depressive disorders, etc.); and other disorders that do not fit into the two categories, such as anorexia nervosa, tic disorders, autistic syndromes, etc.

### III. CLINICAL BEHAVIORAL DISORDERS IN CHILDREN WITH ENURESIS/ URINARY INCONTINENCE

Children with urinary incontinence show a higher rate of comorbid behavioural and emotional problems than non-wetting children – in both epidemiological and in clinical studies. The overall relative risk is 1.4 – 4.5 times higher (table 4) [7].

#### 1. EPIDEMIOLOGICAL STUDIES

Epidemiological studies have the advantage of revealing representative associations. They often cannot differentiate well between subgroups

Not all epidemiological studies on enuresis actually assess behavioural problems in a standardised form [13]. Therefore, only those studies that clearly define the group of clinically deviant children shall be reported in table 2. If a control group is reported, the relative risk for a behavioural problem can be calculated; otherwise the normative data is used.

**a) Nocturnal enuresis**

In the Isle-of-Wight study, 25%-28% of enuretics were seen by their parents to show problematic behaviour according to the Rutter Child Scale – 3-4 times more often than the controls [14]. Using the same instrument, the longitudinal Study from Christchurch (New Zealand) came to similar rates for the primary children with nocturnal enuresis, while the secondary children with nocturnal enuresis showed a much higher rate of 52% [15]. The same study assessed rates of DSM-III diagnoses at a later age – with marked differences between the primary and the secondary children with nocturnal enuresis [16].

In the Dutch study by Hirasing et al [18] 23% of children with enuresis scored in the clinical range of the CBCL total problem scale. In the cross-sectional Chinese study by Liu et al [17] a third of all wetting children were in the clinical range – 3.6-4.5 more often than the controls. The US-Study by Byrd et al [12] used the 32-item BPI (Behavior Problem Index), which is modelled after CBCL. The rates are lower than in the other studies, but included infrequent wetters of as few as one wetting episode per year.

In summary, the epidemiological studies show clearly that, depending on definitions and instruments used, 20-30% of all nocturnal enuretic children show clinically relevant behavioural problems – 2 to 4 times higher than non-wetting children.

Children with primary nocturnal enuresis were not more deviant than controls in epidemiological studies [16]. Secondary nocturnal enuresis was preceded by a higher rate of weighted life-events [20] and was significantly associated with a higher rate of DSM-III psychiatric disorders, which can persist into adolescence [16]. By adolescence, the attainment of dryness after the age of 10 years increased the risk for behavioural problems - independently of the primary or secondary status [13].

The only epidemiological study addressing monosymptomatic nocturnal enuresis included 8242 children aged 7.5 years [21]. Though not adhering to the ICCS criteria, children with monosymptomatic nocturnal enuresis showed fewer behavioural symptoms than those with daytime problems (i.e. the non-mono-symptomatic forms) – although the differences did not reach significance.

**b) Urinary incontinence (daytime wetting)**

Daytime wetting has been neglected in epidemiological research. Only recently, the first study was published based on a cohort of 8213 children aged 7.5 to 9 years [19]. Children with daytime wetting had significantly increased rates of psychological problems, especially separation anxiety (11.4%), attention deficit (24.8%), oppositional behaviour (10.9%) and conduct problems (11.8%). In other words, externalising disorders predominate in daytime wetting children which, in turn, will interfere with treatment. In the same cohort, 10000 children aged 4 to 9 years were analysed. Delayed development, difficult temperament and maternal depression/anxiety were associated with daytime wetting and soiling [22].

#### 2. CLINICAL STUDIES

Clinical studies are limited by selection biases, but allow a much more detailed assessment of patients. Overall, children with nocturnal enuresis have lower rates of comorbid disorders (33.6%) than children with daytime wetting (52.6%) [23]. In another study, the rates were 29% and 46%, respectively [24]. Van
Hoecke et al. [25] could also show that children with daytime wetting (or combined DW/NW) had significantly higher CBCL total problem scores than pure nocturnal enuretics or controls (Table 5).

In an early study of Berg et al [26] nearly 30% of children presented in a paediatric department clinic were deemed “clinically disturbed”. In another study in a paediatric setting, similar rates of 26% were found 20 years later using the CBCL [27]. These rates are almost identical to our own studies in a child psychiatric setting using the same instruments [23]. The rates of a selected group of treatment-resistant children with nocturnal enuresis undergoing Dry Bed Training were 2.2 times higher [28]. In the study of Van Hoecke et al [29], internalizing symptoms predominated in a mixed group of day and night wetting children with significantly higher scores for withdrawal, physical complaints, anxious/depressed, social problems and internalising behaviour scales compared to controls.

According to the ICCS terminology, four subgroups of nocturnal enuresis can be differentiated:

- primary monosymptomatic nocturnal enuresis
- primary non-monosymptomatic nocturnal enuresis
- secondary monosymptomatic nocturnal enuresis
- secondary non-monosymptomatic nocturnal enuresis

Regarding the subtypes of nocturnal enuresis, children with primary nocturnal enuresis showed behavioural problems less frequently (19.5%) than those with the secondary type (75.0%) [23]. The group with the lowest comorbidity – no higher than in the normative population – were those with monosymptomatic nocturnal enuresis (10.0%) without any daytime symptoms such as urge, postponement or dysfunctional voiding. In a replication study, 29% of children with nocturnal enuresis had at least one ICD-10 diagnosis – 24% of those with monosymptomatic and 33% of those with non-monosymptomatic nocturnal enuresis [24].

Regarding the types of behavioural and emotional disorders, externalising disorders predominates [23]. The most specific comorbid disorders with enuresis are ADHD (according to DSM-IV) or the Hyperkinetic Syndrome (according to ICD-10). In our own studies, the rates ranged from 9.3% (HKS) to 13.5% (HKS and ADHD) [23, 31]. ADHD is not associated with any specific type of nocturnal enuresis [30].

In a retrospective study, of patients with ADHD, 20.9% wetted at night and 6.5% during the day. The odds-ratios were 2.7 and 4.5 times higher, respectively, which means that there is unspecific association of ADHD and both night/ daytime wetting [32]. 25% of

*NW = night wetting (nocturnal enuresis) *DW = daytime wetting (urinary incontinence)
140 children with ADHD were affected by nocturnal enuresis compared to 10.8% of 120 controls [33]. The highest comorbidity rates of 40% for ADHD and nocturnal enuresis were reported by Baeyens et al. [30], possibly due to selection effects. 15% had a combined, 22.5% an inattentive and only 2.5% a hyperactive type of ADHD. In a community based sample, the prevalence rate was much lower [34]. ADHD continued to be present in 72.5% of children in a two-year follow-up indicating a high stability [34]. Children with ADHD continued to wet at follow-up much more often (65%) than controls (37%) (Odds-ratio 3.17) [34]. At a 4-year follow-up, 64% still had ADHD. Of these, 42% continued to wet at night (compared to 37% of the controls) [35].

In clinical practice, children with ADHD are more difficult to treat. In a retrospective study, 113 children with ADHD and nocturnal enuresis had a far worse outcome on alarm treatment than controls (with nocturnal enuresis only): 43% (vs. 69%) were dry at 6 months and 19% (vs. 66%) at 12 months. There was no difference if they were treated with medication, which does not require active cooperation. Non-compliance was reported in 38% of child with ADHD, but only in 22% of the controls [36]. Therefore, the comorbid diagnoses of both enuresis and ADHD require special attention – and both need to be treated separately.

b) Urinary incontinence (daytime wetting)

Far fewer studies have addressed the specific problems of daytime wetting children. In a study in a paediatric setting of 418 children aged 5 – 17 years, day wetting children were described as being more stubborn, oppositional and secretive than nocturnal enuretic children [37]. In a subgroup of 58 children, those with and without urinary tract infections were compared. 11 % of day wetting children with urinary tract infections had a CBCL total score in the clinical range, 35 % of day wetting children without urinary tract infections and 16 % of nocturnal wetters. In other words, the subgroup with a higher risk for behavioural problems were day wetting children without urinary tract infections [37]. In another study, 90 girls with recurrent UTI’s had significantly more behavioural abnormalities than controls [38], so that the issue of behavioural problems in children with and without UTI’s remains to be settled.

ADHD is a common problem among day wetting children, as well. Compared to controls, children with ADHD had more symptoms of incontinence, constipation, infrequent voiding and dysuria [39]. With ADHD, treatment outcome is worse. In a retrospective analysis, 68% of day wetting children with ADHD became dry compared to 91% of controls. Non-compliance was much higher for timed voiding [36].

*NW = night wetting (nocturnal enuresis)  
*DW = daytime wetting (urinary incontinence)
Daytime wetting (urinary incontinence) is a heterogeneous group of disorders. According to the ICCS terminology, following subgroups can be differentiated [8]:

- Over-active bladder including urgency incontinence
- Voiding postponement
- Underactive detrusor
- Dysfunctional voiding
- Obstruction
- Stress incontinence
- Vaginal reflux
- Giggle incontinence
- Extraordinary daytime urinary frequency

Only some of these subgroups have been studied regarding comorbid psychological disorders.

Children with urgency incontinence have previously been considered to have few behavioural problems [40]. 29% of children with urgency incontinence had an ICD-10 diagnosis and 14% had an internalizing disorder. 13.5% had a clinical total problem score in the CBCL – again mainly internalizing problems [41, 42]. The children are distressed by their wetting and family functioning is intact [42]. In a new study, 35% of children with urgency incontinence fulfilled the criteria for an ICD-10 diagnosis [24]. In summary, children with urgency incontinence have only a slightly increased rate of comorbid psychiatric disorders. If they are affected, emotional, introversive symptoms predominate.

Children with voiding postponement, on the other hand, fall into two groups: in some it represents an acquired habit, in others, it is associated with externalising psychological disorders, especially oppositional defiant disorder (ODD). In a systematic study of children with voiding postponement in a paediatric and child psychiatric setting, 53.8% fulfilled the criteria for at least one ICD-10 diagnosis [41]. These were mainly externalizing disorders in a third of all children such as Oppositional Defiant Disorder (ODD). Also, 37.3% of children had a CBCL total score in the clinical range, again, with externalizing symptoms predominating. In addition, family functioning was impaired [41, 42]. In a new sample, 53% of children with voiding postponement had at least one ICD-10 diagnosis [24]. In summary, children with voiding postponement have highly increased psychiatric risks.

Systematic studies on comorbid behavioural problems in children with underactive bladder have not been performed, although by clinical impression the rate of associated problems is high. In the original article, the “lazy bladder syndrome” was described as an acquired behaviour: it has “developed from the habitual neglect of the patient to empty the bladder on getting the urge to micturate” [43].

Systematic investigations of psychological aspects of dysfunctional voiding are rare. Again, in some children it represents an acquired habit, in others severe psychological disturbances are present [44]. Also, dysfunctional voiding following severe sexual abuse and deprivation as well as other familial stressors such as migration has been described in case reports [45].

There have been no systematic investigations of children with giggle incontinence. From clinical experience, they are highly distressed by the symptom and try to avoid situations in which they might be forced to laugh. Social withdrawal, not going to parties and meeting with friends have been observed. It is not known if the rate of behavioural disorders is increased, however.

Regarding the other subtypes of urinary incontinence, not even anecdotal data is available.

### IV. CLINICAL BEHAVIORAL DISORDERS IN CHILDREN WITH FECAL INCONTINENCE (FAECAL INCONTINENCE)

According to the Rome-III classification, two subtypes of faecal incontinence can be differentiated [9]:

- Functional constipation (with or without incontinence)
- Nonretentive fecal incontinence.

#### 1. EPIDEMIOLOGICAL STUDIES

In the large Alspac study of 8242 children aged 7-8 years, children with faecal incontinence had significantly increased rates of separation anxiety, specific phobias, generalised anxiety, ADHD and ODD (Table 6) [46].

In other words, soiling children show a completely heterogeneous pattern of both internalising and externalising disorders. Again, these will require assessment in the individual child, as they will interfere with treatment of the incontinence.

#### 2. CLINICAL STUDIES

As many studies have used the Child Behaviour Check List (CBCL) [47], the results can be compared easily. As shown in table 4, 35% to 50% of all children with faecal incontinence had a total behavioural score in the clinical range in this parental questionnaire. Compared to the normative population (10%), 3.5 to 5 times more children with faecal incontinence have total behaviour scores in the clinical range. As all studies were conducted in a paediatric setting, this rate...
cannot be due to selection effects of mental health clinics. Children with behavioural maladjustment are less compliant than children without psychological disorders (71% vs. 38% non-compliant) – so if these problems are not addressed treatment will be less successful [48].

Encopretic children with constipation have the same rate of behavioural scores in the clinical range as children without constipation (39% vs. 44%, Benninga et al. 1994; and 37% vs. 39%, Benninga et al., 2004). In other words, the two major types of faecal incontinence cannot be differentiated according to the behavioural comorbidity. More importantly, regarding the aetiology, there’s no evidence that one type (i.e. with constipation) has more somatic, while the other type (i.e. without constipation) a more psychogenic aetiology. Also, there is no specific psychopathology typical for faecal incontinence – all types of behavioural and emotional disorders can co-exist.

Internalising clinical behavioural scores (32%) were twice as common as externalizing ones (17%) in one study (54). In others, single behavioural items, denoting oppositional behaviour and attentional problems predominate [49, 55]. Compared to controls, children with faecal incontinence rated significantly higher regarding anxious/depressed behaviour, attentional difficulties and disruptive behaviour on the CBCL subscales. For example, the rate of children with attentional problems in the clinical and borderline range was 6-7 times higher than in controls (20% vs. 3%; norms 5%) [56]. Again, the heterogeneity of behavioural symptoms is apparent.

Only few studies have assessed behavioural and emotional disorders according to standardized child psychiatric criteria. They also show a high general

</table>
rate and heterogeneity of comorbid disorders. Thus, 34% of 41 children with faecal incontinence had an emotional disorder, 12% a conduct disorder and 10% a hyperkinetic syndrome according to ICD-criteria [57]. In another study of highly selected 85 child psychiatric inpatients with faecal incontinence, 83% fulfilled the criteria for at least one ICD-10-diagnosis. 32% had a hyperkinetic syndrome, 21% an emotional disorder and 9% a conduct disorder [58]. Children with faecal incontinence and urinary incontinence have an even higher rate of behavioural and emotional disorders than children with wetting problems alone [59].

The co-occurrence of faecal incontinence and sexual abuse has been described by several authors [60]. In one study, 36% of abused boys had faecal incontinence [61], but other symptoms can co-exist [62,63]. However, in a retrospective analysis of 466 children having experienced sexual abuse, 429 children with externalising disorders and 641 controls, the occurrence of faecal incontinence did not differ between groups (faecal incontinence in 10.3%, 10.5% and 2%, respectively) [64].

V. SUBCLINICAL SIGNS AND SYMPTOMS

Subclinical behavioural signs and symptoms are common, understandable, adequate reactions towards the wetting problem and not disorders. Many studies have addressed the impact of wetting on children.

1. IMPACT ON CHILDREN

Most children are distressed by enuresis. For example, 35% said that they felt unhappy, 25% even very unhappy about wetting at night in one study (40 children aged 5-15 years) [65]. In a Finnish population-based study, 156 day and night wetting children (from 3375 7-year olds) showed significant differences compared to 170 controls regarding following personality traits [66]: they were more fitful (vs. peaceful), more fearful (vs. courageous), more impatient (vs. calm), more anxious (vs. does not worry) and had more inferiority feelings (vs. feels equal). In a large population-based British study of 8209 children aged 9 years, 36.7% of children consider bed-wetting to be “really difficult” – ranking 8th behind other stressful life-events [67].

In a clinical study, 70.3% of day and night wetting children aged 5 to 11 years could clearly indicate that the wetting was of disadvantage [68]. The types of disadvantages or negative consequences were: social (I can’t sleep at friends’ house, friends can’t stay over night – in 32.1%), affective (I feel sad, ashamed, annoyed – in 16.4%), of isolation (I feel like a baby, nobody is allowed to know about it, I feel different from other children – in 6.7%), of sensation (it feels unpleasant, cold, wet, itchy, nasty – in 32.1%) or referred to direct consequences (I have to take a shower, sleep in pampers, won’t get a bicycle – in 17.6%). Only 4.9% reported any advantages of the wetting at all (I like the wet feeling, get more attention from mother).

One construct of special importance is that of self-esteem. In one study, lower self-esteem in children with enuresis disappeared upon attaining dryness [69]. In another, global self-esteem was significantly lower in children with nocturnal enuresis than in controls [70] and in yet another, the self-esteem total score was higher among enuretics than norms [71]. Therefore, it was concluded that there is no clear evidence that bedwetting leads to lower self-esteem [72] – but there can be no doubt that self-esteem can improve upon attaining dryness [71]. Self-esteem even increases even if treatment of enuresis is not successful [73], showing that care and “good doctoring” for children and parents is of great help – regardless of outcome. Recently, a focus has been on quality of life, which is reduced in children with urinary incontinence [74].

In a population-based study of 75 boys with faecal incontinence were compared to 73 matched controls as shown in table 16.9 [75]. Specifically, encopretic boys showed higher rates of food refusal, general negativism, strong anxiety reactions, lack of self-insurance, poor tolerance to stress, both inhibited and aggressive behaviour, a strong fixation to their mother and difficulties in relationships. Also, children with faecal incontinence tended to feel less in control of positive life events and had a lower sense of self-esteem than children with other chronic conditions [76]. However, in a more recent study, self-esteem did not differ between children with faecal incontinence and controls on the Piers-Harris questionnaire [77]. Although some of these subclinical symptoms will diminish under successful treatment [53,54], it is not known which ones will persist and chronify.

2. IMPACT ON PARENTS

Enuresis and urinary incontinence may be just as distressing for parents as for children. Generally, parents are very concerned about the welfare of their child. In a population based study, 17% worried a great deal and 46% some or a little [78]. In one study, the greatest maternal concerns were: emotional impact, social relationships, smell, extra washing and financial aspects [79]. Mothers of children with nocturnal enuresis had a reduced quality of life scores (bodily pain and emotional role) and more depressive symptoms [80].

Parents also believe that their child should be dry at a very early age, which can induce anxiety and stress: the mean anticipated age of dryness was 3.18 years in one study [81] and 2.75 years in another [82]. Also,
many parents think that emotional factors are the cause of nocturnal enuresis and forget that they might be the effect of the wetting problem instead [81,82].

A minority of parents show an attitude that was described as “maternal intolerance” by Butler et al [79]. Convinced that their child is wetting on purpose, the risk for punishment is increased. The reported rates of punishment varied from 37% [85], 35.8% [81], 23% [82] to 5.6% [84]. In other cultures, punishment is even more common: 42% of Turkish children were spanked and 13% beaten [85]. Chinese parents show a high level of parenting stress associated with externalising behavioural problems or their child [86]. These parental attributions and experiences have to be taken into account in all treatment plans for enuresis, as they can decisively influence the outcome.

Parents of children with faecal incontinence are also stressed and worried the problem (87). In one study, children with faecal incontinence had family environments with less expressiveness and poorer organisation than controls (77). In another study of 104 families, nearly half (51%) had no unusual family problems; 23 had severe and widespread difficulties including sexual abuse; 11 families described moderate difficulties and 18 a single traumatic event [88]. In other words, the atmosphere was warm and supportive without major difficulties in at least half of the families.

VI. GENERAL PRINCIPLES: ASSESSMENT

1. SCREENING QUESTIONNAIRES

Due to this high comorbidity of psychological symptoms as well as disturbances, every child should be screened as part of the routine assessment. The best screening instrument is still a good history and careful clinical observation, which requires some training and experience. The second best approach is screening questionnaires, such as the Child Behavior Check List (CBCL) [47], which contains 113 empirically derived behavioural items. These are checked on a three-point scale and are formulated in simple wording. From these items, eight specific syndrome scales and three general scales can be calculated.

Recently, even shorter screening instruments have been derived from the CBCL. Thus, Van Hoecke et al. (89) validated a short questionnaire consisting of 7 items for emotional problems, 3 for attention problems and 3 for hyperactivity/impulsivity. This is an extremely useful short questionnaire both for clinical and research uses.

Also, other useful questionnaires addressing specific aspects of enuresis have been developed [90]. These assess the subjective views and attributions of parents and children, such as parental intolerance. Another potentially useful questionnaire addresses aspects of everyday burden of enuresis on children and their families [91]. Other non-validated questionnaires for the assessment of children with all types of incontinence can be found in von Gontard and Neveus [8].

For children with faecal incontinence, the Virginia-Faecal incontinence-Constipation-Apperception Test (VECAT), a validated, picture-based questionnaire for children and parents was shown to differentiate well regarding bowel-specific problems [92].

One construct of special interest in children with elimination disorders is that of self esteem.

Well-known self-esteem questionnaires include the Piers-Harris Children’s self – concept scale [93] as well as others [94]. Another important construct is that of health related quality of life (HQOL). This is a complex construct that tries to assess health related wellbeing in different domains of daily life. Generic HQOL questionnaires allow comparison between children with different medical disorders [95,96]. These range from short screening to longer, more detailed questionnaires (such as the KINDL-questionnaire) [97]. Recently, the first specific quality of life questionnaire for children with wetting problems was developed by Bower et al. [98]. These have the advantage that the specific, elimination-related effects on daily life can be assessed. For children with faecal incontinence, health-related quality of life questionnaire with good psychometric properties was described. The Defecation Disorder List (DDL) consists of 37 items and can be used in children with all types of faecal incontinence and/or constipation [99].

2. CHILD PSYCHIATRIC ASSESSMENT

A child psychiatric assessment is a professional procedure with the goal to come to a categorical decision: to see if a diagnosis according to the standardised classification schemes (ICD-10 or DSM-IV) is present in the child or not.

The first step is a detailed developmental, behavioural and family history in much greater detail than provided in the outline in the appendix. The next step is to observe the child as well as the parent-child-interaction, followed by an active exploration of the child. The information gained from history, observation and exploration forms the basis of the mental state examination. This is a descriptive, phenomenological assessment of mental and behavioural signs and symptoms (for example: CASCAP-D) [100].

Questionnaires are always an essential part of child psychiatric assessment. They are a time-economical way to gather information from different informants. They can contribute towards but do not provide a diagnosis. Behavioural questionnaires can again be divided into general and specific questionnaires. The best known, most widely used general parental questionnaire is the Child Behavior Check List, which
has been translated into many languages (CBCL/4-18) [47]. In the meantime, Achenbach and co-workers have produced a whole “family” of questionnaires for different age groups (infants, children – adolescents, young adults) and different informants (parents, teachers and for children themselves starting from age 11). In addition, other specific questionnaires address circumscribed areas such as depressive symptoms or ADHD problems.

An intelligence test is not routinely indicated in the assessment of children with elimination disorders, as the IQ is in the normal range for most children with wetting, as well as soiling problems. However, the rate of elimination disorders is clearly increased in children with general developmental disorders, with mental and physical handicap [101-103]. If a lower intelligence is suspected, one-dimensional tests (such as the CFT or CPM/SPM tests) or multidimensional tests such as the Kaufman or the Wechsler tests can be performed. If specific developmental disorders such as dyslexia or dyscalculia are suspected, specific tests for these circumscribed disorders are indicated. Disorders of speech or language (such as articulation, expressive and receptive speech disorders) require a detailed assessment by an audiologist and speech therapist.

Motor disorders can be assessed clinically by including soft neurological signs in the physical examination of children or by standardized tests such as the Zurich Motor Tests [104,105].

After the diagnostic process has been completed, the child’s disorder is diagnosed according to standardized classification schemes. The two standard classification systems are the ICD-10 [10], which is widely used in Europe and in other parts of the world and the DSM-IV [11] employed in the United States. In child psychiatry, a multiaxial classification is used. Six different axes denoting different domains are used, including:

1. Axis: clinical psychiatric diagnosis (such as anorexia nervosa, depressive episodes, etc.)
2. Axis: specific developmental disorders (such as dyslexia)
3. Axis: intelligence (such as dyslexia, speech and motor disorders)
4. Axis: somatic diagnosis (such as epilepsy and other paediatric diagnoses)
5. Axis: psychosocial risks occurring within the last six months (such as distorted intrafamilial interaction, isolated family and other stressful life events)
6. Axis: the global severity of a disorder (ranging from mild incapacitation to disorders requiring constant supervision and guidance)

Only after the diagnostic process has been completed and discussed with parents and children, should therapeutic interventions be planned.

**VII. GENERAL PRINCIPLES: TREATMENT OF PSYCHOLOGICAL DISORDER**

For most children with elimination disorders, a symptom-oriented approach is sufficient. If, however, another, co-occurring child psychiatric disorder is present, additional types of treatment will be necessary. In these cases, a differential indication for therapy is mandatory. The question is: which treatment is most effective for this child in this family at this moment?

For some disorders (such as ADHD), medication plays a major role. For most others, psychotherapeutical interventions are the first-line treatment. There can be no doubt that psychotherapy in children is effective. In one of the best and largest meta-analysis of 150 studies, Weisz et al. [106] conclude that “psychotherapy with young people produces positive effects of respectable magnitude” (i.e. effect sizes in the medium to large range - 0.5 to 0.8). It has been estimated that over 500 different types of psychotherapies exist in the USA for children and adolescents alone [107]. Of those which have been evaluated, four basic schools of psychotherapy can be differentiated: 1. depth psychology (or psychoanalysis), which addresses and works with unconscious aspects of the psyche; 2. Client-(or child) centred-psychotherapy, which focuses on the current conscious experience of the child and the healing aspects of their therapeutic relationship; 3. Family therapy, which focuses on the interaction between family members but not the individual person; 4. Cognitive-behavioural therapy, focussing on cognitions and observable behaviour.

Before initiating any psychotherapy, a differential indication for therapy as to be made. The first basic question should be: is treatment needed at all? In many cases counselling of parents and child is all that is required. In other cases, changes in the child’s environment (such as changing school) or help from social services can be more useful than psychological treatment in the narrower sense.

The modality has to be considered. Although parents are nearly always included, the focus can be on an individual, group or family therapy. The intensity and duration have to be addressed: is a short focal therapy focussed on one specific problem needed or a longer, more general treatment? The age of the patient plays an important role: while older children and adolescents can be reached verbally, younger children require play or other non-verbal media in their therapy.

Psychotherapies can be combined with other methods, such as pharmacotherapy, but also with speech, occupational, physio-, music- and other types of therapies – if indicated. The decision should no longer be based on personal inclinations. Instead, empirically based “practice parameters” or “guidelines” have been
developed in many countries. These interventions are usually performed on an out-patient basis. Day clinic treatment can be indicated in more severe disorders, which require a more intense approach and management. Finally, in-patient child psychiatric treatment is indicated in severe disorders, in which a more intense type of treatment is possible.

A major part of therapy of incontinence in children is non-pharmacological and non-surgical. The term urotherapy is used in some countries. It is an umbrella term which has been defined as a “type of training which makes use of cortical control of the bladder, teaching children to recognize and employ conscious command over their lower urinary tract. Its main ingredients are information about normal lower urinary tract function and the specific dysfunction in the child, instruction about what to do about it and support and encouragement to go through with the training program” [108].

Although not a psychotherapy in a narrow sense, it employs many psychotherapeutical techniques borrowed especially from counselling and cognitive-behavioural therapies. As these approaches have been shown to be most effective, basic principles and findings shall be outlined.

1. UNSPECIFIC APPROACHES

The first step in any diagnostic and therapeutic process is to create a good relationship to both the child and the parent. One should enquire and talk about all relevant facts, signs and symptoms openly. It is also important to ask about the subjective meanings and connotations. Next, the provision of information is essential, because many facts are not known. It is often forgotten that not only parents but each child needs information, as well. This should be provided in words and concepts that a child understands and in a format that is attractive. Increasing motivation and alleviation of stress and guilt feelings are also part of all patient contacts.

2. COUNSELLING

Counselling is already part of the treatment process, which has been defined as the provision of assistance and guidance in resolving personal, social, or psychological difficulties. For many children, even with psychological disorders, counselling is, in fact, sufficient. Sometimes, it can be helpful to enhance the verbal counselling by other techniques. One simple technique is that of “demonstration”, e.g. actively showing how an alarm works. In “coaching”, parents and children take an even more active role, e.g. they set and activate an alarm themselves. They can be observed and corrected. Other techniques might include “modelling” and “role-playing”. The learning effect is much greater in these active forms of teaching than in solely verbal counselling.

3. COGNITIVE-BEHAVIOURAL THERAPY

Cognitive-behavioural therapy (CBT) is a subtype of psychotherapy that has shown to be effective for many disorders. Cognitive therapy focuses on irrational, dysfunctional conditions, thoughts and beliefs. Cognitive therapy encompasses a whole variety of techniques such as “self-monitoring” (observation and registration), “activity scheduling” (organisation of activities) and “labelling” (using positive suggestive statements). Behavioural therapy concentrates on observable behaviour, which it aims to modify with a variety of techniques. These include “classical conditioning” and “operant conditioning”, which basically means learning by success, which can be achieved by different strategies using positive or negative reinforcement.

4. BASELINE AND OBSERVATION

Baseline and observation are effective techniques used in cognitive-behavioural therapy. Children (and parents) are advised to observe a defined symptom. Different parameters such as frequency (how often it occurs), severity (how marked it is), symptomatology (in what form it occurs) and in which situation (associated factors) can be registered, e.g. in an observation chart. The mere observation and registration actually has a therapeutic effect and many symptoms actually diminish simply if they are observed.

In nocturnal enuresis, children are asked to fill out a calendar or chart depicting the wet and the dry nights symbolically for two to four weeks [109,110]. These non-specific measures have been shown to be successful and are associated with fewer wet nights [3,111]. In one clinical trial, for example, 18% became dry after an 8-week baseline [112]. The authors of the recent Cochrane Review conclude that “simple methods could be tried as first line therapy before considering alarms or drugs, because these alternative treatments may be more demanding and may have adverse effects” [3, 5].

In urgency incontinence, the cognitive aspects are stressed in treatment: children are asked to register feelings of urgency, refrain from using holding manoeuvres, to void and register the voiding (or any wetting) in a chart [113,114]. For children with voiding postponement, timed voiding 7 times a day and registration in a chart is recommended [114].

For all children with faecal incontinence, stool regulation is an essential part of treatment. Children are asked to sit on the toilet three times a day after meal-times in a relaxed mode for five to ten minutes.
5. BIOFEEDBACK

Biofeedback has been shown to be effective in some elimination disorders such as dysfunctional voiding [118]. It is defined as a variety of techniques, by which physiological activity is registered, enhanced and presented to the patient in real time by visual and acoustical signals [118]. In faecal incontinence, biofeedback is no more effective than standard behavioural techniques in faecal incontinence both with [119] and without constipation [120] and is not recommended in a systematic Cochrane Review [6].

6. ALARM TREATMENT

Alarm treatment for nocturnal enuresis is also a type of cognitive behavioural therapy. It works by positive reinforcement, as well as aversive, negative experiences and has been shown to be highly effective and was introduced by Mowrer and Mowrer [121].

It is the most effective form of treatment of nocturnal enuresis with the best long-term results (grade I level of evidence according to reviews and meta-analyses). Houts et al. [122] compiled a systematic review and meta-analysis on 78 randomised studies on nocturnal enuresis. 62% were dry at the end of treatment and 47% at follow-up. The authors conclude that “urine alarm treatments should not only be considered the treatment of choice, but the evidence from this review suggests that cure rather than management is a realistic goal for the majority of children suffering from nocturnal enuresis”.

Lister-Sharp et al [111] provided a systematic review, including only RCT’s on nocturnal enuresis. The likelihood for 14 consecutive dry nights was 13.3 times higher than without treatment. The authors conclude that “in the long term, alarm treatment would appear to be the most clinically effective and because the cost of drug therapy, also the most cost effective intervention”. Mellon and McGrath’s [123] compiled a systematic review on 70 well-controlled outcome studies. With a dryness rate of 77.9%, alarm treatment is deemed clearly efficacious. A comprehensive narrative review was written by Moffat [124] concluding that “all the current evidence suggests that conditioning gives the best long-term outcomes for bed wetters”.

Finally, a Cochrane review of 50 RCT’s involving 3257 children concluded: “Alarm interventions are an effective treatment for nocturnal enuresis. Alarms appear more effective than Desmopressin or tricyclics because around half of the children remain dry after alarm treatment stops” [2].

Therefore, when indicated, alarm has been endorsed as a first line treatment by multidisciplinary European [125], world-wide [126], German [110] and American child psychiatric guidelines [109], as well as various individual authors [127].

The effect of alarm treatment can be enhanced by adding additional behavioural components to the treatment. Programmes that include alarm in addition to other behavioural components showed following general effects: 72% of children became dry at the end of treatment, and 56% remained so at follow-up (meta-analysis) [122], so that combinations were considered as “probably effective” [123].

These specific programmes including alarm are all essentially cognitive-behavioural techniques. Arousal training is a simply and easily performed [128,129]. Children are instructed to turn off the alarm within three minutes, go to the toilet and reset the alarm. This goal is reinforced positively with two tokens. If the goal is not reached, one token has to be returned. The initial success rate (89 %) and the rate of dryness after 2 ? years (92 %) were higher than with alarm treatment alone (73 % and 72 % respectively) [128].

Dry Bed Training is a complicated program starting with an intensive night and maintenance treatment and using positive, as well as negative reinforcers [130]. Despite high success rates reported in early studies [130], recent meta analysis have shown that DBT is no more effective than alarm treatment alone [111]. The likelihood to attain 14 consecutive dry nights was 10 times higher than in controls without treatment – but not different from alarm treatment alone. Also, alarm is the most important component of DBT. DBT without alarm showed only a 2.5 times higher likelihood of attaining dryness than controls. The relapse rates were not improved by DBT compared to alarm treatment alone [111]. As it is a cumbersome treatment, it nowadays it is reserved for children and especially adolescents with therapy-resistant nocturnal enuresis, as it “may augment the effect of an alarm” and “might reduce the relapse rate” (3). Thus, Hirasing et al. [28] could show that behavioural problems were reduced in children with persistent nocturnal enuresis treated with DBT.

Other programmes include the Full spectrum home treatment. This is a combination package including a written contract, full arousal, overlearning and bladder retention exercises [122]. 78.5% of children became
CONCLUSION AND SUMMARY

This review summarised the most important psychological aspects in children with enuresis, urinary incontinence and faecal incontinence. The rate of comorbid clinical behavioural disorders is increased. Children with urinary incontinence are more affected than those with nocturnal enuresis. Children with secondary and non-monosymptomatic nocturnal enuresis have especially high rates of comorbid psychological disorders. The most common single diagnosis is ADHD.

Children with daytime wetting have mainly externalising behavioural disorders. Children with urgency incontinence have a low comorbidity, those with voiding postponement are characterised by oppositional behaviour. Children with faecal incontinence have the highest rate of associated disorders – both internalising and externalising. These disorders will not disappear upon attaining dryness. They have to be addressed, as they will interfere with the incontinence therapy due to low compliance.

Even if comorbid disorders are not present, children and parents are highly stressed by the incontinence. These subclinical symptoms will often recede upon successful treatment.

Questionnaires are useful as screening instruments in the assessment process. If a psychological disorder is suspected, a full child psychiatric assessment and treatment or needed. The basic principles, including those of psychotherapy, are outlined. Psychothe-rapeutic techniques are used in urotherapy, especially cognitive-behavioural elements. Non-pharmacological and non-surgical techniques are most effective for most forms of incontinence based on systematic reviews. Therefore, it is important that psychological aspects are integrated into the treatment of children with incontinence problems.

Neurologic Urinary and Faecal Incontinence

J.J. Wyndaele,

A. Kovindha, H. Madersbacher, P. Radziszewski, A. Ruffion, B. Schurch, Y. Igawa, R. Sakakibara

A. INTRODUCTION

This chapter deals with all aspects of neurologic urinary and faecal incontinence. To combine this information related to two different structures makes this chapter rather unique though there are sufficient arguments to do so, as presented below.

Its content is written from data found in literature with the keywords “neurologic”, “neurogenic”, “bladder”, “bowel”, “lower urinary tract”, “anorectal”, “incontinence”, “continence”, “urinary”, “faecal”, “paralysis”, “dysfunction”, “retention”, “constipation” and the list of the specific neurologic diseases as described in chapter E. Important information from the previous ICI report was used as starting point and some is used as such in this chapter, which is intended to be able to stand alone. For some topics more elaborate information will be found in other chapters as on neurophysiology, diagnostics, urodynamic testing, female, male, frail elderly, faecal incontinence and more. To look up the related information in these chapters will be worthwhile. Also in chapter E not all neurologic diseases will be found as we decided in consensus to look into the most prevalent or consisting of the more challenging in diagnosis and or treatment of incontinence. Other colleagues might have made a different choice.

It is known that the lower urinary tract (LUT) and the lower bowel tract (LBT) are interrelated structures. Embryologically bladder and rectum originate from the same basic structure, the cloaca [1]. Anatomically both viscera lay in close communication and share muscular structures of the pelvic floor.

The innervation of both systems depends on autonomic and somatic nerves (Figure 1) that carry fibres of both. In table 1 a simplified overview is given of the action linked to different peripheral nerves.

Table 1. Overview of function of the abdominal sympathetic (Sym), the pelvic parasympathetic (PSym) and somatic (Som) nerves in the LUT and LBT. US = urethral sphincter, AS = anal sphincter. Exp = only suggested in animal experiments, no clinical evidence.

Central control of both continence and evacuation is similar and is discussed in the chapter on physiology [2].

Very generally LUT and LBT act quite similar, both are autonomic organs regulated to necessary social requirements by a somatic innervation. The voluntary control depends on accurate sensation [3]. Continence relates to contraction of smooth closing structures (bladder neck and internal bowel sphincter) and striated urethral and anal sphincters. An inhibitory effect on detrusor and lower rectum resulting from contraction of the pelvic floor and anal or urethral sphincter has been named a “procontinence” reaction. Micturition and defaecation need a proper relaxation of these latter structures to permit a physiological reflex evacuation of urine or faeces.

Interactions between both functions have been demonstrated. The filling status of the bladder influences sensation in the rectum and vice versa [4]. A vesico-ano-rectal reflex permits voiding without
Figure 1: Schematic overview of innervation of LUT and LBT

Figure 2: Frequent sites of neurologic pathology causing neurologic urinary and faecal incontinence.
defaecation [5]. When the bladder is full, sensation of rectal filling is decreased. When healthy people visit the toilet to defaecate, the initiation of micturition often precedes that of defaecation, even if both organs are considered equally full [6]. The prevalence of both urinary and bowel dysfunction is high in many neurological diseases.

There is no study so far on correlation between both functions in patients with neurological pathology.

In this chapter levels of evidence (LOE) and grades of recommendation (A) are used as described in the general introduction of this book.

B. PATHOPHYSIOLOGY

With a neurologic lesion the type of dysfunction that follows in LUT and LBT will depend on the site, the extent and the evolution of the lesion.

Traditionally neurological pathology has been divided in suprapontine, suprasacral spinal cord and subsacral (cauda equina and peripheral nerve) lesions (Figure 2).

I. SUPRAPONTINE LESIONS

Patients with lesions above the pons usually continue to have reflex contractions of the detrusor. But the cerebral regulation of voiding and defaecation is often lost. This is the case in lesions as from stroke, head injury, etc, which mostly continue to have a normal coordinated sphincter function. However these patients may purposely increase sphincter activity during an overactive detrusor contraction [7] to prevent urinary incontinence which would otherwise occur. This has been termed "pseudo-dyssynergia" because it is indistinguishable from true dysynergia on a urodynamic record. Urinary incontinence in suprapontine lesions is due to bladder overactivity [8].

II. SPINAL CORD LESIONS

1. SUPRASACRAL SPINAL CORD LESION

When a lesion is located in the spinal cord below the pons detrusor- urethral sphincter dysynergia is a common finding. Incontinence may still be caused by detrusor overactivity but the outflow obstruction can also cause retention.

Patients with lesions above the cone usually suffer from an overactive bowel with increased colonic wall activity and anal tone. The central control of the external anal sphincter is disconnected and the sphincter remains tight thereby retaining stool (Dyssynergia). The connections between the spinal cord and the colon remain intact, permitting reflex coordination and stool propulsion. This type of lesion provokes faecal retention at least in part due to the activity of the anal sphincter. Incontinence can be a consequence of faecal impaction and constipation.

2. CONUS LESION

If the nuclei of the pelvic nerves are destroyed, the detrusor becomes areflexic. Retention of urine can provoke stress incontinence (formerly termed overflow incontinence).

III. SUBSACRAL LESIONS (CAUDA EQUINA OR PERIPHERAL NERVES)

The same effect as from lesions of the conus medullaris can result from lesions of the subsacral nerves (cauda equina or peripheral nerves). If the nuclei of the pudendal nerves are harmed, a paralysis of the urethral sphincter and pelvic floor muscles will occur often with loss of outflow resistance and stress incontinence.

A neurological lesion affecting the parasympathetic cell bodies in the conus medullaris will eliminate the pelvic nerve function of the bowel. No spinal-cord mediated peristalsis will occur. It will be the myenteric plexus that coordinates segmental colonic peristalsis. If the pudendal nerve is also destroyed, there is an increased risk for incontinence. Apart from the non contractile external anal sphincter, also the puborectal muscles lack tone, which leads to reduction of the rectal angle. Constipation and incontinence are frequent.

While most traumatic spinal cord lesions give LUT and LBT dysfunctions which can be predicted fairly well from the level and completeness of injury [9], the LUT and LBT function in many other neurologic diseases such as meningomyelocele are more difficult to categorise [10]. Therefore in this chapter a number of neurologic diseases will be described more in detail.

C. NEUROLOGIC URINARY INCONTINENCE

I. EPIDEMIOLOGY

NLUTD may be caused by various diseases and events affecting the nervous systems controlling the LUT. The resulting lower urinary tract dysfunction (LUTD) depends grossly on the location and the extent of the neurological lesion.

Overall figures on the prevalence of NLUTD in the
general population are lacking, but data are available on the prevalence of the underlying conditions and the relative risk of those for the development of NLUTD. It is important to realise that most of these data show a very wide range of prevalence figures due to low level of evidence in most published data and smaller sample sizes.

**Methodology**: Pubmed search from 2003 till 2008 with search words- epidemiology, neurologic bladder, neurologic incontinence, neurologic patients, prevalence- gave several references which were added to the list of the previous report 2005. Unfortunately only a very limited number gave data on prevalence and only in specific diseases for which a separate search was done. Data on incontinence are not always present in data on “neurologic voiding dysfunction” or “neurologic cystopathy”. No global meta analysis has been found.

In separate searches for specific diseases the prevalence data were also rather limited. Most studies were case series, some retrospective case control studies.

- Several factors can be the cause for this lack of overall data:
  - Neurologic problems of the LUT are not always specifically studied
  - Some disease are rare or have not been studied in detail
  - Series on urologic items deal mostly with urodynamic data, urologic complications or outcome of treatment and include only patients with a known neurologic bladder
  - In some neurologic diseases as spinal cord injury no data are to be found on those who did not develop a neurologic bladder.

**Results**: Following are the data found. While making an interpretation of these data one must realise that incontinence can be a direct consequence of the neurologic dysfunction of bladder, bladder neck or sphincter, but also because of lack of adequate treatment, infection or other anatomical or functional pathology. Literature review does not permit to differentiate between these causes.

1. **BRAIN-BRAIN STEM**

   **a) Brain tumours**

   Brain tumours can cause LUTD in up to 24% of the patients [1]. Mostly case reports-small series have been published more recently [2-3]. In a series of patients with brain tumours voiding difficulty was reported in 46/152 (30 %) of patients with tumours in the fossa posterior, while urinary incontinence occurred only in 3 (1,9 %) [4]. Urinary retention was found in 12/17 children with pontine glioma [5].

   **b) Dementia**

   One can not easily distinguish LUT problems caused by age-related changes of the bladder from those due to other concomitant diseases [6]. Therefore the true incidence of incontinence caused by dementia is not known. It has been shown that in geriatric patients with dementia, incontinence is much more frequent than in non dementia patients [7-8].

   Alzheimer, Lewy body dementia, Binswanger, Nasu-Hakola and Pick diseases frequently cause non-specific NLUTD [9-13]

   The occurrence of incontinence is reported to be between 23% and 48% [14-15] in patients with Alzheimer’s disease. The onset of incontinence usually correlates with the disease progression [16].

   A male to female ratio of dementia related incontinence was found to be 1:15.

   **c) Mental retardation**

   In mental retardation, depending on the grade of the disorder a 12 % -65 % prevalence of LUTD was described [17-18].

   **d) Cerebral palsy**

   LUTD in around 30 – 40 % has been reported [19-20]

   **e) Normal pressure hydrocephalus**

   Only case reports of LUTD [21-23]

   **f) Basal ganglia pathology** (Parkinson (PD), Huntington, Shy-Drager, etc.)

   Parkinson’s disease is accompanied by NLUTD in 37.9-70% [24-26]

   In the Shy-Drager syndrome almost all patients have NLUTD [27] while incontinence was found in 73 % [28]. Gray et al [29] reported that LUT functional disturbances in PD are not disease specific and only correlated with age. Recent, control-based studies gave a prevalence of LUT symptoms (LUTS) of 27-63.9% using validated questionnaires [30-31], or 53% in men and 63% in women using a non validated questionnaire that included a urinary incontinence category [32]. All these values were significantly higher than in healthy controls. The majority of patients had onset of the bladder dysfunction after appearance of motor disorder.

   **g) Cerebrovascular (CVA) pathology**

   CVA causes hemiplegia with remnant incontinence NLUTD in 20-50% of patients [33-34] with decreasing prevalence in the post-insult period [35]. In 1996 Sakakibara et al [36] reported 53 % significant urinary complaints at 3 months. Without proper treatment six
months after the CVA, 20 % - 30 % still suffer from urinary incontinence [37]. The commonest cystometric finding was detrusor overactivity [38-43].

Sakakibara et al [44] reported the urinary symptoms of 39 patients who had brainstem strokes. Almost half the patients had urinary symptoms, nocturia and voiding difficulty in 28 %, urinary retention in 21 % and urinary incontinence in 8 %. A number of case reports describe difficulties with micturition in the presence of various brain stem pathologies [45-46].

2. BRAIN-SPINAL CORD

a) Demyelination

Multiple sclerosis causes NLUTD in 50-90% of the patients [47-49]. One finds 33 % to 52 % NLUTD in patients sampled consecutively regardless of urinary symptoms, with the incidence being related to the disability status [50]. There is almost a 100 % chance of having LUT dysfunction once these patients experience difficulties with walking. NLUTD is the presenting symptom in 2-12 % of the patients, going to 34 % in some studies [51]. LUT dysfunction appears mostly during the 10 years following the diagnosis [52].

b) Spinal cord lesions

Spinal cord lesions can be traumatic, vascular, medical, or congenital. An incidence of 10.4 to 83 per million inhabitants per year and a prevalence of 223-755 per million inhabitants worldwide. One-third of patients with SCI are reported to be tetraplegic and 50 % of patients with SCI have a complete lesion. The patients sustain their injury at mean 33 years old, with a the sex distribution (men/women) of 3.8/1 [53]. Most patients will develop NLUTD [54]. For spina bifida and other congenital nerve tube defects, the prevalence in the UK is 8-9 per 10,000 aged 10-69 years with the greatest prevalence in the age group 25-29 years [55]. In the USA the incidence is 1 per 1000 births [56]. The incidence of urethrovaginal dysfunction in myelomeningocele is not absolutely known, but most studies suggest it is very high 90%-97% [57]. About 50 % of these children will have detrusor sphincter dyssynergia (DSD) [58-59].

c) Disc disease

Disc disease will cause NLUTD in 28-87% of the patients [60-61]. Cauda equina syndrome due to central lumbar disc prolapse has been reported to be relatively rare, the incidence being from 1 to 5 % of all prolapsed lumbar disc [62-70]. Neurogenic dysfunction of LUT without cauda equina syndrome has been described as case reports [71].

d) Spinal stenosis and spine surgery

Spinal stenosis: About 50 % of the patients seeking help for intractable leg pain due to spinal stenosis report symptoms of LUTD such as sense of incomplete bladder emptying, urinary hesitancy, incontinence, nocturia or urinary tract infections [72]. These symptoms may be overlooked or attributed to primary urological disorders. Sixty one-62 % would suffer from NLUTD [73-74]. The prevalence of neurologic disorders more significantly associated with dural sac anteroposterior diameter than with the cross-sectional area of dural sac.

Spine surgery is related to LUTD in 38%-60% [75-76].

3. PERIPHERAL

a) Peripheral neuropathy

1. DIABETES: This common metabolic disorder has a prevalence of about 2.5% in the American population, but the disease may be sub clinical for many years. No specific criteria exist for secondary neuropathy in this condition, but it is generally accepted that 50% of the patients will develop somatic neuropathy and 75-100% of those will develop NLUTD [77-78]. Amongst different types of polyneuropathies in diabetic patients “diabetic cystopathy” occurs in 43% to 87% of insulin-dependent diabetics, with no sex or age differences [79]. It is also described in about 25% of diabetic patients on oral hypoglycemic treatment [80].

b) ALCOHOL ABUSE: Can cause peripheral neuropathy, but its reported prevalence varies widely: 5-15 % to 64% [81]. The NLUTD is probably more present in patients with liver cirrhosis. The parasympathetic system is attacked more than the sympathetic system [82].

Less prevalent neuropathies:
- Porphyria — bladder dilatation in up to 12% of patients [83].
- Sarcoidosis — NLUTD rare [84].
- Lumbosacral zona and genital herpes — Incidence of LUT dysfunction is as high as 28 % if only lumbosacral dermatome-involved patients are considered. The overall incidence is 4% [85-86]. NLUTD is transient in most patients
- Guillain Barré — The prevalence of micturition disorders varies from 25% to over 80% [87-88] regressive in most [89]. The true incidence is uncertain due to the fact that during the acute phase patients are usually managed by indwelling catheter.

4. OTHER

a) Systemic lupus erythematosus (SLE).

Nervous system involvement occurs in about half of patients. Symptoms of LUT dysfunction can occur; however, data on prevalence are rare and give an incidence of 1% [90-91].

b) HIV

Voiding problems have been described in 12% of HIV-infected patients, mostly in an advanced stage of the disease [92-93].
c) Regional spinal anaesthesia
This may cause NLUTD but no prevalence figures were found [94-95].

d) Iatrogenic
Abdominoperineal resection of rectum has been described to cause NLUTD in up to 50 % [96-97]. It would remain a long-term problem in only 10 per cent [98] though it remains open if this means that the neurological lesion heals or that bladder rehabilitation was successful. Surgical prevention with nerve preservation was shown to be important [99-100]. After simple hysterectomy [101] and after radical hysterectomy or pelvic irradiation for cervical cancer, from 8 to 57% NLUTD was described [102-105]. Surgical prevention is also possible here [106]. After radical prostatectomy neurologic dysfunction of the pelvic floor has been demonstrated [107].

CONCLUSIONS

• Neurologic dysfunction of the LUT occurs in many patients with neurologic disease but exact figures are seldom available
• Meta analysis of prevalence data could give a better idea of how important neurologic bladder is in the patients with neurologic diseases and in the prevalence of incontinence in this population.

RECOMMENDATIONS

• Because many diseases or lesions of the innervation can cause pathology of the LUT, patients with known neurologic disease should be evaluated for such dysfunction . (A)
• Such evaluation should be made not only when urinary symptoms occur but also as a standard diagnostic approach if prevalence of neurologic bladder is known to be high in a specific disease .(A)
• If “idiopathic” LUT dysfunctions occur, the possibility of an unknown neurologic cause should be acknowledged and the diagnostic steps taken to make a proper diagnosis. (A)

II. SPECIFIC DIAGNOSTICS

- Methods for diagnosis in neurologic LUT dysfunction and in neurologic urinary incontinence are not very different from what is done in non neurologic patients. It consists of clinical assessment including history and voiding diary, urodynamic studies including cystometry (+ EMG), video-urodynamics, uroflowmetry, pressure-flow study, diagnostic imaging with voiding cystourethrography and ultrasonography of the kidneys and LUT. These methods will be dealt with in the relevant chapters of this book (basic assessment, dynamic testing, imaging and other investigations) but we will highlight briefly some data specially related to neurologic patients.
  - Some tests developed for the diagnosis of neurologic dysfunction have been evaluated more specifically in this chapter: bethanechol supersensitivity test, ice water test.
  - Neurophysiologic studies can be found in the chapter “Clinical Neurophysiological testing”, and only some clinical relevant data on neurologic patients are given here.

Without any doubt before any functional investigation is planned, all “basic” data should be gathered and used for further interpretation of the NLUTD [1-2].

1. HISTORY

The general history aims at gathering information on the neurological and congenital abnormalities, previous urinary complications or treatments. Important are also use of medication with known or possible effects on the LUT, menstrual, sexual and bowel function, and obstetric history. Hereditary or familial risk factors, metabolic diseases and other must be known. Lifestyle factors such as smoking, alcohol, or addictive drug use as well as an evaluation of Quality of life are important.

The signs and symptoms that brings patient to consultation must be documented. Symptoms related to storage and voiding, continence and/or retention, as well as onset and nature of the NLUTD (acute or insidious) should be determined. If appropriate this information should be compared with the patients’ condition before the NLUTD developed.

Very important data are LUTS, urinary incontinence, bladder sensation, mode and type of voiding (catheterization). Warning signs and symptoms that warrant early further investigation are fever, pain, hematuria, catheterization problems, and clinical infections. However, as in non neurologic patients, the “basic tests” also have limitations: individuals with SCI were frequently not accurate at predicting whether they had a UTI based on their symptoms [3]

A urinary diary offers information on the number of voids (frequency and nocturia), the sensation at each void, volumes voided, incontinence, volume and time fluid intake. Voiding diary of 24 hours was shown to be reliable in women with urinary incontinence, but no information is available in patients with neurologic incontinence [4].
2. PHYSICAL EXAMINATION

a) General physical examination

A general impression of patient’s physical and mental possibilities from the beginning is important to guide the choice of investigations or to decide from the start to go for least invasive diagnosis and treatment. Severely impaired mobility, extreme spasticity, severe mental disorder, general weakness, presence of severe complications are all important in this respect. Patients with very high neurological lesions may suffer from a significant drop in blood pressure when moved in a sitting or standing position. Patients with spinal cord lesion above D 6 may develop autonomic dysreflexia.

The physical examination will evaluate external genital organs, perineal skin, lower abdomen, lower back. Palpation per vagina or per rectum is done in search of pelvic organ descensus or cervix-uterus/prostate disease.

b) Neuro-urological examination

As part of a general neurologic examination specific tests are done related to the lumbo-sacral innervation: sensation of touch in the different perineal dermatomes (Figure 3), evaluation of bulbocavernosus, anal and cremaster reflexes, tone of anal sphincter (Figure 4) and possibility to voluntarily contract the anal sphincter/pelvic muscles. A high correlation exists between the clinical neurological findings and the NLUTD in some types of neuropathy such as single level traumatic spinal cord lesions [5-6] but less in other types as in meningomyelocele or combined traumatic spinal cord lesions [7]. Urinary symptoms and pathological urodynamic findings increase along with the degree of motor function impairment in infantile cerebral palsy [8].
CONCLUSION

- A combination of data from a clinical neurological examination gives useful information which acceptably corresponds with the LUT function in patients with one level spinal cord injury but not in meningomyelocele patients
- To decide on a detailed individual diagnosis of LUT function in neurologic patients, history and clinical examination prove insufficient.
- In elderly male neurologic patients with possible BPH related obstruction, symptoms and clinical examination are not sufficient to differentiate between outflow obstruction and neurologic DOA.

3. URODYNAMIC TESTS

Classic urodynamic techniques permit us to get multiple functional parameters in patients with neurologic bladder [9].

The recently published International Urodynamic Basic Spinal Cord Injury (SCI) Data Set proposed data to be included in the urodynamic evaluation of patients with spinal cord injury: Variables included bladder sensation during filling cystometry, detrusor function, compliance during filling cystometry, function during voiding, detrusor leak point pressure, maximum detrusor pressure, cystometric bladder capacity and post-void residual [10].

- CMG + EMG has been studied by several authors:

  Sundin and Petersen [11] used cystometry-electromyography (EMG) investigation in patients with known or suspected neurologic disorders in whom a defect in bladder emptying, in spite of an active detrusor contraction, was found at cystometry. A voluntary control of the external urethral sphincter relaxation— independent of the degree of bladder filling—was found in most of the healthy volunteers. The cystometry-EMG investigation gave reliable information as to whether a DSD exists. Perkash [12] found rhythmic detrusor contractions on cystomanometry with associated marked increase in EMG activity on attempted voiding to be relevant characteristics of patients with DSD. Rodriguez et al [13] used EMG-gas cystometrogram to select SCI patients for removal of the Foley catheter. Important factors governing success were the amplitude of the detrusor contraction, the presence of detrusor-sphincter synergy and the presence of a flaccid sphincter. Mayo and Kiviat [14] used multichannel urodynamic studies in patients with incomplete bladder emptying secondary to suprasacral SCL. They found that bladder pressure and sphincter EMG measurement during voiding, combined with fluoroscopy, are ideal methods to identify the factors responsible for incomplete emptying in problem cases. Also Perlow and Diokno [15] and Koyanagi et al [16] found CMG-EMG very useful in SCI patients.

Blaivas et al [17] described on the basis of CMG-EMG 3 types of dyssynergia: type 1 had a crescendo increase in electromyographic activity that reached a maximum at the peak of the detrusor contraction, type 2 had clonic sphincter contractions interspersed throughout the detrusor contraction and type 3 was characterized by a sustained sphincter contraction that coincided with the detrusor contraction. There was no correlation between the clinical neurologic level and the type of dyssynergia.

Simultaneous recording of intravesical pressure, sphincter electromyography and uroflowmetry (CMG.UFM.EMG study) was compared by Aoki et al [18] with cystometry + EMG. They found some influence of the catheter in the urethra. Micturition pressure and opening pressure were larger with CMG+ EMG, incidence of detrusor-sphincter dyssynergia was greater. The authors also found that the Credé manoeuvre exaggerated the DSD. Urodynamics with EMG permitted Kirby [19] to differentiate between patients with pelvic nerve injury, distal autonomic neuropathy, progressive autonomic failure - multiple system atrophy, and idiopathic Parkinson’s disease. This influenced the selection of patients for transurethral surgery. Pavlakis et al [20] studied CMG concomitant with perineal floor and rectus abdominis EMG and concluded that the addition of EMG can improve the recognition of intravesical pressure elevation owing to voluntary contraction of the abdominal musculature. EAS motor unit potential (MUP) analysis and EMG cystometry were used to differentiate multiple system atrophy (MSA) from Parkinson’s disease in the first five years after disease onset. It showed that involvement of Onuf’s nucleus in MSA is time dependent. Before the fifth year of illness, the prevalence of neurogenic change does not seem to be high, so a negative result cannot exclude the diagnosis of MSA,[21]. Rapidì et al used combined urodynamic and electrophysiological study of diabetic cystopathy [22].

The importance of detrusor pressure has been acknowledged for many years. Also recently Bruschini et al [23] evaluated the upper and lower urinary tract in myelomeningocele patients without adequate urological management with clinical, urodynamic and imaging evaluation. The urodynamic data were correlated with the status of the upper urinary tract (UUT). The cystometry showed detrusor overactivity (DO), poor compliance, increased bladder capacity and normal cystometry in 48, 49, 2 and 1% of the patients, respectively. Detrusor leak point pressure (DLPP) over 40 cm H(2)O was associated with UUT damage. Patients with decrease on functional bladder capacity (FBC) < or= 33% had more renal scars than their counterparts. No difference in cystometric capacity
and intravesical leak point pressure at terminal detrusor overactivity was shown between complete and incomplete spinal cord injury patients in a survey by Moslavac et al [24]. Incomplete SCI patients with neurogenic detrusor overactivity should be tested with cystometry and observed with the same caution as complete SCI patients.

The importance of urodynamic tests for diagnosis and follow-up is demonstrated in the study by Abrahamsson et al [25] on cystometrical changes with untethering in myelomeningocele children. After untethering 35% of the patients experienced improved bladder function and 5% deteriorated. All of the patients who deteriorated before untethering improved afterward, and 90% of those who were stable preoperatively continued to be stable postoperatively. Regular evaluation of bladder function in children with myelomeningocele is recommended. Also Kang et al [26] used urodynamic tests to determine prognostic factors affecting urological outcome after untethering surgery for lumbosacral lipoma.

Perkash and Friedland [27] found simultaneous transrectal ultrasonography helpful. They also recommended not to irritate the bladder when introducing the urodynamic catheter and to examine the entire curve of the CMG and not simply the initial rise. [28]

Pressure-flow study can demonstrate an obstructive pattern (high pressure voiding) also in neurologic patients due to urethral relaxation failure [29-30].

Video urodynamics permit a clear image of bladder neck and urethral sphincter activity during filling and voiding [31-32].

Zerin et al [33] found that the urographic position of the bladder neck in relation to the pubic symphysis was correlated with lower motor neuron (LMN) denervation of the urethral sphincter as detected with electromyography in infants and children with myelodysplasia. They concluded that, although not as precise as urodynamic testing, significant descent of the bladder neck is a reliable urographic finding of complete LMN denervation of the external urethral sphincter in infants and children with myelodysplasia.

CMG filling rate seems to be very important especially in neurologic patients: De Gennaro et al [34] performed continuous urodynamic monitoring over 6 hours (CUM) in children and compared this with standard urodynamics. They found CUM feasible and permitting a better diagnosis than standard cystometry in some. Zermann et al [35] investigated the diagnostic value of natural fill cystometry (NFC) in children with neurologic bladder in comparison to conventional videocystometry (CVC). In 45%, NFC detected new findings compared with CVC diagnoses. CVC findings were confirmed in another 45%.

Hess et al [36] studied how closely the intravesical pressures obtained before filling cystometry resembled those obtained during the filling phase of the CMG. Filling pressures during cystometry were significantly higher than the pressures measured at rest. This study also suggests a strong correlation between both. Ko et al [37] determined in SCI patients with neurologic bladder whether cystometry performed by filling with diuretics (FMCG) reveals different findings compared with conventional CMG. Significant differences were found between both in hyperreflexic neurologic bladders with respect to a decrease in MPdett and increase in compliance with FCMG. However, there were no significant differences in MPdett and compliance in hyporeflexic or areflexic neurologic bladders between the two techniques. Natural filling by the production of urine can change the results of cystometry considerably, and should be considered when performing urodynamic investigations and interpreting the results. Because the effects can increase with the time required to conduct the investigation, effort should be made to decrease the total duration of urodynamic investigations.[38]

In men with SCI, cystometric variables and detrusor overactivity remain consistent over sequential studies as shown in a study by Ockrim et al [39].

The amplitude of the first overactive contraction and the maximal detrusor contraction were found to be statistically greater in female patients with multiple sclerosis and neurogenic detrusor overactivity compared to women with idiopathic overactivity. The threshold volume for detrusor overactivity was greater, likely secondary to the elevated post void residual urine volume in the MS patients. In this study using a cut off value of 30 cm H2O for amplitude of the first overactive contraction achieved a positive predictive value of 88% for identifying multiple sclerosis [40].

The determination of CMG filling sensation is important. In 52 SCI patients, 26 % of those with a supposed complete lesion had sensation of bladder filling during cystometry [41]. Also in 41 patients with myelodysplasia the perception of bladder filling proved, rather unexpectedly, to be present in a majority of patients [42].

In a large cohort study it was clearly shown that impaired perception of bladder filling during CMG is a sign of neuropathy [43]. Ersoz and Akyuz [44] investigated bladder-filling sensation in 73 SCI patients with complete lesions above T11 and below T10 and with incomplete lesions Bladder-filling sensation was present to some degree in all incomplete SCI patients, in 82.4% of the patients with complete lesions below T10, and in 38.9% of the patients with complete lesions above T11. Bladder-filling sensation investigations were reproducible in terms of bladder filling sensation category in 36 SCI patients who had a second CMG. The authors concluded that presence of bladder-filling
sensation in many SCI patients reveal the potential for sensation-dependent bladder emptying, especially in the ones with complete lesions below T10 and the ones with incomplete lesions. The safe use of sensation-dependent bladder emptying was shown to be dependent on the urodynamic situation [45].

Complications of cystometry in patients with neurogenic bladder have been documented. Hematuria, due to the urethral catheter, the development of oedema in the urinary bladder wall and the development of urinary bladder spasm as a result of catheter irritation can occur. One case report of twist and knot formation in the double lumen urethral catheter after cystometry of a patient with a hypo-compliant bladder has been published [46]. Another case report describes bladder rupture during filling cystometry many years after bladder augmentation in a girl with meningomyelocoele [47]. Symptomatic urinary tract infections after cystometry were found not to be infrequent and antibiotic prophylaxis is advocated [48]. Randomised controlled trials (RCTs) comparing effectiveness of prophylactic antibiotics with placebo or nothing in reducing bacteriologically proven UTI after invasive cystometry not only in patients with neurologic bladder were evaluated by Latthe et al [49]. The use of prophylactic antibiotics in urodynamics reduced the risk of significant bacteriuria.

Though urodynamic tests are recommended in all cases of neurologic bladder dysfunction a recent Japanese study showed that cystometry for the evaluation of vesico urethral function was performed routinely by 52.3% of 333 urologists answering a questionnaire survey to examine current practice patterns of physicians in the urological surveillance and management of spinal cord injury patients in Japan.[50].

CONCLUSIONS

- Urodynamic tests are very useful in patients with neurologic urinary incontinence though not as generally applied as often thought (LOE 2)
- A combination with EMG and/or imaging adds to the diagnostic possibilities (LOE 2)
- Filling rate can influence the outcome of several urodynamic parameters (LOE 2)
- Pressure development in the bladder is one of the important parameters to be studied and high leak point pressure is dangerous for the kidneys. (LOE 2)
- Evaluating sensation of filling during CMG is important for the neurological diagnosis and for treatment options. (LOE 2)
- Complications are rare but antibiotic prophylaxis can be advocated (LOE 2)

4. SPECIAL TESTS

a) Ice water test

The ice water test was first described as a way to differentiate upper from lower motor neuron lesions. It is based on the principle that mucosal temperature receptors can elicit a spinal reflex contraction of the detrusor, a reflex that is normally inhibited by supraspinal centers. An upper motor neuron lesion interrupts these inhibitory pathways, resulting in manifestation of the reflex, whereas a lower motor neuron lesion does not. A positive test should therefore theoretically occur in patients with upper motor neuron lesions, whereas those with lower motor neuron lesions and neurologically normal patients should have a negative test. Simultaneous measurement of intravesical pressure permits us to rule out false negative tests.

In the more recent literature Geirsson [51] showed in a large cohort study that 97% of patients with complete and 91% of those with incomplete neurologic DOA had a positive or a false negative IWT. About 75% of the patients with multiple sclerosis, Parkinson’s disease or previous cerebrovascular accident had a positive IWT. All patients with lower motor neuron lesions or pure stress incontinence had a negative IWT. There was a significant correlation between a positive IWT and an abnormal sensation of bladder filling and inability to inhibit micturition voluntarily, as well as between a negative IWT and the occurrence of phasic detrusor contractions during cystometry. The study shows that the IWT is a sensitive test for differentiating upper from lower motor neuron lesions. It is also a useful parameter for functional subdivision of overactive bladders. In patients with voiding dysfunction in the absence of LUT inflammation, a positive test is an indicator of a silent or overt neurological disorder.

Geirsson and Fall [52] used the ice-water test, in patients suspected of DSD (cystometry and needle EMG). A positive test with a high detrusor pressure indicates detrusor-external sphincter dyssynergia whereas the contrary applies to the negative test. All patients who responded to cold stimulation with detrusor contraction but without fluid leakage (called positive non-leakage IWT), presented DSD according to EMG. The authors conclude that in this situation, the cheap, non-invasive and simple IWT can replace a needle EMG study.

Ishigooka et al [53] evaluated urinary bladder sensation to ice water instillation in patients with diabetes mellitus. There was no apparent relationship between prevalence of peripheral neuropathy and that of negative sensation of ice water test. Impairment of ice water perception was less frequent than that of mechanoreceptor sensation in patients with diabetic cystopathy.
Ronzoni et al [54] studied ice-water test in 148 patients with neurologic bladder dysfunction resulting from a traumatic lesion and in 130 patients with neurologic bladder dysfunction and multiple pathogenic disorders. IWT was positive in 95% of patients affected by complete and in 86% of patients with incomplete medullary lesions. The IWT in patients with lower motor neuron medullary lesions was always negative. The test was used diagnostically in patients with lower motor neuron lesions. In those with upper motor lesions it was used as a rehabilitation method during the medullary-shock phase to accelerate the appearance of the micturition reflex. In 9% of patients it was used to induce micturition during cystography. The authors consider IWT as a useful complement to urodynamic examinations in patients with neurological bladder disease.

Chancellor et al [55] determined the clinical utility of IWT during urodynamic evaluation in spinal cord injured (SCI) patients and found that it did not contribute to their management because of the insensitivity and non specificity. Autonomic hyperreflexia can occur during evaluation. The IWT did not influence clinical management in this group of SCI patients.

Repeating the IWT has been shown to increase its positivity [56]. Combining the IWT and EPT will reinforce the results of both tests and can indicate more clearly the possibility of an unsuspected neurologic pathologic finding in patients with idiopathic DOA. In multiple sclerosis it may have pathophysiologic value, indicating a spinal rather than cerebral mechanism of overactive bladder, and diagnostic value, indicating multifocal demyelination. [57]. In vue of these recent data clinical utility should be further assessed.

CONCLUSION

- The literature results from IWT show value in the diagnosis of neurologic bladder and in the differentiation between reflex and areflex neurologic bladders. It was also shown that the outcome can be improved by repeating the test. (LOE 2)

RECOMMENDATION

- The ice water test should be interpreted in the light of all data from the diagnostic evaluation. (B)

b) Bethanechol supersensitivity test

Bethanechol is a muscarinic agonists known to be able to increase bladder sensitivity correlated with improvement in bladder emptying in some non neurologic patients [58] and can be evaluated by studying the sensation of filling and EPT. The Bethanechol test was developed by Lapides et al in 1962 [59] to try to distinguish between a neurologic and a myogenic etiology in the presence of an acontractile bladder. It is based on the observation that after an organ is deprived of its nerve supply, it develops hypersensitivity to the normal excitatory neurotransmitters for that organ. A neurologically intact bladder should have a pressure increase of less than 15 cm H2O above the control value, whereas a denervated bladder shows a response greater than 15 cm H2O. A positive test suggests an interruption in the afferent or efferent peripheral or distal spinal innervation of the bladder. However, the test has been considered not very reliable by some [60].

Penders [61] considered the test reliable when the indications are good (large capacity, hypotonic bladder, clinical suspicion of lower neuron lesion) and when the interpretation is based on a right understanding of its mechanism. Pavlakis et al [62] suggest that the bethanechol chloride supersensitivity test is more sensitive and more specific than perineal floor electromyography in corroborating bladder neuroopathy. Sidi et al [63] studied patients with neurologic or nonneurologic detrusor areflexia with the bethanechol supersensitivity test, EMG of the urethral rhabdospincter and bulbocavernous reflex latency and found the sensitivity of these tests in detecting neurologic areflexia to be 90, 87.5 and 78.1 per cent, respectively, and the specificity 95.6, 76 and 80 per cent, respectively. When all 3 tests were performed together the combined accuracy approached 100 %. They conclude that these combined tests are useful in the diagnosis of patients with equivocal bladder neurologic conditions and in those with subtle neurological lesions. Denervation supersensitivity to bethanechol was demonstrated recently in acute idiopathic autonomic neuropathy [64].

Wheeler et al [65] found the positive BST not diagnostic of neurologic detrusor areflexia because of the many variables that can influence the test. In a later study the same authors [66] suggest that flow rate, surface electromyography, and bethanechol supersensitivity test can not help differentiate neurologic from non-neurologic detrusor failure. Although no one test can accurately differentiate neurogenic from nonneurologic female urinary retention, careful neurourolologic evaluation will help guide to more appropriate management.

The clinical utility has not been studied in detail recently. This seems an interesting subject for clinical research.

CONCLUSION

The literature on the value of the bethanechol test for the diagnosis of neurologic pathology is contradictory. Several authors state that a positive bethanechol supersensitivity test (BST) usually indicates neurologic detrusor areflexia.
5. ELECTRODIAGNOSTIC TESTS

There are several tests that explore the innervation of the LUT and can be of interest in the diagnosis.

\textbf{a) EMG of the urethral sphincter}

EMG of the urethral sphincter has been used for decades in the diagnosis of neurologic LUT dysfunction. Its value in practice remains uncertain as well as the best method to use, needle or surface electrodes. Urethral concentric needle electrodes were found to be superior to surface patch electrodes for evaluating relaxation of the muscle during voiding in non neurologic women [67]. Nordling and Meyhoff [68] used cystometry in combination with urethral and anal sphincter EMG in patients with suspected neurologic bladder dysfunction and found anal sphincter EMG to be highly unreliable. Koyanagi et al [69] also found in male patients with SCI, discordant activities between the anal and the external urethral sphincters in 39%. The degree of bladder dysfunction was related more to the degree of dyssynergia of the urethral than the anal sphincter. But nevertheless Podnar states that although in patients with LUT disorders, external urethral sphincter (EUS) electromyography (EMG) would seem the most appropriate, anal sphincter EMG is the single most useful diagnostic test, particularly for focal sacral lesions, and atypical Parkinsonism [70]. Fowler et al [71] introduced a technique of recording EMG activity of striated muscle in the urethral sphincter by using a concentric needle electrode and an oscilloscope with a delay line and trigger. Individual motor units were isolated and measured. Also Vodusek [72] studied individual motor units. Both conclude that quantitative EMG may be a helpful technique in the investigation of patients with disorders of micturition.

Light et al [73] found in patients with detrusor areflexia and a high spinal cord lesion EMG of the pelvic floor muscles the most predictive neurophysiological test for developing detrusor contractility.

Ziemann and Reimers [74] found the sphincter EMG the most sensitive technique in the diagnosis of chronic pudendal lesions. However, pure afferent lesions cannot be detected by the sphincter EMG. In this case, the BCR, using unilateral stimulation of the dorsal nerves of the penis, provides the opportunity to distinguish between afferent and efferent lesions of the sacral innervation.

Fowler [75] concluded that sphincter electromyography (EMG) has proved to be particularly valuable in identifying patients with parkinsonism who have multiple system atrophy. Tests which examine aspects of nerve conduction velocity have proved to be of lesser value both because such investigations test conduction of nerve fibres rather than levels of innervation, and furthermore examine large myelinated fibre conduction rather than that of the unmyelinated fibres which comprise the autonomic innervation.

De E J et al [76] found a significant disagreement between needle EMG and VCUG for a positive diagnosis of DSD. A combination of EMG and voiding cystourethrogram (VCUG) may identify more cases of DSD than either modality alone and underscores the need for more strict criteria when defining this entity from a urodynamic standpoint.

External urethral sphincter EMG can be used to detect the onset of detrusor contractions in patients with both neurogenic detrusor overactivity (NDO) and detrusor sphincter dyssynergia (DSD) opening a door for the use of triggered devices to inhibit unwanted contractions through continuous electrical stimulation of sensory nerves [77-78].

EMG of the urethral sphincter has been used recently to investigate retention in multiple-system atrophy [79], LUT function in Machado-Joseph disease [80], the impact of pregnancy and delivery on vesico urethral disorders in patients with multiple sclerosis [81], children with cerebral palsy [82], neurourological findings following sacro-coccygeal teratome resection in the newborn period [83].

\textbf{CONCLUSION}

- EMG can be valuable in the diagnosis of patients with neurologic bladder dysfunction (LOE 2).
- EMG of the anal sphincter is considered unreliable by some (LOE 4).

\textbf{RECOMMENDATION}

EMG of the urethral sphincter can be recommended as diagnostic method in patients with neurologic LUT dysfunction and neurologic urinary incontinence (B B)

\textbf{b) EMG of Detrusor muscle}

Has been very little studied in neurologic patients. La Joie et al [84] recorded simultaneous EMG recordings from the bladder detrusor muscle and the inferior...
rectus abdominis muscle in 6 normal subjects, in 4 patients with LMN bladder disease and in 2 patients with an UMN type of bladder lesion. Results of the study demonstrated that the bladder electrodes did not record remote muscle activity from the abdominal muscles so that any increased detrusor electrical activity with abdominal contraction must have some other explanation such as a possible abdominodetrusor reflex or the production of increased intra-abdominal pressure from abdominal contraction. Also Kaplan and Nanninga [85] analysed of upper motor neuron type neurologic bladders by bladder EMG. Recent data are lacking and therefore we have to consider the technique as not fit for clinical diagnostics today.

c) Dynamic Bulbocavernosus reflex (BCR)

Walter et al [86] studied a dynamic BCR during micturition induced by using periodic dorsal penile nerve stimulation; the evoked reflex response was recorded with an anal sphincter pressure sensing balloon. Results indicate that an enhanced BC reflex is a major factor causing increased urethral resistance during micturition.

Kaiho et al [87] recorded the evoked potential of the BCR (BCR-EP) with a concentric needle electrode at the periurethral striated muscle. They found BCR-EP suppressed during voluntary voiding in normal subjects, but insufficiently suppressed in the patients with neurologic bladder. It was suggested that the measurement of BCR-EP could distinguish involuntary voiding caused by pathological urethral sphincter relaxation from voluntary voiding.

Kaiho et al [88] investigated the change of sacral reflex activity of the striated urethral sphincter in the urine storage phase using evoked potential reaction of the bulbocavernous reflex (BCR) With BCR-EP in normal male subjects and male patients with neurologic bladder due to suprasacral spinal cord injury. Sacral reflex activity was accelerated by bladder filling in both the normal subjects and SCI patients. And the acceleration in the SCI patients was more remarkable than that in the normal subjects. In addition to the conventional evaluation of the integrity of sacral reflex arc by BCR examination, the observation of changes of BCR affected by bladder filling may provide the information for the continuity of sacral segment and supraspinal micturition center.

CONCLUSION

Very little data on detrusor EMG and BCR-EP in literature and thus these techniques have to be considered as experimental.

d) Motor evoked potentials

MEP has been used to assess neurogenic lesions of the somatomotor efferent nervous pathway to the urethral compressive musculature with and simultaneous recording of evoked pressure curves [89]. MEP recording has been shown to be an accurate and easily applicable test for the diagnosis of lumbosacral spinal cord lesions [90].

Examination by transcranial magnetic stimulation (TMS) was shown to be useful in the diagnosis of cervical spondylotic myelopathy but the possibility of negative central motor conduction time (CMCT) findings upon TMS must be borne in mind.

e) Nerve conduction study

Andersen and Bradley [91] showed in patients with diabetes mellitus decreased conduction velocities in patients with the detrusor reflex as well as in detrusor areflexia. The findings indicated that diabetic vesical dysfunction is principally the result of segmental demyelinization in the peripheral nerve supply to the detrusor muscle and urethra.

Vereecken et al [92] found urethral and anal responses produced by electrical stimulation of penis, bladder neck and anus delayed and the duration reduced.

Carbone et al [93] assessed the effect of urinary bladder filling on the excitability of somatic spinal motor neurones in patients affected by overactive bladder secondary to neurologic and non-neurologic causes with the H-reflex evoked by electrical stimuli applied to the tibial nerve at the Poplitea fossa and recorded from the Soleus muscle. In healthy subjects, a progressive reduction in the H-reflex amplitude during bladder filling was observed.

In spinal cord-injured patients affected by a neurologic overactive bladder, bladder filling failed to inhibit the H-reflex amplitude; a decrease in the H-reflex amplitude similar to that displayed by normal subjects was observed in patients with a non-neurologic overactive bladder. By contrast, H-reflex behaviour was unmodified in neurologic under active bladder patients and was similar to normal subjects in psychogenic under active patients. H-reflex modulation may be considered a useful tool in the differential diagnosis of voiding dysfunctions.

CONCLUSION

Not many data are found in literature on nerve conduction studies for LUT neurologic problems.

RECOMMENDATION

There are some arguments that the technique can be useful in the further differentiation of the nerve deficits in cases of neurologic pathology of the bladder (C).
f) Somatosensory evoked potentials (SSEP)

Badr et al [94] described techniques of recording evoked potentials in humans in response to stimulation of the urinary bladder.

Galloway et al [95] described a simple method of sacral evoked response to measure the integrity and function of the lower sacral segments of the cord by stimulation at the urethral and anal sphincters.

Mochida et al [96] studied evoked spinal cord potentials (ESCP) in surgical patients with cervical myelopathy. The presence of neurologic bladder was closely correlated with severe limb symptoms and relatively slow ESCP velocity. However, for 47% of the patients with urinary complaints, findings of urodynamic examinations were negative; these patients probably had pathologic or psychosomatic factors other than neurologic bladder due to cervical myelopathy.

Curt et al [97] studied the significance of SSEP recordings in predicting the recovery of bladder function in acute, traumatic spinal cord injury (SCI). They found a good correlation with the recovery of the external urethral sphincter function but not with the urodynamic impairment.

Somatosensory evoked potentials in response to stimulation of the tibial nerve were recently studied in patients with hyperactive urinary bladder to clarify their role in prognosis of tibial neuromodulation efficacy.[98]

RECOMMENDATION

Somatosensory evoked potentials can be of use in the further diagnosis of nervous deficits related to LUT dysfunction (C).

g) Use epidural recording of evoked spinal cord potentials

These showed clinical value in investigating the pathology of cervical spondylotic myelopathy in patients with normal central motor conduction time in upper and lower limbs [99]

h) Afferent nerve recording on sacral roots

Afferent nerve activity from the sacral dermatome, bladder and rectum can be recorded using cuff electrodes placed on the extradural S3 sacral root in humans but improvements in recording quality and sophisticated signal processing methods are needed for chronic application.[100].

CONCLUSION

Epidural recording and direct measurement on sacral nerves is still experimental.

i) Electro sensation in the LUT

Measurement of the sensory threshold of the LUT towards electrical stimulation was performed by Frankl-Hochwart and Zuckerkandl as early as 1899 [101]. After re-introduction of the technique by Markland et al [102] several authors have studied its value in neurologic bladder dysfunction.

Frimodt- Möller [103] described pathological electro sensation in patients with Parkinson's disease, with multiple sclerosis and meningomyelocoele. He also found abnormal electro sensation in half of patients with diabetes and generalized sensory neuropathy but only in 10% of the diabetic patients with a neurologic bladder.

Kieswetter [104] and Powell and Feneley [105] demonstrated abnormal electro sensation in patients with neurologic LUT dysfunction.

Wyndaele [106] determined the threshold of sensitivity to electrical stimulation in several parts of the LUT in 436 consecutive patients. In the groups with different patterns of disturbed sensation a higher incidence of neuropathy was found than in the group with a normal sensation. Further neurological investigation revealed abnormal innervation in 29% of patients who lacked electro sensitivity in one or more parts of the LUT but who had no previous evidence of neuropathy.

Electro sensation proved present in many meningomyelocoele patients with absent skin sensation and absent reflexes and in many patients with suspected complete spinal cord injury on clinical evaluation [41-42].

Standardization is necessary to come to reproducible results [107].

While it is a dream to be able to determine threshold of different fibre types selectively [108] so far no such fibre selectivity has been demonstrated in the bladder [109].

The clinical utility needs to be further studied.

CONCLUSION

To determine the electro sensation in the LUT is valuable to evaluate the afferent innervation in cases of neurologic bladder. Absent electro sensitivity is valuable to decide on further neurologic tests in patients with LUT dysfunction. (LOE 2)

RECOMMENDATION

The determination of electro sensitivity in the LUT is recommended in patients with a known neurologic disease and in patients with idiopathic LUT dysfunction if neurologic pathology is suspected. (B).
j) Sympathetic skin response (SSR)

Schurch et al [110] assessed the degree of sparing of the descending sympathetic spinal tract and correlated these findings with bladder neck function in SCI patients. Evidence is presented that the integrity of the descending sympathetic spinal tract is necessary for a synergic function of the vesicourethral complex and that sympathetic skin responses are of value in the diagnosis of bladder neck dyssynergia. For lesions below the T12 level other investigative methods to exclude bladder neck dyssynergia are necessary.

Rodic et al [111] investigated whether recording the perineal sympathetic skin response, which reflects the sympathetic function of the thoracolumbar spinal cord, represents a reliable and accurate diagnostic tool for assessing bladder neck competence and incompetence. They found that recording the perineal SSR in addition to that of the hand and foot represents a sensitive diagnostic tool for assessing sympathetic nerve function within the thoracolumbar spinal cord. It is of diagnostic value for evaluating neurologic bladder neck incompetence in spinal cord injured patients.

SSR recordings above a spinal lesion level after urethral electrostimulation might provide a useful and technically simple objective diagnostic tool to assess integrity of autonomic (visceral) afferent nerves from the LUT.

Somatosensory deficits are not always paralleled by viscerosensory loss and vice versa. A recent study showed that SSR were superior to visceral sensory evoked potentials which are more difficult to record. The subjective sensations reported by subjects during stimulation could be confirmed in an objective way in 100% of cases by positive/negative SSR findings.[112] The clinical utility needs to be further studied.

CONCLUSION

These publications indicate that sympathetic skin responses are of value to evaluate the integrity of the LUT related sympathetic function and especially for bladder neck competence, incompetence and dyssynergia. (LOE 2)

RECOMMENDATION

Sympathetic skin responses seem promising and the further study of them are recommended for the evaluation of the LUT sympathetic innervation (B)

III. CONSERVATIVE TREATMENT

Therapeutic principles in different patterns of LUT dysfunction depend on the cause of NUI: dysfunction of the detrusor, dysfunction of the sphincter or a combination of both.

Neurogenic detrusor overactivity leads to reflex-incontinence, detrusor areflexia to incontinence with retention (overflow incontinence). An areflexic (ineptent) sphincter causes neurogenic stress-incontinence, a hyperreflexic (spastic) sphincter overflow-incontinence. Quite often detrusor and sphincter are affected simultaneously by the neurogenic lesions with basically four combinations. In most patients the storage problem, leading to incontinence, is associated with an emptying problem; therefore both aspects have to be considered at the same time.

Therapy of neurogenic incontinence is primarily a conservative one. Timed bladder emptying, by whatever means, controlled fluid-intake and avoidance of urinary tract infections are the prerequisites for successful treatment.

In (a) SUPRASPINAL LESIONS neurogenic detrusor overactivity is mostly combined with normal sphincter function, reflex incontinence is the main symptom and antimuscarinic therapy together with behavioural treatment, especially in patients with cognitive impairment, is the method of choice.

(b) SPINAL LESIONS mostly cause simultaneous dysfunction of the detrusor and the sphincter.

In suprasacral lesions the combination of a overactive detrusor with a hyperreflexic sphincter is characteristic for the spinal reflex bladder.

Basically spontaneous reflex voiding is possible; however, it is uncontrolled, causing reflex-incontinence and is mostly unbalanced and basically unphysiologic. Detrusor contractions are mostly inadequate, and detrusor striated sphincter dyssynergia is present, both leading to unbalanced voiding.

Triggered reflex voiding is recommended only if it is urodynamically safe and reflex incontinence is manageable. The method of choice nowadays to empty an unbalanced reflex bladder and to manage reflex-incontinence is intermittent (self-) catheterisation. However, to achieve the aims of therapy, - a low pressure LUT situation and continence between catheterisations - additional pharmacotherapy may be necessary.
If bladder relaxing agents fail or are not tolerable, electrotherapy is an alternative in incomplete lesions: ano-genital electrostimulation (penile, clitoral, vaginal and anal) can inhibit neurogenic detrusor overactivity by stimulating pudendal nerve afferents.

If none of the above mentioned treatment modalities is effective to control reflex incontinence and if operative procedures are not indicated or possible, appliances, pads or condom-catheters, are the first choice in males and pads in females. To improve outflow, treatment to lower tone and spasticity of the urethral sphincter can be used.

The indwelling catheter – a suprapubic catheter is preferable to transurethral – remains the last resort for conservative therapy.

For complete conus lesions, also named lower motor neuron lesions, areflexia of the detrusor with areflexia of the sphincter is characteristic. Sphincter incompetence causes neurogenic urinary stress incontinence and may be combined with overflow-incontinence if adequate emptying is not achieved.

Basically, regular bladder emptying achieved by bladder expression, according to the individual bladder capacity, in combination with controlled fluid intake may decrease neurogenic urinary stress incontinence. However, continence is hard to achieve. Bladder expression is potentially dangerous. Pharmacotherapy is not helpful in this situation, appliances and condom catheters are therefore often necessary. Continence can often be achieved only by operative therapy.

Areflexia of the detrusor combined with hyperreflexia of the sphincter may occur in epiconal lesions; however, this pattern may be also due to a decompensation of a neurogenic overactive bladder after chronic urinary retention. With this combination overflow incontinence can be controlled by intermittent catheterization mostly without adjunctive additional pharmacotherapy. If intermittent catheterization is not possible, an indwelling catheter, preferable suprapubic, may be needed.

If overactivity of the detrusor is combined with areflexia of the sphincter, a pattern sometimes found in epiconal lesions, especially in myelomeningocele, reflex incontinence is combined with neurogenic stress incontinence. Bladder relaxant agents may abolish or diminish neurogenic detrusor overactivity.

In incomplete lesions electrical stimulation of the pelvic floor musculature may improve sphincter function. Thus the combination of pharmacotherapy to treat reflex incontinence with electrotherapy of the pelvic floor muscle may improve continence. However, with this type of neurogenic LUT dysfunction conservative treatment alone is generally unable to restore continence; therefore either appliances or operative treatment must be considered.

(c) **SUBSACRAL (CAUDA EQUINA AND PERIPHERAL NERVES) LESION** are often incomplete lesions. Hypoactivity or areflexia of the detrusor may be combined with a normally functioning external striated sphincter, a combination which can be seen after intrapelvic surgery, when the pudendal nerves remain intact. On the other hand if the pudendal nerve is lesioned and the pelvic plexus remains more or less intact, a combination of a normally functioning detrusor with a hypo- or areflexic external sphincter may be present. For the neurogenic overactive detrusor, again, pharmacotherapy is the first choice. In the hyporeflexic detrusor cholinergics may increase the tone, and the sensation of filling. If the lesions were incomplete, intravesical electrotherapy was reported to increase detrusor contractility. The chances for pharmacotherapy to improve external sphincter weakness as well as to decrease external sphincter spasticity are poor. Injection of botulinum toxin in the striated sphincter has created a new treatment option.

If conservative treatment fails several surgical options are available. They will be discussed in the corresponding part of this chapter.

Since only some conclusions and recommendations are changed and some new references are added to the 2005 chapter, this chapter presents only the new literature, justifying the changes and actual conclusions and recommendations. For previous references as well as for general outlines please refer to the ICI 2005 chapter. Also some recommendation have been compared/changed according to the recent consortium for spinal cord injury [1].

The following text will not deal specifically with the period of spinal shock or cerebral shock in acute neurological lesions when the urologic treatment consists of proper bladder drainage. For the post shock period or for slowly developing dysfunctions several conservative treatments exist:

1. **BEHAVIORAL THERAPY**
   a) Triggered reflex voiding
   b) Bladder expression (Crédé and Valsalva maneuver)
   c) Toileting assistance

2. **CATHETERS**
   a) Intermittent catheterization
   b) Indwelling urethral catheters
   c) Condom catheter and external appliances

3. **PHARMACOTHERAPY**

4. **ELECTROSTIMULATION**
   a) Electrical Neuromodulation
   b) Repetitive transcranial magnetic stimulation
   c) Deep brain stimulation
   d) Electrical stimulation of the pelvic floor musculature
   e) Intravesical electrical stimulation (IVES)
1. BEHAVIOURAL THERAPY

a) Triggered reflex voiding (references see ICI 2005 report)

BACKGROUND

The true automatic or reflex bladder occurs following recovery from spinal shock in spinal cord lesions not involving the conus or cauda equina. If the efferent branches of the pelvic nerve are involved, the reflex emptying is much less complete, and considerable voluntary straining is required to empty the bladder to a satisfactory degree. The stimulation of the sacral and lumbar dermatomes should be used to elicit reflex contractions of the detrusor in cases with upper motor neuron bladders.

The aims of regular triggered reflex voiding are to achieve balanced voiding, to decrease incontinence and/or to achieve continence. Prerequisites for this type of bladder emptying are: the possibility of collecting the urine in a socially acceptable way and an adequate time needed for bladder emptying. The urodynamic function must be safe (low pressure).

Bladder reflex triggering comprises various manoeuvres performed by patients in order to elicit reflex detrusor contractions by exteroceptive stimuli. The most commonly used manoeuvres are: suprapubic tapping, thigh scratching and anal/rectal manipulation.

Frequency of use, intervals and duration has to be specified for each patient. Integrity of sacral reflex is requested for such voiding technique.

Today, learning triggered voiding should not be done without considering bladder outlet obstruction management, continence, appliances, gender, and level and type (complete or incomplete lesions, paraplegic versus quadriplegic patients) of lesion.

Assessment of management by triggered reflex voiding is difficult because of the mostly retrospective nature of the reports and because the management of concomitant bladder outlet obstruction is not specified or incompletely described.

An additional indication could be a quadriplegic patient who is unable to perform self-catheterization but is able to do tapping or triggered voiding. They may choose this option because it gives more independence.

Before considering triggered reflex emptying, one must check if the bladder situation is urodynamically safe (mainly low pressure bladder) and if regular follow-up is guaranteed. The frequency of check-up is not validated, depends on risk factors, but should be between 6 months and 2 years.

To improve emptying and, control autonomic dysreflexia related to bladder filling and contraction as well as to avoid upper tract damage, alpha-blockers or botulinum toxin sphincteric injections (see related part of this chapter) should be tried before sphincterotomy and/or bladder neck incision is performed.

Triggered voiding should not be recommended as first line management of bladder hyperreflexia and neurogenic LUT dysfunction. Intermittent catheterisation has become the gold standard to achieve continence, upper urinary tract protection and improvement of quality of life (see recommendations in the section of intermittent catheterisation).

CONCLUSIONS

• Reflex voiding is based on an unphysiological sacral reflex. It is potentially dangerous and has a limited role in managing the reflex bladder (LOE3).
• The long-term complication rate is not as high as with indwelling catheter, but enough to suggest a trend to avoid this triggered reflex voiding in detrusor overactivity (LOE2).
• Costs of appliances and of adjuvant therapies (pharmacotherapy, surgery, urethral prosthesis etc) have to be evaluated (LOE 2).
• Treatment of co-existing sphincteric spasticity/ bladder neck obstruction (botulinum toxin, a-adrenolytics) and comorbidity should be taken into consideration (LOE 1 and 2).

RECOMMENDATIONS

• Triggered voiding could be recommended for patients whose situation has proven to be urodynamically safe and stable, and who can manage reflex incontinence. Moreover it is recommended for patients after sphincterotomy and/or bladder neck incision and/or alpha-blockers and or intrasphincteric botulinum toxin injections, in order to improve spontaneous reflex voiding (C).
• Reflex voiding can be recommended only if an adequate follow-up is guaranteed (C).

b) Bladder expression (Crédé and Valsalva) (References see ICI 2005 report)

BACKGROUND

Bladder expression has been recommended for a long time for patients with a combination of an areflexic detrusor with an areflexic sphincter or with an incompetent urethral closure mechanism of other origin (e.g. after sphincterotomy). Difficulties in emptying the bladder by expression may be due to an
inability to open the bladder neck. However, especially in men, these techniques induce a functional obstruction at the level of the striated external sphincter despite complete paralysis of the musculature of the pelvic floor.

Bladder expression comprises various techniques aimed at increasing intravesical pressure in order to facilitate bladder emptying. The most commonly used are the Valsalva (abdominal straining) and the Crédé (manual compression of the lower abdomen).

With increasing time, using Valsalva and Crédé techniques, more than 50% of patients could show demonstrable reflux into the prostate and the seminal vesicles and other complications, e.g. epididymo-orchitis. Moreover, the high pressures could cause reflux into the upper urinary tract with all known complications. The stress to the pelvic floor with these techniques several times a day also has a negative influence on the existing minimal storage function of these structures and therefore makes incontinence worse, causes additional genital-rectal prolapse and hemorrhoids.

Adjunctive therapy to decrease outflow assistance includes alpha-blockers, sphincterotomy or botulinum toxin injections. If effective, they usually cause or increase neurogenic urinary stress incontinence. Expression of the bladder for voiding by Valsalva and Valsalva can be effective. To empty the bladder, the pressures measured may be high and potentially dangerous for the upper urinary tract. Bladder expression is often not safe. Sphincter-hyperreflexia and detrusor-sphincter dyssynergia are contraindications for bladder expression.

CONCLUSIONS

- Bladder expression by Valsalva or Crédé is potentially hazardous for the urinary tract due to functional obstruction at the level of the pelvic floor (LOE 3).
- It is contraindicated if it creates a high intravesical pressure, or/and if vesical reflux or/and a vesico-uretero-renal reflux are present. In addition, hernias, recto-genital prolapse and hemorrhoids as well as urethral pathology (striction formation) and recurrent symptomatic UTIs are further contraindications (LOE 3).
- It may have a negative influence on an existing minimal outflow resistance of a flaccid pelvic floor and therefore incontinence may become worse (LOE 3).
- Alpha-blockers, sphincterotomy or botulinum toxin may reduce the outflow resistance, but may also induce or increase urinary stress incontinence (LOE 3).

RECOMMENDATIONS

- Before recommending bladder expression by Valsalva or Crédé, it must be proven that the situation in the LUT is urodynamically safe. Basically the method is dangerous. (B)
- Exclude contraindications, such as a vesico-uretero-renal reflux, vesical reflux, genito-rectal prolapse, hernias, urethra pathology and symptomatic UTIs before recommending this type of bladder emptying. (B)
- In general, bladder expression should be replaced by CIC in most patients with neurogenic bladder-sphincter dysfunction. (B)
- Adjunctive therapy of outflow obstruction can be considered. (B).
- Valsalva and Crédé guarantee a good quality of life and are cost-effective in the long term only when the indication is proper and when the situation remains stable throughout the years. (B)

c) Toileting assistance: timed voiding, habit retraining, prompted voiding (references see ICI 2005 report)

For a more complete overview consult the chapters “adult conservative treatment” and “frail elderly”.

1. BACKGROUND

Adaptation of the drinking and voiding regimen is determined by education and can be implemented by the patient and/or caregivers.

In patients with neurogenic incontinence related to brain diseases, when independent continence cannot be achieved, social and/or dependent continence is sometimes achievable.

The aim of the behavioural process in adults is to re-establish the control of urinary continence. The goals include correcting faulty habit patterns of frequent urination, improving ability to control bladder urgency, prolonging voiding intervals, increasing bladder capacity, reducing incontinent episodes, and building a patient's confidence in controlling his/her bladder.

Behavioural measures would seem to be beneficial for most neurologic patients in one way or another. Good indications are most common in brain diseases as cerebro vascular disease, Parkinson’s disease, multiple system atrophy, dementia, and cerebral palsy. Other diseases can also be good indications such as multiple sclerosis, incomplete spinal cord injury, transverse myelitis, diabetes mellitus and others. Frail elderly neurologic patients who need assistance can also benefit from these techniques independent of the disease they suffer from.
In dependent patients all these techniques can be proposed and tried, provided that caregivers (physiotherapist, nurse, member of the family…) are aware of them and are motivated to use them.

The following toileting assistance techniques require caregivers’ assistance in many of the patients:
- Timed voiding
- Prompted voiding
- Habit retraining
- Bladder retraining
- Patterned urge response toileting

2. TIMED VOIDING

Timed voiding is characterized by a fixed interval between toileting. It is a passive toileting assistance program. It is initiated and maintained by caregivers. This technique is considered appropriate for patients who cannot participate in independent toileting. It has been used in patients whose incontinence may be associated with cognitive and/or motor deficits. Its aim is more to avoid incontinence than to restore a normal bladder function.

For neurologic patients it has also been considered as an adjunct therapy to tapping and/or Crédé manoeuvre and/or intermittent catheterisation. Timed voiding is one of the first steps of treating too high bladder volumes, as in diabetes patients with loss of bladder filling sensation.

3. HABIT RETRAINING AND PROMPTED VOIDING

Both of these techniques have to be initiated and maintained by caregivers. They are more adapted to patients with brain diseases than to spinal cord diseases and for patients with cognitive and/or motor deficits.

The aim of habit retraining is to help patient to avoid incontinence and/or involuntary bladder contractions by decreasing voiding intervals. Such program has to be adapted to each patient and needs a specific analysis of voiding patterns to select a good individual schedule for voiding. Such a program is very useful for institutionalised patients.

Prompted voiding is used to teach people to initiate their own toileting through requests for help and positive reinforcement from caregiver when they do this. This technique needs an outside individual’s participation in the process. There are no specific evaluations on neurologic patients in literature, though the technique may be useful in patients with incomplete neurologic lesions, and in patients with high dependence and good cognitive function.

CONCLUSIONS

- Behavioural techniques have to be used in conjunction and/or in addition with other therapies (pharmacological treatment, catheterisation) (LOE 2)
- There is no consensus, either on the definition of each technique or on the population that can benefit from it. When available, toileting assistance should be used to improve continence of neurologic impaired patients (LOE 3)
- There is still some evidence that prompted voiding is able to decrease incontinence episodes. Long-term effect of this therapy is not validated. Moreover there is evidence that patients who should have more benefit of this technique are those with less cognitive impairment and higher dependency (LOE 2/3)

RECOMMENDATIONS

- Behavioural techniques could be recommended as a part of each individual rehabilitation program. (C)
- No guidelines or consensus on correct intervals between bladder emptying has been reported. They should be fixed, but have to be adapted to voiding diary and other related factors as was detailed in the previous report: bladder volume, fluid intake, post-void residual urine volume, urodynamics parameters. (C)
- The mental status of a patient must be taken into consideration, and a rehabilitation program realistically tailored to the patient’s possibilities. (B/C).

2. CATHETERS

All technical aspects of incontinence devices can be found in the chapter “Technical aspects of continence devices” of this report. Detailed description of catheter use in neurologic patients can be found in the previous ICI 2005 report under “Conservative management in neurogenic urinary incontinence”, page 697 and following. Only literature data published since are summarized here.

a) Intermittent catheterization [IC]

1. BACKGROUND

Intermittent catheterization (IC) and self-catheterization (ISC) have become properly introduced during the last 40 years. In general, the purpose of catheterization is to empty the bladder and of IC is to resume normal bladder storage and regularly complete urine evacuation. With IC and ISC there is no need to leave the catheter in the LUT all the time, thus avoiding complications of indwelling catheterization (ID).

It is clear that IC can improve incontinence or make patients with neurogenic bladder continent if bladder capacity is sufficient, bladder pressure kept low, urethral resistance high enough, and if care is taken
to balance between fluid intake, residual urine and frequency of catheterization. In young children with SCI, early clean intermittent catheterization and use of anticholinergics appear to prevent upper tract deterioration, improve continence and decrease infections. Serial urodynamics confirm increasing safe capacity with growth in most children. [2,3].

The main aims of IC and ISC are to empty the bladder and to prevent bladder overdistension in order to avoid complications and to improve urological conditions. The optimal post-void residual indicating the need to start bladder catheterization remains to be clarified, though Dromerick et al. [4] (LOE 2) demonstrated in a series of stroke patients that a post-void residual greater than 150ml is an independent risk factor for development of UTI.

2. Technique

There exists neither one best technique nor one best material, as both depend greatly on patients’ individual anatomic, social and economic possibilities [5] (LOE 1).

Two main techniques have been adopted, a sterile IC (SIC) and a clean IC (CIC). The sterile non-touch technique involves the use of sterile materials handled with sterile gloves and forceps. In an intensive care unit, some advocate wearing a mask and a sterile gown as well [6].

De Ridder et al. [7] compared the performance of SpeediCath hydrophilic-coated catheters versus uncoated polyvinyl chloride (PVC) catheters, in traumatic spinal cord injured patients presenting with functional neurogenic bladder-sphincter disorders. This 1-year, prospective, open, parallel, comparative, randomised, multi centre study included 123 male patients, > or =16 y and injured within the last 6 months. Primary endpoints were occurrence of symptomatic urinary tract infection (UTI) and hematuria. Secondary endpoints were development of urethral strictures and convenience of use. The results indicate that there is a beneficial effect regarding UTI when using hydrophilic-coated catheters. Bjerklund Johansen et al. evaluated patient openness to changing and satisfaction with catheters used in intermittent catheterisation (IC) for urinary retention from neurogenic bladder dysfunction. They also compared patient response to conventional catheters and a novel packaged hydrophilic catheter: LoFric Primo [8]. 409 neurogenic patients were recruited and 378 (283 males, 95 females; mean age: 43.5 yr) completed a 12-d trial of the novel catheter. Patients evaluated their current catheter at recruitment and the novel catheter after the 2-wk trial by questionnaire. Patient satisfaction was expressed on a Visual Analogue Scale for seven topics covering use and general satisfaction. The main finding was that more than 50% of the patients wished to continue with the novel catheter and reported increased satisfaction regarding introduction of the catheter, handling, time spent, and perception of IC, general satisfaction, and ability to cope with daily life. Kovindah and Madersbacher investigated whether a silicone catheter reused over years for clean intermittent catheterization (CIC) was safe for spinal cord injured (SCI) men [9]. A cross-sectional study was obtained from SCI men who had used CIC with a reusable silicone catheter for more than a year. The clinical outcome, especially with regard to urethral abnormalities with this reusable silicone catheter was as good as with a disposable one. However, to reuse urinary catheters, one should consider the increased risk of infection. Therefore, these authors suggest that for SCI patients in developing countries, CIC with a reusable silicone catheter may be a suitable and safe choice if one cleans and applies it. In the same way, Getliffe performed a systematic Cochrane review summarizing current evidence on the relationship between sterile single-use catheters or clean reused catheters and the incidence of UTI’s [10]. 13 trials met the inclusion criteria on intermittent catheterization protocols. There was considerable variation in length of follow-up, definitions of UTI, and numbers of subjects. Attrition was a problem for several studies, and all were underpowered. Several studies were more than 10 years old, and outcome measures were imprecise, making it difficult to draw conclusions on the benefit of one catheterization method over another. They concluded that there are no definitive studies illustrating that incidence of UTI’s is affected by sterile single-use or coated catheters compared to clean reused catheters. However the current research base is weak and design issues are significant. Based on the current data, it is not possible to state that one catheter method is better than another and further research on the topic is strongly recommended (LOE1).

Frequency of catheterization: This depends on many factors as bladder volume, fluid intake, postvoid residual, urodynamic parameters (compliance, detrusor pressure). Usually it is recommended to catheterize 4 – 6 times a day during the early stage after spinal cord lesion. Some will need to keep this frequency if IC is the only way of bladder emptying. Others will catheterize 1 – 3 times a day to check and evacuate residual urine after voiding or on a weekly basis during bladder retraining

Adjunctive therapy: To overcome high detrusor pressure antimuscarinic drugs or other bladder relaxants can be indicated. For those who develop a low compliance bladder, upper tract deterioration or severe incontinence, injection of Botulinum toxin in the bladder wall or surgery, such as bladder augmentation, may be necessary.

3. Complications

If catheterization is begun by patients with recurrent
or chronic UTI and urinary retention, the incidence of infection decreases and patients may become totally free of infection. If symptomatic infections occur, improper CIC or misuse often can be found. Chronic infection persists if the cause of the chronicity remains. Treatment of UTI is necessary if the infection becomes symptomatic. Lindehall et al. evaluated the rate of complications associated with catheterization and the risk of urethral lesions in girls with myelomeningocele treated with clean intermittent catheterization for a minimum of 10 years. They found that there were remarkably few problems associated with clean intermittent catheterization despite long treatment periods and use of noncoated polyvinyl chloride catheters. Clean intermittent self-catheterization and large size catheters were associated with few complications [11]. Similarly, they evaluated the risk for urethral lesions and epididymitis in boys with neurogenic bladder dysfunction treated by clean intermittent catheterization (CIC) for a minimum of 10 years and found that the overall rate of complications was low. The incidence of major urethral lesions did not increase during puberty. Self-catheterization and 12C catheter or greater seemed to be protective against major lesions [12] (LOE3). As opposed, Chen et al found that the incidence of urethral strictures increases with a longer follow-up and bladder stone formation was found to be associated with long-term use of CIC in SCI patients [13] (LOE3).

4. Health related quality of life

Oh et al aimed at determining the psychological and social status of patients using clean intermittent catheterization for neurogenic bladder according to health-related quality of life (HRQOL). They conducted a prospective trial involving 132 patients (81 men and 51 women, mean age 41.8 years, range 18 to 80 years) using clean intermittent catheterization because of neurogenic bladder secondary to spinal cord injury [14]. The 150 controls (90 men and 60 women) lived in the same region as the patients and were frequency matched to ensure equal age and sex distributions. HRQOL was measured using the Medical Outcomes Study 36-Item Short-Form General Health Survey (SF-36). Their findings suggest that patients using clean intermittent catheterization because of neurogenic bladder secondary to spinal cord injury generally exhibit a reduced quality of life in all health domains as assessed by the SF-36 (LOE3) [15].

CONCLUSIONS

- **IC is effective and safe to treat the neurogenic bladder in the short term and in the longterm.** (LOE 1)
- **Complications such as UTI are regularly seen and seem to be related to both the catheterization itself and the existing LUT condition (LOE 2)**

RECOMMENDATIONS

- **Urethral and bladder complications seem to increase in the long term (LOE 3)**
- **In order to reduce and prevent complications, appropriate materials and correct techniques should be taught and performed (LOE 3)**
- **Adequate frequency of CIC, a non-traumatizing technique and suitable materials are the key factors for a successful outcome (LOE 2)**
- **Patients using clean intermittent catheterization because of neurogenic bladder secondary to spinal cord injury generally exhibit a reduced quality of life in all health domains as assessed by the SF-36. (LOE1).**

Implications for research

- There is a clear need for robust research in the area of IC, both evaluating clean vs. sterile PVC catheter use and hydrophilic vs PVC use (both sterile and reused). Researchers need to consider the design of the study if comparisons across trials are meaningful. Although cross-over designs mean lower sample size and control for within subjects variation, unless the data at cross-over point is available, these studies cannot entered into a meta-analysis. There it is recommended that journal editors who are publishing cross-over trials request that the authors include first set of data before cross-over (10).
b) Indwelling Urethral Catheters – transurethrally/ suprapublically

1. Transurethral catheterisation (ID)
   a. Background

In early 19th century, a urinary catheter with a balloon bag (Foley catheter) was developed. After the World War I, the majority of spinal cord injured (SCI) as well as other neurologic patients were treated with indwelling urethral catheterization (ID) or suprapubic catheterization (SC) due to difficulty in voiding or urinary incontinence. Nowadays, intermittent catheterization (IC) is recommended for neurologic patients. Nevertheless many choose ID as a mean of treating urinary incontinence due to difficulty in performing IC or persistent leakage between catheterizations. In developing countries ID is still the method of choice for those with urinary retention or incontinence.

Studies have shown that ID causes various complications such as urethral trauma and bleeding, urethritis, fistula due to pressure effect caused by improper size of the urethral catheters and improper technique of securing the catheters, bladder and renal stones, cystitis, acute and chronic urinary tract infection (UTI), bladder neck incompetence, meatus and urethral sphincter erosion, and bladder carcinoma. Many of these complications were related to long-term use. Therefore many experts advocate removal of the urethral catheter as soon as possible, and usage of other methods such as IC or SC to decrease urethral complications. However, nowadays the complications of ID seem less, due to better materials, the use of smaller size catheters and a proper technique of securing the catheter. For CIC wet patients contemporary balloon catheter indwelling at night seems to decrease risk of febrile episode due to UTI as compared to CIC alone [16]. The contemporary balloon catheter used consisted of a reusable balloon catheter and a reservoir to inflate the balloon. The patients self-inserted the catheter every night before sleeping, and then removed it the next morning. After use, the catheter is washed with tap water, and stored in a special purpose case filled with disinfectant (LOE3). Transurethral ID needs a lot of meticulous skill and care. Materials used should be sterile and handled properly by a well-trained person. In some centers, a well-trained catheter team has proved to lessen complications related to catheterizations. It is suggested that more frequent catheter change should be performed in patients with recurrent urinary tract infections (once a week or every two weeks) (LOE 4).

The study by Pannek (LOE 3) reported 0.11% incidence of bladder cancer amongst SCI individuals (48 out of 43,561 patients) which is similar to that observed in the general population [17]. However, more than 60% of the patients with SCI initially presented with muscle-infiltrating bladder cancer. The expression of inducible nitric oxide synthase was demonstrated in patients with SC or ID by Wall et al [18] (LOE 3), a finding which may potentially lead to the sustained production of nitric oxide and its oxidative products, the nitrosation of urinary amines and the formation of potentially carcinogenic nitrosamines in the bladder. Hamid et al.[19], however, in their retrospective series, did not find bladder cancer on bladder biopsies in patients with SC I and a mean catheter time of 12.1 years.

A case of osteomyelitis of the pubis was reported by Stern et al.[20] LOE 3).

b. Antibiotic prophylaxis

Routine antibiotic prophylaxis for patients with SC or ID is not recommended. Attempts at eliminating bacteriuria associated with indwelling or intermittent catheters are generally unsuccessful [21] (LOE 4).

For prevention of UTI, general cleanliness and local hygiene should be encouraged. If the patient has a symptomatic UTI, it is important to check for catheter blockade and complications as urinary stones. Symptomatic urinary infections have to be treated with the most specific, narrowest spectrum antibiotics available for the shortest possible time.

Guidelines for selecting antimicrobial agents in SCI patients are similar to guidelines for the treatment of complicated urinary infections in the general population. Characteristics of the quinolones make them well suited for treating UTI in SCI patients [22] (LOE 4).

CONCLUSIONS

- Transurethral ID is not a safe method for a long-term use in neurologic patients. (LOE 2)
- To control urinary incontinence, ID is effective if there is no blockade or urethral/bladder neck erosion (LOE 3)
- Catheters size 12-16F with as large a lumen as possible and smaller (5-10 ml) self-retaining balloons are recommended for adults to minimise the pressure effect on the bladder neck and to maximise time to blockage by incrustation. (LOE 4)
- Use of less irritating catheters and closed drainage system should be encouraged to minimise complications. (LOE 2)
- If available, siliconised catheters may be used with more frequent change. (LOE 3)
- Frequency of change largely depends on materials and size of catheter lumen e.g., every 1-2 weeks for siliconised latex catheters, every 2-4 weeks or longer for silicone or hydrogel-coated catheters. (LOE 3)
2. Suprapubic Catheterisation — Special Aspects

An alternative to indwelling urethral catheterization is an indwelling catheter placed through the lower abdomen into the dome of the bladder, called a suprapubic catheter (SC).

Overall the benefit and risks of the SC are very similar to the indwelling urethral catheter including the risk for urinary tract infection, stone formation, bladder cancer, and maintenance cost of catheter and bag. However, there are several benefits and one key disadvantage. Its advantages include: minimized risk of urethral trauma in men and women, minimized risk of urethral destruction in neurologically impaired women with even relatively short-term indwelling urethral catheters, and minimized urethral pain. The key disadvantage is that it requires a minor ‘surgical’ produce to insert the suprapubic catheter with potential to injure structures adjacent to the bladder, especially the large intestine [23]. The preferred insertion technique appears to be quite variable by region and country. There is no evidence that there is one best way to insert the SC.

Long-term management of the neurogenic bladder with the SC is a controversial topic in neurourology. The issue of controversy is that some rehabilitation centers across the world highly favor the suprapubic catheter as a safe and effective long-term management of the neurogenic bladder. On the other hand, a large number of experts have personal experience with suprapubic tube complications during its long-term use.

The literature on suprapubic catheterization is limited, and most of publications are 20 years or older. There are no prospective studies and no RCT’s on suprapubic catheterization. The bias of single center case series is the short follow-up with a worrisome large number of patients who are lost for follow-up. It is unclear if these patients may have developed complications and have died or were treated with alternative bladder management at a different hospital.

CONCLUSIONS

- Suprapubic catheter is a reasonable alternative to indwelling urethral catheter, but both are clearly inferior to intermittent catheterization (LOE 3).
- It is a safe and effective short-term management of urinary retention. (LOE 3)
- It is not recommended for the routine use for the long-term management of the neurogenic bladder. (LOE 2)
- Complications of SC are similar to that of ID, except the unique complication of bowel perforation and no urethral complications. (LOE 3)
c) Condom catheter and external appliances

**BACKGROUND**

Male patients with neurogenic bladder and chronic urinary incontinence can be candidates for a condom catheter (CC) connected to a urine or leg bag to collect the urine. However, some have difficulty in applying CCs, e.g., due to overweight and/or some degree of penile atrophy or retraction.

**CONCLUSIONS**

- Condom catheter still has a role in controlling urinary incontinence in neurologic male patients (LOE 3)
- Long-term use may cause bacteriuria, but it does not increase the risk of UTI when compared to other methods of bladder management. (LOE 3)
- Complications may be less if applied properly with good hygiene care, frequently change of the CC and maintenance of low bladder pressures. (LOE 3)
- Special attention should be paid to people with dementia (LOE 3)

**RECOMMENDATIONS**

(All grades of recommendation = B/C)

- To have better control of leakage, a more secure CC should be used, and patients should be educated and cooperative.
- To prevent latex allergy, a silicone CC should be used and serological examination of latex-specific IGE is recommended in addition to patient history to better identify patients at risk.
- To prevent compressive effects, choose proper size CC with self-adhesive.
- To prevent infection, a daily change of the CC could help.
- To prevent bladder and upper tract damage, regular bladder emptying with low bladder pressures and low post void residual should be pursued.

3. PHARMACOTHERAPY

Detailed data on pharmacotherapy are presented in a specific chapter of the Committee on Pharmacologic treatment. Our chapter deals only with specific issues of pharmacotherapy in neurologic patients. We strongly recommend consulting the Drug Treatment chapter for levels of evidence and recommendations. References can also be found in the ICI 2005 chapter on conservative management of the neurogenic bladder.

The principal causes of urinary incontinence in this subpopulation are neurogenic detrusor overactivity (NDO) and/or incompetence of urethral closing function. To improve urinary incontinence the treatment should aim at decreasing detrusor activity, increasing bladder capacity and/or increasing bladder outlet resistance. This picture is blurred by the occurrence of detrusor/sphincter dyssynergia which can be present concomitantly with NDO.

Pharmacologic therapy has been particularly helpful in patients with relatively mild degrees of neurogenic bladder dysfunction. Patients with more profound neurogenic bladder disturbances may require pharmacologic treatment to improve results of other forms of management such as intermittent catheterization. Although the two most commonly used classes of agents are antimuscarinic and alpha-adrenergic blockers, the drugs used for treating neurogenic bladder/urethral dysfunction should be classified as follows. (Most but not all drugs action was evaluated in neurologic patients).

**Drugs for incontinence due to neurogenic detrusor overactivity and/or low compliant detrusor**

- **a) Bladder relaxant drugs**
  1. **Oxybutynin**
  2. **Propiverine**
  3. **Trospium**
  4. **Tolterodine**
  5. **Propantheline**
  6. **Oxyphenyclimine**
  7. **Flavoxate**
  8. **Tricyclic Antidepressants**
  9. **Solifenacin Succinate**
  10. **Darifenacin**
  11. **Fesoterodine**

- **b) Intravesical application**
  1. **Oxybutynin, Lidocaine, Nociceptin/Orphanin FQ, Atropine**
  2. **Vanilloids**
     a. Capsaicin
     b. Resiniferatoxin
  3. **Botulinum toxin**

**Drugs for incontinence due to neurogenic sphincter deficiency**

- **a) Alpha-adrenergic agonists**
- **b) Estrogens**
- **c) Beta-adrenergic agonists**
- **d) Tricyclic antidepressants**
Drugs for facilitating bladder emptying

a) Alpha adrenergic blockers
b) botulinum toxin
c) Cholinergics

DRUGS FOR INCONTINENCE DUE TO NEUROGENIC OAD AND/OR LOW COMPLIANT DETRUSOR

a) Bladder relaxant drugs

Antimuscarinic agents are by far the most useful drugs in the management of the neurogenic bladder: they are used to suppress NDO.

General indications of pharmacological treatment in NDO are to improve or eliminate reflex incontinence, eliminate/ prevent a high intravesical pressure and enhance the efficacy of intermittent catheterization (IC), triggered voiding and indwelling catheters. Neurogenic detrusor overactivity is mostly associated with a functional outflow obstruction due to detrusor-sphincter-dysynergia (DSD). For the most part, pharmacotherapy is used to suppress reflex NDO completely and facilitate IC. On the other hand bladder relaxant drugs would seem to decrease detrusor- contractility also during voiding. With this situation residual urine may increase and must then be assisted or accomplished by IC. It must be stressed that with the current level of knowledge antimuscarinic therapy is not a causative treatment, but a symptomatic one.

1. OXYBUTYNIN

Oxybutynin hydrochloride is a moderately potent antimuscarinic agent with a pronounced muscle relaxant activity and local anesthetic activity as well. In a prospective, 12-week dose titration trial of controlled release oxybutynin (OXY-XL), Bennett et al. [24] evaluated the efficacy and tolerability of higher dose oxybutynin chloride in patients with neurogenic bladder and multiple sclerosis, spinal cord injury or Parkinson’s disease. A 7-day washout period was used before initiation of the starting dose of 10 mg OXY-XL. Doses of OXY-XL were increased by 5 mg at weekly intervals to a maximum dose of 30 mg per day guided by patient perception of efficacy versus side effect. At the end of the study statistically significant decreases in the number of voids in 24 hours, episodes of nocturia and incontinence episodes were observed. Residual urine remained unchanged. No patient experienced serious adverse events (LOE2). In a prospective, open label trial of 3 formulations of oxybutynin (tablets, syrup and extended release tablets), Franco et al [25] evaluated the efficacy and safety of oxybutynin in children with NDO due to neurological conditions. The effect of treatment on average urine volume per catheterization and on secondary urodynamic outcomes was evaluated. Maximal cystometric capacities increased, and mean detrusor and intravesical pressures were significantly decreased at week 24. Improvements in bladder function were consistent across all oxybutynin formulations (LOE2).

2. PROPIVERINE

In a randomized, double-blind, prospective multicenter clinical study, Stöhrer et al. [26] compared the efficacy and tolerability of propiverine and oxybutynin in patients with neurogenic detrusor overactivity. Propiverine and oxybutynin were equally effective in increasing bladder capacity and lowering bladder pressure. The trend for better tolerability of propiverine compared to oxybutynin achieved significance for dryness of the mouth (LOE1). Propiverine hydrochloride has also been shown to be effective in neurogenic detrusor overactivity in children and adolescents, even in some of those cases unresponsive to other anticholinergics [27,28]. The low incidence rate of adverse events evidenced a favourable risk-benefit profile of propiverine hydrochloride (LOE3).

3. TROSPURIM

Trospium is a quaternary ammonium derivative with mainly antimuscarinic actions, it’s effectiveness and safety has confirmed in meta-analysis (see reference ICI 2002). Trospium has been shown to significantly reduced the number of urinations, increased cystometric capacity and mean effective volume of the bladder, and reduced the number of urgent voiding in neurogenic patients [29,30] (LOE1).

4. TOLTERODINE

Tolterodine is a potent, competitive muscarinic receptor antagonist specifically developed fro the treatment of overactive bladder. Tolterodine has a high selectivity in vitro and exhibits selectivity for the urinary bladder over the salivary glands in vivo. Several phase II study have demonstrated the efficacy and safety of tolterodine in patients with overactive bladder [32]. Ethans conducted a prospective, randomized, double-blind, crossover trial plus open-label comparative stage, aiming at comparing tolterodine with oxybutynin and placebo in people with neurogenic detrusor overactivity. Tolterodine, when used at at self-selected doses (SSDs) was comparable with oxybutynin at SSDs in enhancing bladder volume and improving continence, but with less dry mouth. Tolterodine at the recommended dosage of 2 mg twice daily improves incontinence and bladder volumes compared with placebo, and without significant dry mouth (LOE1). It seems however that larger doses of tolterodine is needed to achieve best effect on neurogenic bladder [33-34] (LOE3).

5,6,7,8. PROPANTHELINE, OXYPHENCYCLIMINE, FLAVOXATE AND TRICYCLIC ANTIDEPRESSANTS

are used by many clinicians around the world for bladder relaxation in patients with neurogenic bladder. Local reports claim good clinical effectiveness. In
literature no new data in neurogenic patients on their effect and safety have been reported since ICI 2. Flavoxate does not seem to be effective for treating detrusor overactivity (references in ICI 2005 report).

9. SOLIFENACIN Succinate

Solifenacin succinate is a newer anticholinergic drug, used once daily, which has a functional selectivity for the bladder over other organs. Solifenacin has been extensively studied in OAB [35-39] (LOE1). There is up to date no data on the effect of solifenacin in neurogenic detrusor overactivity.

10. DARIFERACIN

Dariferacin is a chiral diphenylacatamide tertiary amine, marketed as a water hydrobromide salt, and is a selective M3 receptor antagonist. It has been shown to have a higher degree of selectivity for the M3 receptor compared with other anticholinergics. It is extensively metabolized by the liver after oral dosing. Metabolism is mediated by CYP enzymes to its main metabolite. Dariferacin has been extensively studied in OAB [40-43] (LOE1). There is up to date no data on the effect of Dariferacin in neurogenic detrusor overactivity.

11. FESOTERODINE

Fesoterodine acts functionally as a prodrug. It is rapidly and extensively hydrolysed by nonspecific esterases to 5-hydroxymethyl tolterodine. The conversion is rapid and virtually complete such that, after oral dosing, only the metabolite, not the parent compound, can be detected in patient plasma. This active metabolite, responsible for the antimuscarinic activity of fesoterodine is also the active metabolite of tolterodine, 5-hydroxymethyl tolterodine (5-HMT). In contrast to tolterodine, the conversion of fesoterodine to 5-HMT bypasses the CYP system, although CYP3A4 and CYP2D6 are involved in subsequent inactivation of the active metabolite. Phase 3 trials have suggested that fesoterodine is an effective and well-tolerated therapy for OAB [44-46] (LOE1). There is up to date no data on the effect of fesoterodine in neurogenic detrusor overactivity.

b) Intravesical application

1. OXYBUTYNIN, PROPANTHELINE, NOCICEPTIN/ORPHANIN FQ, ATROPINE

Since the first use of the intravesical application by Brendler et al. [47], there have been over 100 peer review articles reporting successes of intravesical oxybutynin to treat overactive bladder and NDO. The main findings were, at least at short term follow up, an improvement of overactive bladder symptoms, including a decreasing number of incontinence episodes, an increase of maximum bladder capacity and a decrease of the detrusor overactivity in the urodynamic recordings. George et al. compared the therapeutic response of intravesical oxybutynin, propantheline, and capsaicin in the treatment of neurogenic detrusor overactivity [48]. Oxybutynin 5 mg in solution or propantheline 15 mg in solution and capsaicin were instilled intravesically in each patient. Urodynamic studies were done before and after the intravesical instillation of each drug. There was a significant difference in therapeutic response between intravesical oxybutynin, propantheline, and capsaicin in the treatment of detrusor overactivity for leak volume (LV) and leak frequency at 2nd week. When comparing responses of oxybutynin and propantheline, more subjects demonstrated improvement with intravesical propantheline than oxybutynin for reflex volume, detrusor leak point pressure, clean intermittent catheterization volume, and LV (LOE3). Up to now there is however no standard instillation protocol concerning the use of intravesical oxybutynin for overactive bladder. The doses vary between 5-30 mg diluted in 30-40 ml saline [48-49]. Also the instillation frequency is not standardized and varies between 1 to 3 times /d.

Nociceptin/orphanin FQ (N/OFQ), where F and Q represent the first and last amino acid, respectively, phenylalanine (F) and glutamine (Q), is a hepta-decapeptide that exerts several physiologic actions at both the central and the peripheral level by activating a specific G-protein-coupled receptor named nociceptin orphan peptide (NOP) receptor. Among the, animal studies have demonstrated that N/OFQ exerts a robust inhibitory effect on the micturition reflex in the rat [50]. Lazzeri et al. recently studied the feasibility, safety and efficacy of daily intravesical instillation of 1 mg of the endogenous peptide N/OFQ in a selected group of patients who performed clean intermittent catheterization for neurogenic detrusor overactivity (NDO) [51]. A total of 18 patients with NDO and incontinence on clean intermittent catheterization were prospectively randomized to receive 1 mg nociceptin/orphanin FQ in 10 ml saline or placebo (saline) at the first catheterization for 10 days. Mean daily urine leakage episodes significantly decreased from 2.18 at baseline to 0.94 during nociceptin/orphanin FQ treatment, while no significant changes were reported in the placebo group. The total mean voiding diary bladder capacity significantly increased in patient receiving nociceptin/orphanin FQ, while mean voiding diary bladder capacity remained unchanged in patients receiving placebo. The urodynamic parameters recorded during the study showed an increase in cystometric capacity and a decrease in maximum bladder pressure compared to baseline only in patients assigned to the nociceptin/orphanin FQ group. These findings support the use of nociceptin/orphanin FQ peptide receptor agonist as an innovative approach for controlling neurogenic detrusor overactivity incontinence (LOE2).

Fader et al. [52] tested the efficacy and side effect
profiles of intravesical atropine compared to oxybutynin immediate release (IR) when used by individuals with multiple sclerosis. They performed a study to determine the most effective dose of atropine. Eight participants used increasing doses of intravesical atropine (2 to 6 mg in 20 ml NaCl 0.9%) during a 12-day period. Bladder diary data showed that the instillation of 6 mg atropine 4 times daily was most effective for increasing bladder capacity (voided/catheter volumes). Afterwards they performed a randomized, double-blind crossover trial. Participants received 14 days of treatment with oral oxybutynin IR 5 mg twice daily (range 2.5 twice to 5 mg 4 times daily) or with intravesical atropine, followed by 14 days of alternative treatment. Participants recorded a bladder diary and rated side effects and quality of life. The primary outcome variable was bladder capacity. A total of 57 participants with multiple sclerosis completed the study. Average change in bladder capacity was higher in the atropine arm. Changes in incontinence events and voiding frequency were not statistically different between the arms. Changes in total side effect and dry mouth scores were significantly better in the atropine treatment arm. These findings suggest that intravesical atropine is as effective as oxybutynin immediate release for increasing bladder capacity and it is probably better with less antimuscarinic side effects (LOE2).

2. Vanilloids

Have been discussed in the ICI 2005 report, and references before 2002 are to be found there.

a. Capsaicin (CAP) (see background and reference ICI 2002)

The use of capsaicin is still largely experimental and limited by the fact of prolonged and painful excitation of the sensory c-fibers. The alcoholic solvent may be a major factor in the poor tolerability of alcoholic CAP instillation, as suggested by the result of one placebo controlled study showing that side effects appeared to be the same after intravesical instillation of CAP diluted in 30% ethanol as after instillation of ethanol alone (LOE2).

b. Resiniferatoxin (see background 2002)

Resiniferatoxin (RTX) acts without the potent neuronal excitatory effect of capsaicin, and therefore elicits less discomfort. Groups comparing RTX in saline or 10% ethanol with CAP in 30% ethanol found better tolerability of RTX (see ICI 2002). The difference in tolerability of the 2 vanilloids (CAP vs. RTX) was usually attributed to the differential pungency of the 2 agents. Nevertheless, because we know the role of the solvent in the irritative effect on bladder mucosa, it is reasonable to assume that differential effects could be related to the use of different vectors. From a technical point of view the choice of the solvent is limited because of the poor hydrosolubility of CAP, imposing the use of an alcoholic, lipidic or glucidic vector. The safety of the lipidic solution could be imperfect because of difficulty of achieving complete elimination of lipidic solution from the bladder. On the contrary, a glucidic solution may represent a safe and valuable alternative to the alcoholic vector. De Seze et al. [53] compared the efficacy and tolerance of intravesical instillations of CAP and RTX using a glucidic solvent for CAP and the 10% ethanol solvent for RTX in a controlled randomized, double blind study in patients with severe urinary incontinence due to spinal cord injury. On day 30, improvement was found clinical and uroodynamical respectively in 78% and 83% of patients treated with CAP vs. 80% and 60% treated with RTX. No significant difference between the 2 groups was observed. The benefit remained in two-thirds of the 2 groups on day 90. There were no differences in regard to incidence, nature or duration of side effects in CAP vs. RTX treated patients. These results once more strongly argue for the importance of accounting the role of vanilloid solute when interpreting efficacy and tolerance of vesical vanilloid instillation in detrusor hyperreflexia cases. They suggest that a glucidic solution is a valuable solvent for CAP instillation (LOE2).

RTX seems to have a beneficial effect on NDO (LOE 2). However, good randomized controlled studies are needed to determine its place in the treatment of NDO. Also the optimum doses (concentration) as well as the inter treatment intervals need to be determined.

Moreover, the long-term safety of vanilloid agents, particularly concerning mutagenic and carcinogenic effects on the bladder wall is not perfectly known. The use of CAP solved in ethanol seems not to cause morphological changes in the bladder urothelium in patients receiving repeat instillation for as long as 5 years. To our knowledge the long-term safety of RTX remains unproven. Furthermore, RTX belongs to the family of tumor promoting phorbol esters, strengthening the need to ensure the safety of RTX before extending its therapeutic applications.

3. Botulinum toxin A See background ICI 2002

Botulinum neurotoxin (BoNT) decreased neurogenic detrusor overactivity in four full published LOE1 studies [54-56], one LOE2 study [57], and several LOE3 studies. Only 5 complete full publications [54-57] and three abstracts[58-60] were included in this chapter. The majority of the studies involved only participants with neurogenic bladder. Two studies had participants for which as a group, the aetiology of overactive bladder was mixed. In one LOE1 study, 59 patients with spinal cord injury and MS were enrolled in a single treatment, randomized, placebo-controlled, 6-month safety and efficacy study [54]. Patients received either BoNT-A or placebo. Injections were given into the detrusor muscle, leaving out the bladder base and trigone. Injection volume was 30 cc and 30 sites...
were injected. A single administration of 200 or 300 units of Botox® into the detrusor muscle was well tolerated and more effective than placebo in reducing the frequency of incontinence episodes, enhancing bladder function, and improving quality of life.

In another LOE1 study, the use of BoNT was studied for refractory neurogenic and non-neurogenic detrusor overactivity [55]. Twenty patients were injected with either placebo (20 ml normal saline) or BoNT-B (Myobloc®, 5000 IU diluted up to 20 ml). After six weeks, treatments were crossed over. The primary outcome was the paired difference in change in average voided volumes. Secondary outcome measures included frequency, incontinence episodes, and paired differences in quality of life, as measured by the King’s Health Questionnaire. There were significant paired differences in the change in average voided volume, urinary frequency, and episodes of incontinence between active treatment and placebo. There were also differences in the change in quality of life affecting five domains of the King’s Health Questionnaire. This study is limited in that the study population was comprised of a mixed population of patients, with diverse aetiologies of detrusor overactivity (neurogenic and non-neurogenic). This limits the generalizability of the findings. The absence of a sustained washout period before the crossover might have biased the findings, and the low dose of BoNT-B used may have affected the duration of the results.

In another study, BoNT-A injection was compared to resiniferatoxin intravesical instillation into the bladder in 25 patients with spinal cord lesions and concomitant neurogenic detrusor overactivity [57]. There was a significant decrease in catheterization and incontinence episodes for both treatments at 6, 12, and 18-months of follow-up. However, the BoNT injections provided superior clinical and urodynamic benefits as compared to intravesical resiniferatoxin. There were no significant side effects with either treatment (LOE1).

A recently published study compared a single injection of BoNT-A (500 units Dysport®, diluted in 25 ml saline and injected into 25 injection sites) to placebo in 31 patients with neurogenic detrusor overactivity and urinary incontinence. Time of follow-up was 26 weeks. Patients in the BoNT-A group had a significant change regarding intake of anticholinergic drugs, cystometric bladder capacity, maximum detrusor pressure, frequency of urinary leakage and quality of life parameters (LOE1) [61].

There is one study (LOE3) that addressed different injection technique. Karsenty et al. compared to different technique of injections of 300 units of BoNTA (Botox®) [58]. They compared 10 versus 30 injections sites and reported a significant reduction in post-procedure pain only in the group receiving 10 injections. There was no significant difference found in any other measures including incontinence episodes or cystometric capacity. In addition to the study from Schurch et al. two trials (LOE2) assessed the efficacy of different doses of Botox® (100 versus 300 and 200 versus 300) [59,60]. No study reported significant difference between the different dose and the confidence interval were wide.

The safety seems to be quiet acceptable though generalised paraparesis/fatigue has been described especially in patients with high spinal cord lesions. The effect resolves spontaneously after 4-6 weeks.

There are several major reviews coming up in literature that will highlight the actual knowledge of long-term treatment, overall safety and different techniques of application.

### DRUGS FOR INCONTINENCE DUE TO NEUROGENIC SPHINCTER DEFICIENCY

Several drugs, including alpha-adrenergic agonists, estrogens, beta-adrenergic agonists and tricyclic antidepressants, have been used to increase outlet resistance. No adequately designed controlled studies of any of these drugs for treating neurogenic sphincter deficiency have been published. In certain selected cases of mild to moderate stress incontinence a beneficial effect may be obtained.

### DRUGS FOR FACILITATING BLADDER EMPTYING

#### a) Alpha adrenergic blockers

Alpha-adrenoceptors have been reported to be predominantly present in the bladder base, posterior urethra and prostate. Alpha-blockers have been already reported to be useful in neurogenic bladder by decreasing urethral resistance during voiding (references ICI 2005 report). Only new references are mentioned here.

Tamsulosin has been shown to improve bladder storage and emptying in MS and SCI [62].

Abrams et al. [63] evaluated the efficacy and safety of tamsulosin in patients with neurogenic lower urinary tract dysfunction secondary to suprasacral spinal cord lesions in a 4-week randomized controlled trial (RCT) followed by a 1-year, open label, long-term study. A total of 263 patients were randomized to 4-week double-blind therapy with placebo, or 0.4 or 0.8 mg tamsulosin once daily. The primary efficacy parameter was maximum urethral pressure (MUP). In the long-term study but not in the RCT trial there was a statistically significant mean decrease in MUP from baseline to end point. In the long-term study tamsulosin also decreased maximum urethral closure pressure, improved several cystometry parameters related to bladder storage and emptying, and increased to a statistically significantly degree, from baseline to end point, mean voided volume based on the micturition diary. There was statistically significant improvement for the International Prostate Symptom Score Quality of Life. Both doses were effective and well tolerated. (LOE1)
b) Botulinum toxin

In a LOE1 study, the effects of botulinum toxin versus placebo was studied on DSD in 86 multiple sclerosis (MS) patients[64]. The study employed a single transperineal injection of BoNT-A, 100 units in 4 cc normal saline, or placebo, into the striated sphincter with EMG guidance. The primary endpoint was post void residual volume at 30 days. The secondary endpoints included voiding and urodynamic variables. Results showed that a single injection of BTX did not decrease post-voiding residual volume in this group of MS patients. These findings differ from those in patients with spinal cord injury and may be due to lower detrusor pressures in MS patients.

c) Cholinergics

In general, bethanechol chloride seems to be of limited benefit for detrusor areflexia and for elevated residual urine volume. Elevated residual volume is often due to sphincter dyssynergia. It would be inappropriate to potentially increase detrusor pressure when concurrent DSD exists.

CONCLUSIONS

- Bladder relaxant agents, including oxybutynin, propiverine, trospium and tolterodine have a documented suppressive effect on incontinence by controlling overactive bladder, thereby improving storage function (LOE 1).
- However, all of these drugs presently available have considerably high incidence of side effects (dry mouth, constipation, urinary retention, etc.), which limits their usage. Tolterodine, propiverine, trospium and controlled-release oxybutynin have significantly less side effects compared to immediate-release oxybutynin (LOE 1).
- High doses of OXY-XL seem safe and effective in patients with neurogenic bladder (LOE 3)
- Although the oral application is the usual way, intravesical instillation or intrarectal (oxybutynin) may be an alternative (LOE 4).
- Intravesical instillation of capsaicin/resiniferatoxin has been reported to improve spinal reflex incontinence for several months after instillation (presumably blocking sensory input). Resiniferatoxin is preferable (LOE 3).
- Botulinum toxin injections into the detrusor muscle was reported to improve incontinence and increase functional bladder capacity in spinal cord injured patients with neurogenic DOA (LOE 1).
- Long-term α-adrenergic antagonists are effective and well tolerated in patients with MS and suprasacral spinal cord lesion with neurogenic lower urinary tract dysfunction (LOE1)
- Data on the use of botulinum toxin (BonT) for DSD are conflicting. BoNT is probably safe and effective for the treatment of DSD in spinal cord injury patients (LOE2). However, on the basis of one LOE1 study, BonT does not provide significant benefit for the treatment of DSD in MS patients,
- There is no adequately designed controlled study of any drug for neurogenic sphincter deficiency.

RECOMMENDATIONS

- Bladder relaxant agents should be recommended for the treatment of reflex incontinence evoked by neurogenic detrusor overactivity in patients in whom IC alone is unable to control it (A).
- Titration of the dosage of these drugs individually should be done to achieve maximum therapeutic effect and minimal side effect. If one drug is not tolerated, try another drug as it may have less side effects (C/D).
- BoNT should be offered as a treatment option for neurogenic detrusor overactivity (A).
- Vanilloid intravesical therapy still remains experimental and therefore is not recommended except within clinical trials (C/D)
- Further attempts for the treatment of NDO should be undertaken to develop the ideal drug in terms of good efficacy, tolerability and safety (D).
- For decreasing outlet resistance in neurogenic bladder a-adrenergic antagonists may be used (B/C).
- BoNT may be considered for DSD in spinal cord injury patients (B)
- For neurogenic sphincter deficiency no effective drugs are available up to now; further research is needed (D).
- For detrusor areflexia no effective drugs are available up to now (IC remains the gold standard) ; further research is needed
4. ELECTROSTIMULATION

a) Electrical Neuromodulation

1. BACKGROUND

In the last decade sacral nerve neuromodulation has been confirmed as a valuable treatment option for patients with symptoms of overactive bladder. The success with sacral neuromodulation has increased the interest in other neuromodulation techniques.

The current techniques of neuromodulation for treating overactive bladder – which includes detrusor overactivity of neurologic origin - are (a) anogenital hypertension, (b) pudendal nerve stimulation, (c) sacral nerve neuromodulation, (d) percutaneous posterior tibial nerve stimulation (Stoller afferent nerve stimulation, SANS), (e) magnetic stimulation and f) deep brain stimulation.

It is not really known how neuromodulation works, however, there is strong evidence that neuromodulation works at a spinal and at a supraspinal level [65]. For more details about possible mechanism of actions see ICI report 2005.

2. PUDENDAL NERVE STIMULATION

It has been shown that electrical stimulation of pudendal nerve afferents can inhibit bladder contractions in patients with SCI, and bladder capacity can be increased by continuous [66] as well as conditional stimulation [67] (LOE3). Implants such as the InterStim® system have made this treatment modality commercially available (see sacral nerve stimulation). Common to these implantable systems is that they use continuous stimulation. Detrusor inhibition is in principal only necessary during an involuntary contraction and, thus, stimulation could be turned off between contractions. Such a stimulation scheme could have a number of advantages. Power consumption may be decreased and, thus, extend battery lifetime. Furthermore, continuous stimulation of a reflex may lead to habituation, which would be minimized or prevented by conditional stimulation. Hansen et al.[68] examined the effect of the automatic, event driven electrical stimulation of pudendal nerve afferents on bladder capacity in patients with SCI. The study included 2 women and 14 men older than 18 years with NDO, bladder capacity below 500 ml and complete or incomplete suprasacral spinal cord injury. Detrusor pressure (Pdet) was recorded during ordinary, natural bladder filling. In a similar subsequent recording Pdet was used to trigger electrical stimulation when pressure exceeded 10 cm H2O. Of the 16 patients enrolled in this study 13 had increased bladder capacity together with a storage pressure decrease as a result of automatic, event driven electrical stimulation. During stimulated filling Pdet never exceeded 55 cm H2O. Thus, storage pressure was sufficiently low to prevent kidney damage. An average bladder capacity increase of 53% was achieved (LOE 3).

3. CHRONIC PUDENDAL NERVE STIMULATION

Direct pudendal nerve stimulation has beneficial effects on numerous pelvic floor function impairments such as urinary and/or fecal incontinence, retention, and constipation. In preceding literature the implant technique required a fairly complex and invasive surgery, although recent advances with percutaneous placement of the lead through an introducer have made the procedure much less invasive. Spinelli et al.[69] performed staged procedure similar to that of sacral neuromodulation (SNM) to place tined lead near the pudendal nerve, using neurophysiological guidance. They named this approach chronic pudendal nerve stimulation (CPNS).

Fifteen neurogenic patients (eight male, seven female) with symptoms of urge incontinence due to neurogenic overactive bladder underwent CPNS. All patients had complete neurophysiological and urodynamic evaluation at baseline and follow-up and were asked to complete voiding and bowel diary for 7 days. During screening, average number of incontinent episodes per day decreased from 7+/- 3.3 to 2.6+/- 3.3 (<0.02, paired t-test). Eight patients became continent, two improved by more than 88% (from 9 to 1 daily incontinence episodes) and two patients reduced the number of incontinence episodes by 50%. The implantable pulse generator (IPG) was subsequently implanted in those 12 patients. Three patients without improvement did not continue to second stage. In implanted patients with 6 months follow-up, urodynamic evaluation showed an objective improvement in the maximum cystometric capacity which increased from 153.3+/- 49.9 to 331.4+/- 110.7 ml (<0.01, paired t-test). The maximum pressure decreased from 66+/- 24.3 to 36.8+/- 35.9 cmH2O (P=0.059, paired t-test). Eight patients reported significant improvement in bowel function (LOE3).

4. POSTERIOR TIBIAL NERVE STIMULATION

Posterior tibial nerve stimulation was described 20 years ago as a minimally invasive treatment for urge incontinence due to neurogenic detrusor overactivity (NDO) in spinal cord injury (SCI) patients. Interestingly, the site involves the Sanyijioa (Sp6) point use in Chinese acupuncture for urinary incontinence problems.

Pudendal nerve afferent (S2 to S4) are well know to suppress NDO but it is not intuitively obvious that PTN afferents should have similar effect. However, the PTN is derived from L4 and L5 and S1 to S3 nerve roots and therefore shares common roots with those serving bladder functions. In few reports, SCI and Parkinson patients have been treated with PTN because of NDO and neurogenic incontinence. PTN seems to increase cystometric bladder capacity, enhance bladder volume at which hyperreflexic contraction and associated leakage occurs [70,71] (LOE3).
b) Repetitive transcranial magnetic stimulation

Repetitive transcranial magnetic stimulation (rTMS) of the motor cortex induces a long-lasting modulation of spinal cord excitability [72]. Thus, it represents a potentially useful tool for the treatment of neurogenic urinary disturbances. Centonze et al. [73] investigated the effects of high frequency (5 Hz) excitatory rTMS over the motor cortex on LUT dysfunction in a population of 10 MS patients complaining of urinary symptoms. All but one of the patients reported an improvement of voiding phase LUT symptoms and a significant reduction of post void residual volume. In patients with pure detrusor underactivity, this finding seems to be produced by a better contraction of the detrusor muscle, with consequent increase of Pdet@Qmax and Qmax.

Notably, a similar finding was reported in female Fowler’s syndrome patients after sacral neuromodulation, a procedure that probably shares some central actions with rTMS. In patients with DSD, on the other hand, rTMS produced negligible effects, although the observation of a reduction of Pdet@Qmax seems to suggest a better relaxation of the urethral sphincter (LOE3).

c) Deep brain stimulation

1. Subthalamic nucleus deep brain stimulation (STMN-DBS)

A large proportion of patients suffering from Parkinson’s disease presents with urinary dysfunction including urgency, increased frequency or incontinence as predominant symptoms [74]. Deep brain stimulation (DBS) of the subthalamic nucleus (STN) has been established as a surgical treatment of motor symptoms in Parkinson’s disease patients [75]. However, data from experimental urodynamic measures in men [76] and animal models [77] have also demonstrated a significant influence of STN-DBS on urinary bladder function. In these studies, the main effect of STN-DBS appeared to be a normalization of urodynamic parameters in the storage phase with a delayed first desire to void and an increased bladder capacity. Herzog et al. aimed at investigating the effect of STN-DBS on the neural mechanisms underlying cerebral bladder control. Using PET to measure changes in regional cerebral blood flow (rCBF), 11 patients with bilateral STN-DBS were studied during urodynamically bladder filling in STN-DBS ON and OFF condition. A filled bladder led to a significant increase of rCBF in the anterior cingulate cortex, which was further enhanced during STN-DBS OFF.

A significant interaction between bladder state and STN-DBS was observed in lateral frontal cortex with increased rCBF when the bladder was filled during STN-DBS OFF [78,79] (LOE3).

2. Thalamic deep brain stimulation

The precise mechanisms underlying cerebral regulation of lower urinary tract function are still poorly understood. Essential tremor (ET) is not known to induce lower urinary tract symptoms (LUTS) or neuropathological changes in the thalamus. Consequently, DBS in patients with ET offers the unique opportunity to investigate the role of the VIM nucleus in lower urinary tract function. Kessler et al. [80] evaluated the effect of thalamic DBS on urodynamic parameters in patients with ET. Seven patients were examined (two females, five males) with ET 15–85 mo after implantation of DBS leads into the ventral intermediate nucleus of the thalamus. They compared urodynamic parameters during thalamic DBS (ON state) and 30 min after turning the stimulator off (OFF state). In the ON compared with the OFF state, there was a significant decrease in bladder volume at first desire to void (median, 218 ml vs. 365 ml, p = 0.031), at strong desire to void (median, 305 ml vs. 435 ml, p = 0.031), and at maximum cystometric capacity (median, 345 ml vs. 460 ml, p = 0.016). No significant differences between the ON and OFF state were detected for changes in detrusor pressure during filling cystometry, bladder compliance, maximum detrusor pressure, detrusor pressure at maximum flow rate, maximum flow rate, voided volume, and postvoid residual (LOE3).

CONCLUSIONS

- Electrical neuromodulation mostly is not the first line treatment for neurogenic detrusor overactivity. There are some limited reports showing that it may be beneficial (LOE 3).
- Automatic, event driven electrical stimulation in the treatment of NDO is feasible (LOE 3).
- Chronic pudendal nerve stimulation is feasible. Neurophysiological guidance seems to be mandatory to place the lead near the pudendal nerve either using perineal or posterior approach (LOE3).
- Enhancing corticospinal tract excitability by rTMS might be useful to ameliorate detrusor contraction and/or urethral sphincter relaxation in MS patients with bladder dysfunction (LOE3).
- Thalamic deep brain stimulation resulted in an earlier desire to void and decreased bladder capacity, suggesting a regulatory role of the thalamus in lower urinary tract function (LOE3).
- STN-DBS appeared to be a normalization of urodynamic parameters in the storage phase with a delayed first desire to void and an increased bladder capacity (LOE3).
CONCLUSIONS

- Although from the theoretical point of view and based on limited personal clinical experiences electrical stimulation via anal or vaginal plugs could be able to improve the strength of pelvic floor musculature, including that of the striated sphincter muscle, there is no study published which deals with this matter (LOE 4)

RECOMMENDATION

If pharmacotherapy fails to relax the hyperreflexic detrusor, electrical neuromodulation may be optional in patients with neurogenic detrusor (C/D)

- Although the setup for automatic, event driven electrical stimulation is not suitable in a clinical setting, the treatment modality is promising and it warrants further investigation (D).

- Further studies on chronic pudendal nerve stimulation must be carried out to identify the best stimulation parameters and to verify the long term results (D).

- The thalamus may be a promising target for the development of new therapies for lower urinary tract dysfunction. Further investigation on this matter is critical before one speculates, that the thalamus will emerge as a target for treatment of lower urinary tract symptoms such as urgency and bladder pain (D).

- STN-DBS might ameliorate bladder dysfunction and that this modulation may result from facilitated processing of afferent bladder information (D).

e) Intravesical electrical stimulation (IVES)

BACKGROUND (read ICI 2002 page 741 and following)

The afferent stimuli induced by IVES travel along afferent pathways from the LUT to the corresponding cerebral structures. This “vegetative afferention” results in sensation of bladder filling/urge to void, with subsequent enhancement of active contractions, and possibly also in voluntary control over the detrusor. Feedback training is mediated by enabling the patient to observe the change of the detrusor pressure on a water manometer, which enables the patient to notice when a detrusor contraction takes place. This also facilitates voluntary control.

The technique involves a catheter with a stimulation electrode, introduced into the bladder and connected to the stimulator. Saline (0.9 %) is used as the current leading medium within the bladder. The neutral electrode is attached to the skin in an area with preserved sensation, usually in the lower upper abdomen.

Intravesical electrical stimulation of the bladder (IVES) is still a controversial therapy for patients with neurogenic detrusor dysfunction.

It is worthwhile to apply intravesical electrostimulation, bearing in mind inclusion and exclusion criteria, especially to verify functional afferent fibers within the bladder and the cortex. Intravesical electrotherapy is able to improve neurogenic bladder dysfunction, primarily by stimulating a-delta mechanoaffersents inducing bladder sensation and the urge to void and consequently increasing the efferent output with improvement of micturition and conscious control. Therefore IVES is the only available option to induce/improve bladder sensation and to enhance the micturition reflex in incomplete central or peripheral nerve damage. However, proper indication is crucial and this type of therapy should only be applied in those with afferent fibers between the bladder and the cortex, proved by the evaluation of viscerosensory cortical evoked potentials. If these conditions are respected, IVES can be effective. In ICI 2002 30 studies about IVES have been reviewed. The conclusions for this consultation are not different from what was given in 2002.

Techniques of electrical stimulation involving surgery are to be found in the surgery section.
CONCLUSIONS

- Basic research during the last decade has proved the underlying working concept of IVES (LOE 3)
- The results reported in the literature are controversial, mainly because of different inclusion and exclusion criteria (LOE 3).
- In the only sham-controlled study the treatment period is too short and the inclusion and exclusion criteria are not really defined (LOE 3).
- The alternative may be either life long intermittent catheterization or bladder augmentation. In this regards IVES is cost-effective (LOE 3)

RECOMMENDATIONS

- Intravesical electrotherapy is able to improve neurogenic bladder dysfunction, inducing bladder sensation and the urge to void and consequently increases the efferent output with improvement of micturition and conscious control in patients with incomplete central or peripheral nerve damage. However, proper indication is crucial and this type of therapy should only be applied in those with afferent fibers between the bladder and the cortex, (B/C)
- IVES is the only available option to induce/improve bladder sensation and to enhance the micturition reflex in patients with incomplete central or peripheral nerve damage. (B)
- Selection of patients is crucial and IVES should be applied only if afferent fibers between the bladder and the cortex are still intact and if the detrusor muscle is still able to contract. If these premises are respected, IVES is effective. (B)
- The ideal indication is the neurogenic hyposensitive and hypocontractile detrusor (C)

IV. SURGICAL TREATMENT

1. SACRAL NEUROMODULATION

Literature survey with the words neurogenic bladder; spinal cord injury; spina bifida; meningomyelocele; multiple sclerosis, sacral neuromodulation

Two indications for neuromodulation are clearly valid in urology: urinary incontinence (for overactive bladder syndrome) and chronic urinary retention (aside from vesicosphincteric dyssynergia) [1]. We will not discuss in detail the principles of these treatments and their modalities, which are covered in detail in a specific committee report of this ICI. We will focus solely on the possible application of sacral neuromodulation in patients with neurological bladder dysfunction symptoms.

a) Hypotheses on the modes of action of neuromodulation

The first effects of electricity on the bladder were reported during electro stimulation treatment of pelvic floor muscles (with the aid of electrodes situated in the anus, the vagina, on the penis...) during urinary incontinence reeducation [2-6]. Inhibition of bladder contractions by electrostimulation was seen. Tanagho and Schmidt, the pioneers of neuromodulation, attributed the benefits of neuromodulation in urinary incontinence to a hypertrophy of the pelvic muscles allowing better efficacy and better control [7]. Now, it has long been known that voluntary contractions of the pelvic floor muscles cause a reflex along the somatic afferent branches of the pudendal nerve that leads to relaxation of the bladder. However, such explanation seems simplistic and poorly explains other reported effects of urinary neuromodulation (in the treatment of vesical hypocontractility or pelvic pain). The most widely held hypothesis today is that neuromodulation allows a restoration of normal vesical reflexes [8] [9] [10](LOE4). This hypothesis explains that the stimulation can inhibit the guarding reflex pathway and restore normal urination or turn off supraspinally mediated hyperactive voiding by blocking ascending sensory pathways and therefore decreasing incontinence. The role of cortico-subcortical structures was recently emphasized in studies of incontinent [11, 12] (LOE4) or retentive patients [13](LOE4).
Regardless of the hypothesis authors agree that the somatic afferents are the vectors for neuromodulation signals. Actually, the visceral nerve fibers cannot be activated by the intensities normally used today with this technique [14](LOE4). Despite data obtained in animals [15](LOE4), it seems that neuromodulation cannot be effective in patients with a non functional peripheral nerve circuit.

b) Sacral neuromodulation in the treatment of reflex urinary incontinence in patients with a neurological bladder dysfunction

There is little in the literature concerning sacral neuromodulation (SNM) in this specific indication. Many studies recorded results for incontinence and for retention at the same time, without always separating the results.

Since the technique’s first stages, Vodusek [5, 6](LOE4) reported that non-muscular electrical stimulation of the sacral somatic afferents can induce bladder inhibition in patients who present with detrusor overactivity secondary to a medullar lesion, be it due to trauma or to multiple sclerosis (MS).

Two points must be kept in mind when treating patients with neurological bladder:

- the disappearance of wettings between catheterizations can be considered a success by itself in patients who have already used intermittent catheterization (however, in able-bodied patients treating retention with intermittent catheterization is most often considered a failure);
- On the other hand (especially, for example, in comparison with botulinum toxin injections), neuromodulation does not systematically require the use of intermittent catheterization. If this is the case, then stopping the neuromodulation current quickly causes cessation of bladder paralysis; the treatment’s reversibility is therefore a strong point that must be considered when devising a therapeutic plan.

The main published series are summarized in Table 2. Author definitions for neurological pathology differed widely: some authors considered a history of pelvic surgery as a possible etiology while others included only patients with medullar neurological lesions. Despite this, several points considering the neurological etiology of the bladder dysfunction can be discussed.

A majority of the authors consider that a diagnosis of multiple sclerosis is not a contra-indication for neuromodulation [10, 16, 17](LOE3-4). However, it seems important to propose this treatment only in patients who present with a stabilized form of multiple sclerosis. In addition, patients must be clearly informed that the results of neuromodulation may be altered by the evolution of their underlying illness.

Patients with incomplete medullar lesions, whether of traumatic or other origins, may benefit from neuromodulation [10, 18-23](LOE3-4). On the other hand, all authors agree on excluding patients with complete medullar lesions from neuromodulation’s scope of application. This attitude rests upon a cluster of arguments. First, the presumed modalities of neuromodulation’s actions, such as this, were given above (LOE4). In addition, the clinical data, especially from the Hohenfellner series [20](LOE3), support among others those reported by Schurch et al in 2003 [24](LOE4). These authors published a study in which they recorded external anal sphincter (EAS) electromyographic activity caused by stimulation of the S3 sacral root during a PNE test in three patients who presented with detrusor hyperactivity and vesicosphincteric dyssynergia at the same time secondary to a complete traumatic medullar lesion. They describe a reflex response with early and late latency in the three patients. They also demonstrated that the EAS contraction observed during the PNE represented an indirect motor response mediated by the afferent nerves towards the spinal cord. Despite the recording of an EAS motor response in the three patients, they did not obtain any urodynamic or clinical effect. This suggests the participation of supraspinal neuronal centers—spino-bulbo spinal pathway—in the SMN mode of action. However, these data are contradicted by an experimental study using bilateral neuromodulation in the cat [15] (LOE4).

The use of chronic neuromodulation of the pudendal nerve, appears promising [23] (NP3). Pudendal nerve stimulation and electrode positioning were carried out under neurophysiological monitoring (using a St. Mark’s electrode) in order to guide the electrode in Alcock’s Canal as close as possible to the pudendal nerve. Electrode implantation was carried out by a rear approach under local anesthesia according to the method described by the same authors in 2003 [25, 26]. Naturally, these short term results must be confirmed in a larger prospective patient sample. On the other hand, a recent anatomical study [27] demonstrated that the technique for implanting electrodes at the pudendal level can be slightly risky (NP4).

Guys et al [28] determined sacral neuromodulation results to be encouraging. The authors demonstrated significant but limited urodynamic differences between implanted and children without implant (LOE3). However, the clinical translation of these modifications has not been reported. It must be emphasized that, in the absence of electrodes adapted to child sizes, the study was carried out using an implant that was put in use immediately without a test period. Moreover, the utilization of percutaneous electrodes is no longer possible. This necessitates a surgical placement attaching the electrode to the sacral periosteum. Frequent displacements in adults have been seen. A

</table>
multicenter study on a larger patient population with more severe neurological lesions was done. Essentially, they estimate that the lack of results, especially in the urodynamic study, was due at least in part to the severity of neurological conditions in the population studied.

Despite these encouraging short term results reported by different authors in reflex incontinence secondary to neurological bladder dysfunction, the series published by Hohenfellner et al [20](LOE2) incites some caution. It demonstrates that despite a positive test in about half of the patients tested, long term (54 months) results were poor in almost all patients (1/12 had neuromodulation efficacy).

d) Criteria predictive of successful neuromodulation tests in patients with reflex incontinence secondary to a neurological bladder dysfunction

In 2002 Scheepens et al [21] reported their results of patients tested in their department (six incomplete medullar injuries, five patients with cauda equina syndrome, six with multiple sclerosis, and one with myelomingocele). They found two prognostic factors for poor response (LOE3): The duration of the symptoms (more than seven months in this study) and the existence of a neurological cause for bladder dysfunction. Neurological patients with a very localized and incomplete nervous condition were the most successful. Patients with herniated disc surgery had a greater chance of good response. Patients with complete medullar lesions were a priori poor neuromodulation candidates, as were patients with large sacral lesions.

In general, it is the conviction that urodynamic tests carried out when the electrode is placed are not of value for predicting neuromodulation results. Moreover clinical results of neuromodulation do not necessarily correlate to urodynamic results. Bosch indicated in his series [18] that almost half of the patients considered to have been cured kept a certain degree of bladder overactivity. Essentially, the only publication to find parallelism between urodynamic test data and clinical data was carried out only on injured patients with a neurogenic bladder [10](LOE4). In this particular subgroup of patients, urodynamic monitoring during the acute test may have a benefit. In 2001 Chartier-Kastler [29] et al published the results of a prospective study (NP2) concerning the evolution of urodynamic parameters during the acute phase of the PNE test in 14 patients who presented with a neurogenic detrusor hyperactivity (DH) with UUI (urge urinary incontinence). The authors concluded that the acute phase of PNE was accompanied by a significant change in urodynamic parameters in more than 2/3 of the patients, and that this should be a possible means for selecting patients who present with neurogenic DH who are likely to benefit from the PNE chronic phase. However these promising results are not as yet confirmed.

e) Neuromodulation results in patients with urinary retention in patients with a neurological bladder dysfunction

There are less publications on the urinary retention (especially Fowler’s syndrome) than on urinary incontinence [22, 30-33].

The only study which reported specific results for neurogenic bladders is from Hohenfellner et al [20](LOE3), in which a subgroup of 11 patients had bladder retention problems. Of these patients, three were implanted and there were temporarily satisfactory results in only two. Several years previously the same author published an interesting study on the benefit of bilateral pudendal neuromodulation, especially in patients with urinary retention [34](LOE4). The preliminary results did not appear to have been confirmed in the long term.

It seems that neuromodulation has a marginal place in retention patients with neurological bladder. Patients need to be clearly informed of the high risk of failure. It is also necessary to be especially prudent in patients with cauda equina sequel, who may have the illusion of recovering urination by simply making a greater abdominal push to evacuate their bladder. In reflex incontinence, patients with complete spinal cord or cauda equina lesions are poor candidates (LOE4).

Before attempting sacral neuromodulation, patients also have to be informed that intermittent self-catheterism remains the best therapeutic option in the case of urinary retention in patients with a neurological bladder dysfunction.

RECOMMENDATIONS

• Sacral neuromodulation can have an inhibitory effect on neurological detrusor hyperactivity. (C)

• While sacral neuromodulation has a place in the care of neurological urinary incontinence or neurological urinary retention, the proportion of patients whose condition is improved is much less than in non-neurological pathologies (B).

• The definition of the best indications for sacral neuromodulation (neurological illness) in the care of vesicosphincteric dyssynergia in neurological bladders is still imprecise (D).

• Utilization of neuromodulation in neurology presupposes a urodynamic evaluation and carrying out a clinical test under sacral electrode (C).

• New neuromodulation techniques may allow further improvement of results from the use of neuromodulation in neurology (medial pudendal nerve or pudendal nerve) (D).
2. SURGERY FOR INCONTINENCE ASSOCIATED WITH POOR BLADDER EMPTYING DUE TO DRETRUSOR UNDERACTIVITY

Search for neurogenic bladder; spinal cord injury; spina bifida; myelomingingocele; multiple sclerosis; sphincterotomy; stent

Introduction

In some cases, incontinence in neurological patients can be aggravated by deficient bladder emptying and retention. Two mechanisms can be involved: detrusor sphincter dyssynergia (DSD) or bladder hypotonicity. This chapter focuses on alternatives that could be proposed to the patient in this situation, when conservative management fails.

a) Surgical treatment of detrusor external sphincter dyssynergia

Detrusor sphincter dyssynergia (DSD) is a characteristic feature of suprasacral and infrapontine lesions.

The aim of sphincterotomy is to produce reflex micturition into a condom catheter, thus protecting the upper urinary tract. For the last thirty years, endoscopic sphincterotomy has been the technique of choice for patients who cannot or do not want to do clean intermittent catheterization. It is invasive, irreversible and the patient has no adaptation period [1, 2](LOE3). This explains the recent development of prosthetic sphincterotomy using a urethral endoprosthesis (or stent).

1. INDICATIONS AND CONTRA-INDICATIONS OF SPHINCTEROTOMY

Indication supposes a diagnosis of a neurological cause of DSD that is complicated by hydronephrosis, vesico-urethral reflux, autonomous hyperreflexia or repeated urinary infections secondary to poor bladder voiding. Patient should have failed or refused intermittent catheterism.

2. MAIN CONTRA-INDICATIONS ARE [3, 4]:

- Impossibility to retain a condom catheter. All sphincterotomy techniques, including stenting, are contra-indicated for men who cannot retain a condom catheter (and a fortiori for women). A semi-rigid penile prosthesis can be placed to help retain the condon catheter [5](LOE3). However, patients must be informed that there is a 20% to 30% risk of erosion and infection of the penile prosthesis for those with spinal cord injury, as opposed to only 2.7% in the general population [6, 7] (LOE3).

- Detrusor acontractility or hypocontractility. Patients with spinal cord injury and no reflex detrusor contraction during urodynamic tests are poor candidates for the various techniques of sphincterotomy.

- Patients who wish to father children and are candidates for vibro/electro-ejaculation and an artificial insemination program.

3. ENDOSCOPIC SPHINCTEROTOMY

Emmett [8] first described endoscopic sphincterotomy in 1948. He performed cervico-prostatic incisions in patients with spinal cord injury, but later realized that the problem lay in the striated sphincter. External sphincterotomy was performed in 1958 by Ross et al. [9]. They carried out heavy cold-blade surgery and placed a catheter (CH 22 to 26) for tamponade since nearly all patients required transfusion (one of the ten patients in the series died after surgery).

A few attempts at surgical sphincterotomy via the perineal and subpubic myotomy routes were tried later. The complexity of these interventions, together with frequent and serious complications, explains why they were abandoned [10] [11]. Spincterotomy with electrocoagulation was finally found to be the best technique.

a. Endoscopic sphincterotomy morbidity

The most frequent morbidity is post-operative hematuria which can be abundant and sometimes difficult to control, requiring transfusion in 2-13% of patients (see Table 3, LOE2-3). Twelve o’clock sphincterotomy seems to offer the lowest risk of hemorrhage, with three and nine o’clock sphincterotomies entailing the highest risk [12] (LOE4).

Post-operative impotence is also a common complication. Rates of up to 56% were reported in early series [13-16](LOE3). More recent series (table1, LOE 2-3), most using a median, or slightly deviated incision, have not seen an affected sexual function. However, it should be noted that the population concerned may have many other reasons (neurological, psychological, etc.) for suffering from erectile dysfunction.

When sphincterotomy is accompanied by complete incontinence there are obvious reasons for psychological difficulties during intercourse. This issue must be discussed with the patient before surgery. In our experience, the fear of this sequel sometimes causes the patient to decide against surgery and is a reason why we propose incontinent prosthesis as first-line therapy, to enable the patient to simulate the effects of surgery.

If striated sphincter section fails, the patient must be checked and the possibility of bladder neck sclerosis investigated. Depending on the particular series, this problem is seen in from 2 to 21% of patients. Section of the bladder neck may then improve voiding, but will result in permanent incontinence. Before surgery, the surgeon must make sure that the patient accepts this situation and can use a condom catheter.

b. Results of endoscopic sphincterotomy

Results are summarized in Table 2 (LOE2-3). Any analysis is made difficult by the absence of univocal criteria of success. Some patients are improved by sphincterotomy, even with a 200 ml residue. Most authors use indirect urodynamic criteria to evaluate success (decrease in bladder pressure during micturition, decrease in PVR). The most obvious result is the improvement in autonomic dysreflexia observed in tetraplegic patients. It also appears that the intervention reduces the rate of symptomatic urinary infections. However, the patient must be informed that surgery will not prevent the chronic bacteriuria so often suffered by these patients [17]. The reported results concerning resolution of hydronephroses and vesicorenal reflux differ, and in each series, there are very few patients. Another essential point, well known in practice but rarely reported, is the recurrence of neurogenic DSD in many patients [2, 18, 19] (LOE3). Riccotone et al (LOE3) [19] reported 82% recurrence of symptoms after ten years of follow-up. Juma et al [2] (LOE3) report similar results after eleven years, with patients undergoing an average of 1.7 sphincterotomies, and about 30% of patient having some impairment of the upper urinary tract. Patients who have undergone this surgery must therefore be regularly monitored to detect any distension of their upper urinary tract.

4. PROSTHETIC SPHINCTEROTOMY

In 1990, Shaw et al. were the first to propose using a wire mesh stent (Urolem™) to treat patients with spinal injury presenting with DSD [20] (LOE3). Since then, various stents have been used.

Table 4 lists the types of stent used for DSD, according to classification criteria [21, 22].

They can be placed in various sections of the urinary tract: prostatic urethra, through the striated sphincter or more distal in the sub-sphincteric urethra. Our review is limited to placement through the striated sphincter for which there are two solutions: temporary or permanent stents.

a. Temporary prosthetic sphincterotomy

Temporary stents make it possible to carry out a therapeutic test to check the feasibility of condom catheterization, check that placing a foreign body in the urethra does not induce autonomic dysreflexia and ensure the patient accepts the mode of micturition. Moreover, during this trial period, it is possible to study how the bladder empties in the seated position, assess the necessity of a combined treatment for smooth muscle sphincter dyssynergia at the level of the bladder neck. Moreover, as this treatment is simple and reversible, it is possible to propose it very early to the patients, rendering the patient autonomous with regard to carer-assisted catheterization, if this were the prior mode of micturition and leaving the possibility to discuss any fertility and sexual issues, and considering the possibilities of preserving sperm.

Finally, for patients with spinal cord injury, the aims of early temporary stent placement (within six months of trauma) are as mentioned above, but with the

theoretically added advantages of waiting for recovery of upper limb motility to enable self-catheterization, decrease the risk of nosocomial infection during rehabilitation by reducing carer-assisted catheterization, and relieve nursing load during rehabilitation. The last two points, though logical, are yet to be proved by relevant studies. After using a temporary stent, the patient may choose his mode of micturition; i.e., return to his former state, change to an identical stent, depending on the known life span of the temporary stent, replace by a permanent stent or choose surgical sphincterotomy.

By definition, temporary stents should be self-retaining, easy to remove and must not epithelialize. Apart from the temporary stent Diabolo™, which is under assessment [23], no temporary stent is specific for the external urethral sphincter. The results of two types of temporary stenting (test) for incontinence have been published in the same series[24] (LOE3). In a retrospective study of 147 patients, the authors demonstrated a significant effect on incontinence throughout the mean ten month test period, with very low morbidity (15%). The temporary stents were removed easily from all patients without sequellae. After this period, 62.6% of patients chose permanent sphincterotomy, usually by means of a permanent stent. During the study, the authors abandoned the first used stent (Nissenkorn™), preferring a temporary stent currently being developed, Diabolo™.

Memokath™ stent is another device that has been studied in neurological patients[25-29](LOE3-4). Several authors report complications (38-100%) using this stent, which seems to induce a lot of bladder stones and to be quite difficult to remove especially if it is left longer than 18 months.

b. Permanent prosthetic sphincterotomy

Permanent stents are designed to integrate the urethral wall [30]. They resist the striated sphincter and prevent it closing during reflex contraction. They can be removed if necessary, or at the patient’s request, with recovery of striated sphincter contraction [31, 32].

Permanent stents are made of biocompatible materials such as nitinol (a nickel and titanium alloy) and titanium. They usually consist of a mesh comprising a single (Urolume™) or several threads (Ultraflex™). None of the stents are specifically adapted for the urethral striated sphincter. Three have been reported for treating neurological patients with DSD: Urolume™, Memotherm™ and Ultraflex™. All can be placed under local anesthesia. Table 5 summarizes the principal series published on these devices. Only Urolume™ was studied according to strict prospective criteria [17](LOE1-2). Using stringent clinical and statistical methods, they classified the stent as LOE 1 for effectiveness and morbidity in DSD with a 5-year follow-up. 160 patients with spinal cord injury (mean age: 36.3 years; standard deviation = 12.1 years) in 15 North American centres, were treated prospectively with Urolume™ for DSD. Urodynamic parameters for micturition pressure, PVR and functional bladder capacity were measured before treatment and then 1, 2, 3, 4 and 5 years afterwards. Mean micturition pressure, the primary criterion, was significantly lower

5 years after stenting. PVR decreased significantly and was maintained after 5 years. Mean bladder capacity remained constant. Hydronephrosis, suffered by 28 patients before surgery, disappeared in 22 (78.6%) and was improved in the others. Autonomic hyperreflexia resolved in 70% of cases. The indwelling catheters of 63 of the 86 (74.4%) patients catheterized before surgery could be removed. The percentage of positive urine cultures remained unchanged after stenting. No case of peri- or post-operative bleeding, soft tissue erosion or bladder lithiasis were observed during the study. One case of prosthetic incrustation occurred during the first year; three during the second year; three during the third year; two during the fourth year and five in the fifth year. Urothelial reaction was reported in 44.4% of cases, but 93.3% of these were mild and none required treatment. No erectile dysfunction was reported. Stents had to be removed from 24 patients (15%), four of whom received new implants. 80% of the patients considered their situation improved by stenting, and 84% of physicians considered the treatment effective. 47 patients required supplementary treatment on the bladder neck (endoscopic section in 20 cases). In the mid-term, prosthetic sphincterotomy using a Urolume™ stent appears to be satisfactory. However, over the long-term, the situation is not so clear. It is not always easy to remove the stent, especially from patients who have not been monitored regularly. Some teams report highly complex surgery for stent removal, especially in the event of associated urethral stenosis [33-36] (LOE3).

5. SHOULD PATIENTS BE OFFERED PROSTHETIC OR ENDOSCOPIC SPHINCTEROTOMY?

Endoscopic sphincterotomy is the preferred standard treatment for DSD, where clean intermittent catheterization cannot be performed. The superiority of a new procedure can only be demonstrated by a randomized clinical study with sufficient follow-up. Two prospective studies were carried out in the US in 1994 by Rivas and Chancellor and indicated that prosthetic sphincterotomy was at least as effective as standard sphincterotomy in patients with spinal cord injury, and offered advantages in terms of morbidity, duration of hospitalization and cost [37, 38]. The two studies were not randomized. Follow-up was too short (mean: 15 months), introducing a bias in the case of Chancellor’s study. He concluded that external sphincter balloon dilatation was as effective as endoscopic and prosthetic sphincterotomy. After sufficient follow-up, external sphincter balloon dilatation was abandoned because it was ineffective in the long-term [39].

A prospective, multicenter, randomized study comparing endoscopic sphincterotomy with prosthetic sphincterotomy was published in 1999 by Chancellor and Rivas, using the Urolume™ stent [40]. Fifty-seven patients in three specialist spinal cord injury centers were included. The study concluded that prosthetic sphincterotomy was as effective as endoscopic sphincterotomy and required shorter hospitalization. As we have already reported, these findings are relevant only for the short and medium-term. The long-term outcome of prosthetic sphincterotomy for incontinence remains unreported. At present, it is vital that stented patients be monitored carefully at least once a year during the years following implant surgery.

6. OTHER SPHINCTEROTOMY TECHNIQUES

As well as prosthesis placement, alternative techniques to surgical sphincterotomy have been reported.

Two authors reported using Nd-YAG lasers for sphincterotomy [41, 42]. Although no randomized study has been conducted, comparison with results from the literature (with very short follow-up), suggests that these techniques are not as good as standard endoscopic sphincterotomy. However, the reported morbidity (particularly hemorrhage) was reduced (LOE2).

External sphincter balloon dilatation was recommended by Chancellor et al. [37], with short-term results similar to those of surgical sphincterotomy. However, the technique has been abandoned by its sponsors and the device has not been distributed, probably indicating poor efficacy in the medium and long-term, compared with other mini-invasive methods such as stenting.

RECOMMENDATIONS

- Where clean intermittent catheterization is not possible, the long-term use of indwelling catheters should be avoided (B).
- Whatever type of sphincterotomy is chosen (surgical or prosthetic):
  - Patients must think carefully about the different modes of micturition possible for them (A).
  - The few studies reporting long-term results of sphincterotomy demonstrate the vital importance of regular patient monitoring for the recurrence of DSD or blockage (B).
  - This mode of micturition is contra-indicated in women and men with acontractile bladder and difficulty in maintaining a condom catheter (B).
  - Men who wish to have children should be warned of the risk of ejaculatory duct obstruction (B).
- For patients who have chosen surgical sphincterotomy:
  - The reference technique involves an elective 11, 12 or 1 o’clock incision of the urethral sphincter (B).
b) Surgery to increase detrusor strength

For some patients, the cause of bladder hypocontractility lies in the bladder wall. In this case, the control circuit functions but the bladder muscle is too weak. At present there is no medical treatment for this situation. The general objective is to reduce peripheral resistances as much as possible and wherever this fails, to propose intermittent catheterization.

However, over recent years, some teams have suggested placing rolled strips of muscle around the bladder. Some authors have also suggested a strip of rectus abdominus muscle. This is easier to perform and may be used essentially for reconstructive surgery, such as bladder extrophy [43-45] (LOE4). The only team to have published results on bladder hypocontractility in man is that of Ninkovic et al. [46] (LOE2). They recently reported interesting results from twenty patients suffering from bladder hypocontractility of neurological origin and requiring self-catheterization. They reported a technique that they had designed in animal experiments [47, 48] (LOE4) and which consisted of transferring a free strip of great dorsal muscle, which was anastomosed to the epigastric vessels and the lowest branch of the intercostal nerve. Out of twenty patients, with a mean follow-up of 44 months, 60% no longer required self-catheterization, with PVR below 100 ml. After complementary surgery on the bladder neck, there was a 90% success rate that was stable over time. The authors reported no heavy morbidity, particularly with regard to the donor site. Other teams need to confirm these results, but it appears to be a very promising approach. Future development could use tissue-engineering techniques to construct vascularized and contractile strips implanted around the bladder with the same procedure.

RECOMMENDATIONS

The use of a free strip of great dorsal muscle on the bladder is a promising technique that needs to be validated further (D).

3. DENERVATION PROCEDURES FOR TREATING REFLEX URINARY INCONTINENCE DUE TO DETRUSOR OVERACTIVITY

a) Introduction

Neurosurgery has a particular role in the management of neurogenic detrusor overactivity [1]. Many different procedures have been described: open surgery for complete or partial rhizotomies (radicotomies) (ventral or dorsal), selective or otherwise. Direct injection of various neurolytic substances has also been suggested. In this part, we consider the main series reported in the literature and will briefly describe the various possible options together with their functional effects and long-term results.

b) Peripheral bladder denervation

The most popular technique today is the injection of botulin toxin which is dealt with also elsewhere in this report. Various techniques of peripheral bladder denervation, such as prolonged hydrodistension or bladder transsection, are no longer used. Some authors have reported transient improvement in certain patients after prolonged hydrodistension, but unfortunately detrusor overactivity recurs rapidly and the procedure is not quite so simple. Moreover, there are no reports for patients presenting specifically with neurogenic detrusor overactivity [2]. Bladder transsection was briefly popular at the end of the 70s [3-5]. It involved complete section of the bladder wall from one urinary meatus to the other. The technique was indicated essentially for urge incontinence and pollakiuria, and rarely in the context of detrusor overactivity. However, a lack of anatomical and physiological information to support the mechanisms of efficacy of the procedure, and a lack of reproducible results from the initial series, explains why it is no longer used.

Another bladder denervation technique was developed by Ingelman-Sundberg [6, 7] (resection of the inferior hypogastric plexus in contact with the bladder). The procedure is technically simple and can be performed under local anesthetic. The surgeon makes an inverted U-shaped vaginal incision in contact with the trigone and dissects the bladder both laterally and posteriorly,

- Although surgical sphincterotomy is the accepted reference treatment for neurogenic DSD, analysis of the literature highlights the lack of reliable efficacy and reproducibility criteria for the technique (B).
- For patients who have chosen prosthetic sphincterotomy:
  - Different types of stent are used, depending on whether sphincterotomy is temporary or permanent. Stents are complementary, and different designs can be used for different situations (B).
  - Surgical complications depend as much on the surgeon’s competence as on the material and may be reduced by experience (C).
  - Clinical studies have demonstrated that neurogenic patients prefer prosthetic sphincterotomy because it is reversible, even when permanent stents are placed (C).
  - Careful follow-up, using yearly cysto/urethroscopy is mandatory when leaving a permanent urethral stent (B).
and as widely as possible. After dissection, the vaginal mucosa is simply closed in one plane by separate sutures. In the most recent paper [6], the authors report up to 54% recovery over a mean follow-up of about three years. However, it should be noted that each published series is from the same group, is always retrospective, the sample size was small (LOE4). Moreover, the technique is said indicated more often for urge incontinence and pollakiuria than for neurogenic detrusor overactivity. However, we mention it here because of its simplicity and the few reported complications.

c) Sacral root surgery

1. Isolated rhizotomy of ventral and/or dorsal sacral roots

Historically, attempts at sacral root surgery first focused on destroying the motor (ventral) sacral roots. Despite various technical artefacts, it was soon clear that this method failed within three to six months.

With a slightly different objective, Brindley [8] developed a technique involving stimulation of ventral sacral roots to obtain controlled and complete bladder voiding in cases of spinal cord injury. He quickly realised that patients only acquired continence if the stimuli causing reflex bladder contraction could be destroyed [9]. Early techniques consisted in selective destruction of the dorsal sacral roots that produce peri-operative detrusor contractions. These selective rhizotomies did not, however, give the best results. Only after complete de-afferentation of the sacral micturition centre by intradural rhizotomy were better results obtained [10-13] (LOE2-3).

Sacral root surgery may be envisaged for patients who cannot undergo electrostimulation of the anterior sacral roots (evolutive diseases such as MS, patients who cannot mount toilets, etc.).

The technique of “selective” dorsal sacral rhizotomy has been studied more extensively. It involves, as described above for Brindley’s technique, making an extra-dural approach to the sacral roots (S2 to S5), isolating and stimulating the dorsal (sensitive) contingent whilst monitoring any changes in urodynamic pressure within the bladder in order to section only those fibres responsible for hyperactivity. To retain reflex erection, S2 must be preserved, at least on one side. This treatment may be proposed for patients with neurogenic detrusor overactivity, and also those with urge incontinence/pollakiuria (this is important since results are more difficult to evaluate in these patients). The literature records only case series without control groups. Preliminary results were promising but were based on a small number of cases with short follow-up times [14-16] (LOE4). The outcome seemed to deteriorate over time. Opsomer et al. [17] reported deterioration after one year for all their eight patients (LOE4). Torrens, one of the first to use the technique, was led to re-evaluate his long-term results [18]. The most recent article by Lucas et al. [19] concerning 22 patients (LOE3), also reported a significant, but less marked, deterioration at four years. At this mean follow-up interval, 39% of patients retained a urodynamically stable bladder with satisfactory clinical response. The authors ascribe these improved results to a more extensive rhizotomy. However, it should be noted that there was a marked heterogeneity of patients in this series, three out of the eight, considered to be “successes”, were patients with leakage due to detrusor overactivity with an indwelling catheter.

A recent original approach to ablative mini-invasive surgery to treat neurogenic reflex urinary incontinence due to detrusor overactivity was reported by Mertens et al. [20]. It consisted in applying a technique used for limb spasticity, microsurgical DREZotomy. The aim is to destroy the dorsal root entry zone (DREZ). This zone, first defined in 1972 by Sindou [21], is a functional anatomical entity that groups together the proximal portion of the dorsal root, the medial portion of the dorso-lateral tract and the superficial layers of the dorsal horn. The technique involves making a micro-surgical lesion (by micro-coagulation) on the ventro-lateral portion of the entry zone, near the apex of the dorsal zone. The effect of DREZotomies is to selectively block nociceptive afferents, and their relays, and myotatic afferents. The procedure blocks the afferents of the mono and polysynaptic reflexes. The benefit of the limited lesion is to avoid complete abolition of tactile and proprioceptive sensitivity and to prevent the development of deafferentation phenomena. To treat neurogenic detrusor overactivity, the lesion must be made on both sides from S2 to S3 or even S4, according to the case. The results from the first series concerned 38 patients treated for incapacitating lower limb spasticity, treated by extended DREZotomy from L2 to S1. It should be noted that 58% of these patients were permanently catheterized. At six months, detrusor overactivity had disappeared in 82% of these patients, with 63% having significantly improved bladder capacity. At 18 months post-surgery, leakage had disappeared in 89% of cases.

Hohenfellner [22], following Brindley’s experience, proposed “neurogenic bladder augmentation” in certain cases. This involved completely destroying the ventral and dorsal sacral roots, possibly followed by continent cystotomy and simplified urinary catheterization. The author reported his experience with eight patients retrospectively (LOE3). After surgery in all patients, bladder capacity increased from about 177 ml to 670 ml, with complete disappearance of detrusor overactivity. Interestingly, continent vesicostomy was proposed to four patients. If these outcomes persist for the long-term, and if no serious (particularly trophic) complication occurs, this therapeutic option could be an alternative to augmentation enterocystoplasty.

2. Percutaneous sacral root block

Sacral root block is an old technique, since Dogliotti [23] proposed it as early as 1931 to relieve vertebral cancer pain by chemically sectioning several dorsal
roots. An injection of alcohol causes denervation due to the fragmentation of myelin in the endoneurium. In the 1950s, Bors [24] applied the technique to the bladder, standardized the procedure and described preliminary results. Later authors reported on a few series (LOE3) [25, 26], but always with the same result; the benefit disappeared after a few months; an example of neurological plasticity. Phenol, considered to be “selective” for C fibers was then tried but the results were no better [27-29].

Chemical destruction of the sacral nerve roots has proved ineffective and is accompanied by a high rate of minor complications (pain), requiring prolonged hospitalization and significant discomfort (LOE3)[25, 26]. Recently, Mulcahy et al. [30] proposed sacral rhizotomy by percutaneous radiofrequency for neurogenic bladder (LOE4). The initial results are interesting but no medium and long-term results have been published.

3. RHIZOTOMY OF POSTERIOR SACRAL ROOTS AND STIMULATION OF THE ANTERIOR SACRAL ROOTS

Electrostimulation to improve micturition in patients with spinal cord injury has been extensively researched since 1954. Direct stimulation of the detrusor, the spinal cone, the splanchnic and sacral nerves have not produced reliable results. Since 1969, G.S. Brindley has developed a set of electrodes for stimulating the spinal roots in the cauda equina. The technique, first tested in baboons, led to the development of an implanted stimulator to induce micturition in paraplegic patients. Sacral rhizotomy performed during implant surgery makes it possible to control bladder hyperactivity and ensure continence.

The equipment comprises two elements. The energy source and the microprocessor for adjusting the stimulation parameters are not implanted. The transmitter transforms the electric current from the energy source into electromagnetic waves, which are picked up by the implanted receptor and re-transformed into an electric current that circulates to the electrodes in contact with the nerve. Depending on the surgeon’s decision, the implant is placed within the membranes of the dura mater or outside them, so as to stimulate the sacral roots from S2 to S4. At the same time, it is essential to perform posterior rhizotomy from S2 to S4 to remove any detrusor overactivity.

Micturition is not continuous: the detrusor cannot be stimulated without also stimulating the sphincter. The parasympathetic fibers and the fibers destined for striated muscles are stimulated together. The response of detrusor smooth muscle fibers causes a gradual increase in pressure, which continues after stimulation has ceased. The “on-off” response to stimulation of striated muscle fibers is different. When stimulation stops, the striated sphincter immediately relaxes, whilst the detrusor continues to contract. A new wave of stimulation increases and maintains sufficient detrusor pressure to cause micturition after stimulation stops. The careful selection of stimulation and stopping times results in a discontinuous, but satisfactory, micturition. Neurotomy of the somatic fibers destined for the striated sphincter is difficult to perform [31](LOE4). Sphincter fatigue due to electrical stimulations, blocking of pudendal nerve motor fibers [32](LOE4) or use of specific detrusor stimulation by performing an anodal block [33] (LOE 4) have been reported, together with poor efficacy.

Stimulation can help defecation and erection, but it should be remembered that the principal object of sacral nerve stimulation combined with posterior rhizotomy is to achieve urine continence and bladder voiding. Erection is a secondary benefit but not an indication for the procedure.

Not all patients may benefit from this surgery. It can only be performed in those with spinal damage who are para- or tetraplegic. The sacral reflex arc must be preserved. Without going into further detail concerning indications for surgery, alternative less aggressive treatments should be preferred. As previously stated, men about to undergo this surgery should be warned that they would lose reflex erection after posterior rhizotomy (although this could be compensated by erection obtained with another set of parameters using sacral anterior root stimulation).

The results of the intervention are summarized in Table 6. Briefly, the outcome with regard to continence and bladder voiding are good (LOE 2-3). Failures result from incomplete rhizotomy, where bladder hyperactivity persists, or from sphincter insufficiency which may be treated by complementary surgical placement of an artificial sphincter [12, 13](LOE3). Incomplete rhizotomy can be surgically repaired [12, 13, 34] (LOE 2-3). In all reported series, mean bladder capacity increased significantly (LOE 2-3). Micturition was obtained by electrostimulation with a post-voiding residue (PVR) of ≤ 50 ml in 69 to 100% of patients. All series reported decreased incidence of urinary infection, but the defining criteria were too varied to allow conclusions to be drawn. Within the limits of a relatively short mean follow-up, it appears that this surgery preserves the upper urinary tract. Posterior sacral rhizotomy probably protects the upper urinary tract from detrusor overactivity. It can solve the problem of pre-operative reflux [34, 35](LOE4). However, posterior sacral rhizotomy should be complete. Indeed, in a series of 500 patients, Brindley [34] (LOE3) reported twelve cases of impaired upper urinary tract, ranging from grade I reflux to upper urinary tract dilation. Amongst these twelve patients, ten had undergone partial or sacral rhizotomy.

The results of the sacral anterior root stimulation on autonomous hyperreflexia (AHR) may be debated. The authors of many studies report a decreased AHR. Schurch [36] focused on the specific problem of AHR and recorded its persistence during stimulation in all patients who had suffered prior to surgery, but with marked improvement in symptoms.

CONCLUSION

It is interesting to know the various techniques used for bladder denervation, in order to be able to offer patients the whole range of therapeutic options, should medical treatments fail. Currently, bladder denervation is mainly reserved for those suffering complete spinal cord injuries, but increased selectivity may one day make it possible to perform this type of surgery in patients with less neurological damage.

RECOMMENDATIONS

- No peripheral bladder denervation technique has passed the test of time. The only technique used nowadays (the Ingelman-Sundberg technique) is not sufficiently effective to be used to treat neurogenic bladder hyperactivity (D)
- Injections of neurolytic products to treat detrusor overactivity should be abandoned, since they are ineffective in the medium and long term and expose patients to morbidity (A)
- Sacral dorsal rhizotomies need to be quite extensive to treat successfully neurogenic bladder hyperactivity. So they may be performed only in patients with lower limb neurological impairment (B)
- In certain situations, dorsal rhizotomies can be associated with ventral root stimulators (Brindley’s technique) or even with continent cystostomy (B)
- Electrostimulation of the anterior sacral roots is a validated option for managing neurogenic bladder in patients with spinal lesion, with long-term follow-up (B)
- It must be combined with destruction of all or part of the posterior sacral nerves, and cannot therefore be performed in patients with conserved lower limb motility(B)
- The reflex arc must be intact(B)
- Posterior rhizotomy exposes men to a loss of reflex erection and women to a loss in reflex vaginal lubrication(B)
- It is vital to assess the patient carefully before implantation so as to determine whether he/she will be able to mount a toilet or grasp a urinal handrail (B)

4. SURGERY FOR STRESS UI DUE TO SPHINCTERIC INCOMPETENCE

- Keywords used for the medline research
  neurogenic bladder; spinal cord injury; spina bifida; myéloméningocèle; multiple sclerosis; stress incontinence; artificial urinary sphincter; sling; bulking agent; dextranomer; polydimethylsiloxane; Polytetre-fluoroethylen; collagen
- Introduction
  Patients with bladder dysfunction secondary to a neurological cause may have a certain degree of sphincter dysfunction. In certain cases, this is secondary to a neurological impairment (for example in cauda equina syndrome). In other cases, it could be the consequence of previous surgery (for example sphincterotomy). In women, stress urinary incontinence may be related to simple cervico-urethral hypermobility [1].
  
  It is of course very important to confirm that the bladder reservoir is well-balanced and filling under low pressure; where this is not the case, a treatment addressing the bladder condition would need to be added to that for increasing sphincter resistance.

  The context of the neurological disease, and the presence of any concomitant treatment for detrusor hyperactivity of neurological origin, will require stringent, pre-operative investigation. Indeed, the risk of chronic urinary retention is particularly high in such patients (in certain situations, for example patients already using intermittent catheterization , it could even be the goal of surgery). Patients must be informed therefore of the potential need for intermittent catheterization (IC), and they should be capable to perform intermittent catheterization (IC). A patient who has never used this technique should be trained in order to meet any possible future problem. Two situations can be identified: patients not already using IC, patients already using IC.

  a) Patients not using IC

  1. SUBURETHRAL TAPES

  In this case, a pre-operative assessment to look for prognostic factors must be carried out. This point is already treated in a specific chapter. In patients with a neurological disease, clinical examination should be conducted as in non-neurological patients. The clinical examination may include the Bonney test and testing of continence during a TVT procedure [2]. In the event of peripheral neurological disease with perineal floor denervation, it is especially important to check for any associated urogenital prolapse, a condition often exacerbated by the effort involved in micturition and defecation.
The urodynamic investigation must evaluate the quality of sphincter function, since several studies have suggested that suburethral tape techniques gave poorer results in the event of low urethral closure pressure (LOE 4) [3]. Furthermore, recent research based on prospective comparative studies suggests that in the event of low closure pressure, techniques using tapes placed retropubically give better results than transobturator techniques (LOE 2) [4 , 5-7].

To our knowledge, only one study has specifically assessed the efficacy of suburethral tension-free tape in adult women with neurogenic bladders (the use of suburethral slings will be discussed later). It was a retrospective series with 12 women treated by TVT [8] (LOE3). The study revealed that, for those patients who did not self-catheterize (3/12), the treatment was effective and intermittent catheterization was not required. The authors did not report any particular complication.

For adult male patients, the use of synthetic tapes is increasing since the description of bone anchored tape for post prostatectomy incontinence [9](LOE2). To our knowledge, no specific study on patients with a neurological cause to their incontinence has been reported. We could only suppose that the risk for urinary retention is higher than in the general population and therefore prepare the patient to accept IC before consenting to this type of surgery. The different therapeutic options are presented in the following chapter.

2. Bulking agents

The use of various types of bulking agent has been reported in three main indications: stress urinary incontinence in women, post-prostatectomy incontinence and children incontinence. Various agents have been used. Polytetrafluoroethylene (TEFLON®) was one of the first[10, 11]. It was once very popular for treating vesico-ureteral reflux, but it has been progressively abandoned after several authors reported a possible migration and granulomatous reaction of this product [12, 13](LOE2). Collagen has also been used in this indication [11, 14-21]. More recently, several authors shifted to synthetic products like polymethylsiloxane (MACROPLASTIQUE®) or Dextranomer Hyaluronic Acid copolymer (ZUIDEX®), because they found these type of products easier to use without the risk of allergic reaction or previous contamination which may occur with other biological products [10, 22-28]. Henly et al [29] demonstrated that distant migration of particulate silicone was observed in animals after periurethral injection with polymethylsiloxane (LOE4). This was not demonstrated with dextranomer acid copolymer injections [30] (LOE4).

Bulking agent results in female stress incontinence and post-prostatectomy incontinence will be discussed elsewhere. We will focus our review on patients with a neurological problem (Table 7) [10, 11, 14-28, 31-39].

It is important to underline that although a high proportion of the patients in these studies use intermittent catheterisation, some patients have a good result without using it.

One of the main advantages of this technique is that it is easy to perform, usually as an outpatient procedure. Most of the studies are on children. Usually the authors inject the product in the bladder neck, by a retrograde endoscopic approach, in two to four points. The bulking agent is injected until full lumen closure is noted. Dean et al [28] recently suggested performing an antegrade way for injections, using a percutaneous access to the bladder.

The results of the procedure of injection with all the recent bulking agents used are summarized in Table 7. It is very difficult to compare the results because of the various definitions for the surgical results that are used by the authors. We report what many authors call an improvement, or “social continence”. Many authors do not accept this definition. Therefore, it seems reasonable to consider only the more reliable results, namely the rate of “dry patients” (even if some authors add to this result a notion of “dryness for some hours” between voiding or catheterization). Using this definition, 0 to 36% of the patients are considered as cured using bulking agents (LOE2-3). Moreover, these results are observed after a mean follow up that rarely exceeds 2 years (LOE2-3), although one author has reported long-term lasting effect up to 7 years after the last injection [23].

Two other points have to be underlined in the studies published. The first is that the studies in children mix frequently patients with two types of problems: urological malformations (epispadias, bladder extrophy) or neurogenic bladder (mainly myelomeningocele). This is important to know, because it seems that in children, bulking agents work slightly better in patients with malformations than in patients with a neurological bladder dysfunction [10, 17, 23, 25]. The global results of the series are therefore probably more optimistic than the results that could be specifically observed in neurological patients. The second point is that these children have frequently already had a various amount of surgical procedures, which could modify the results of the injection procedure.

Although the authors have reported no severe complication, there is a controversy regarding a possible greater difficulty to perform a bladder neck surgery after repeated bulking agents injection [10, 23, 25]. Some authors [40] advocate that the number of unsuccessful procedure could be considered as a complication. Most of the authors [23, 25] agree that

</table>
there is no need to attempt more than two injections if the patient’s incontinence is not improved or cured on a long-term basis. Gender, previous bladder/sphincter surgery don’t seem to be reliable prognostic factor regarding the success of the injections.

Future studies using autologous myoblasts and fibroblasts are currently under way in patients without neurological impairment [41] and may bring a renewed interest in the field of bladder neck or peri-urethral injections in the next years.

3. ARTIFICIAL URINARY SPHINCTER

The last theoretical option is the use of an artificial urinary sphincter. However, the rate of urinary retention following this procedure is very high in patients with a neurological bladder dysfunction. Therefore, as previously stated for the other treatments, this procedure should be used only after the patient has accepted and is ready to use IC.

b) Patients using IC or prepared to use IC:

A large majority of the series published in this chapter are about children. One of the main questions is whether it is necessary or not it is necessary to perform systematically a bladder augmentation in complement to the treatment of the sphincteric deficiency. A majority of the authors report the necessity to proceed to bladder augmentation in at least a third of their patients. Even with a thorough urodynamic and radiologic preoperative evaluation, some patients will have late bladder compliance deterioration [42-59]. To illustrate that, two retrospective studies were recently published specifically on this topic and gave two opposite conclusions. Snodgrass et al [60] (LOE3) published the retrospective analysis of 30 children (mean age: 8,6 years) who had a bladder neck sling procedure and appendice-vesicostomy without augmentation. At 22 month of mean follow-up, only one patient had to undergo a bladder augmentation procedure. In a subset of the patients (16) who had urodynamics at 24 months, 13/16 had an increase of their maximum bladder capacity at 24 months. However, 67% of the patients have to use anticholinergic therapy. Although this series is interesting, the follow-up is relatively short. On the opposite of this study, Dave et al [61] (LOE3) strongly advocate the case for systematic bladder augmentation. Hence, the authors report a series of 15 children followed at least 5 years after an isolated bladder outlet procedure (5 Pippi-Salle, 5 slings and 5 artificial urinary sphincter). At a mean follow-up of 11.25 years, all the patients underwent a bladder increase procedure, either for recurrence of the incontinence or for upper urinary tract deterioration.

At present, no definitive conclusions can be drawn. The majority of the authors recommend performing a concomitant bladder augmentation when performing a bladder outlet procedures [40] (LOE4). The advent of the botulinum toxin injection in children will perhaps allow having new design for studies that could help to answer to this question.

1. SURGERY OF THE BLADDER NECK

Three main procedures have been described. Historically, the technique of Young[62], later modified by Dees[63] and Leadbetter[64] has been the first used, essentially for reconstruction in cases of extrophy and epispadias. The principle was to dissect extensively the trigone (after ureteral reimplantation) allowing excising most of the tissue from the bladder neck to constrict the trigone around a small catheter. Although some authors[65, 66] described its use in neurogenic patients, it is almost abandoned in this indication. Tanagho [67](LOE3) described a variation of this technique which could be used in difficult situations in incontinent adult patients, when the implantation of an artificial urinary sphincter is not possible [68].

The Kropp’s procedure [69] consists in tubularizing a flap of the anterior bladder wall, pediculized on the bladder neck. This tube is then fixed on the posterior bladder wall between ureteral orifices. In the initial technique, the tube was tunneled submucosally, but this manoeuvre was supposed to augment the risk of tube stenosis [70, 71](LOE3).

The last technique described is the Pippi-Salle technique[72]. It is considered as a variant of the Kropp procedure (also called Kropp-onlay), with an anterior bladder wall flap that is not tubularized. At the beginning, the authors reimplanted systematically the ureters. This was abandoned in the last patients in the absence of reflux [73, 74] (LOE3). In a systematic review, Kryger et al [40] (LOE4) stated that only data on 83 patients for the Kropp technique and 25 with the Pippi sale procedure have been published. Since then, we didn’t found any added study with these techniques. The continence results are good (50-69% for the Pippi Salle procedure, 78-81% for the Kropp procedure) [70, 71] [73, 74] [40]. However, several problems exist with the two techniques. First, the technique doesn’t allow easy endoscopic access to the bladder. This is a major problem, because it prevents or limits future endoscopic procedures (especially uroscopy, botulinum toxin injections). Second, a high percentage of patients (especially male) report catheterisation difficulties in the Kropp technique : 28 to 45% of cases. In Pippi Salle procedure, the continence rate is lower than in the Kropp procedure, but few cases of catheterisation difficulties have been reported [40]. However, a new procedure is necessary in 12 to 17% of cases for uretrovesical fistula [73, 74] (LOE3). Moreover, this procedure has rarely been tried in male patients.

2. COMPLETE BLADDER NECK CLOSURE

This can sometimes be proposed as a complement to continent cystostomy. It is always a difficult
procedure, despite all the technical artefacts presented in the literature (interposition of muscle or omentum), and re-permeation is both frequent and problematic [76]. Moreover, patients with a bladder dysfunction secondary to neurological illness are at high risk of lithiasis of the bladder reservoir or the upper urinary tract, so it does not seem logical to prevent potential endoscopic treatment by closing the ureter (LOE4). Finally, preserving the natural urethra may constitute a safety measure if high pressure persists (dysfunction of the augmentation graft, hyperactive or hypo-compliant residual bladder) or in the event of any complication on the abdominal continent tube [2, 77] (stenosis, transient impossibility to self-catheterize, etc.) (LOE4).

3. APONEUROTIC OR PROSTHETIC BLADDER NECK SLINGS:

For women, suburethral tape can easily be placed during bladder augmentation surgery in order to reinforce stress continence and prevent stress leakage. Results of the main recent series are summarized in Table 8. Complete continence is observed in 83 to 89% of the patients [44, 60, 78, 79] (LOE3). Bladder neck slings appear to provide good results for male children, although the results seem to be less satisfactory than with female patients [60, 79, 80] (LOE3). Studies in adult men need to be awaited.

All the authors report a low morbidity rate of this procedure. The risk of urethral erosion is very low with the fascial slings. When the intention of surgery is to induce urinary retention with subsequent postoperative IC, an aponeurotic sling rather than a synthetic sling seems to be more suitable because of the risk of secondary urethral erosion when the sling must be tight [81-84](LOE3). Although these findings have not been confirmed by comparative studies, some authors report up to 80% erosion with bladder neck slings [81] (LOE3). The risk of erosion with synthetic tapes exists also in suburethral tapes, and excessive tension is often evoked [84](LOE4). It is interesting to notice that the only case of male sling erosion to date was described in a patient with a cauda equine syndrome [85](LOE4). New refinements in the technique for male patients involve a higher tension on the tape, and already one case of urethral erosion has been published [82](LOE4). The use of this type of device in patients with underlying neurological illness should therefore be very cautious(LOE4). High bladder pressure when slings are placed is also supposed to be a risk factor for urethral erosion [84] (LOE3).

At present, there are no specific reports concerning the new perineal slings for men (bone-anchored or...
transobturator route) in patients with a neurologic disease. The use of new minimally invasive devices such as ACT and pro-ACT balloons (Uromedica) [86, 87] for patients with a neurological bladder dysfunction has not yet been published.

4. Artificial urinary sphincter (AUS)

Since it was introduced in clinical practice [88], the artificial urinary sphincter is recognized as one of the most effective treatments for urinary incontinence. The benefit lies in the fact that it mimics bladder function as closely as possible to physiologically normal, with low-pressure micturition. Its effectiveness in regard to stress incontinence ranges from 75 to 87%. The satisfaction rate ranges from 85 to 95%. These rates, given for mixed populations of patients mostly suffering stress incontinence after radical prostatectomy, are probably similar to those of neurogenic patients when the bladder reservoir is stable (LOE4) [89].

Before using AUS in neurogenic patients, several factors must be considered. The risk of infection related to bacteriuria is probably higher, even though little information is available to support this statement. For neurological patients, we recommend pre-operative assessment of bacteriuria and urine decontamination before surgery [90] (LOE4). Theoretically, patients must be strong enough to activate the pump of the AUS, either to open the cuff to urinate or during IC [89]. They must also accept the need for IC should the bladder reservoir be hypocontractile. Recent studies seem to indicate that the cycling activation of the pump could be avoided in patients performing IC (LOE3) [47, 91]. Finally, it is necessary to know the ejaculatory status of males in order to discuss where to implant the cuff.

The cuff implantation site in adult patients with a neurological bladder dysfunction is debated. Partisans of bladder neck implantation argue that perineal incisions may cause cicatrisation problems for patients in wheelchairs. Moreover, traumatic catheterization is a well-known risk factor of urethral erosion in the non-neurological population undergoing an AUS [54] (1 to 5.5% in contemporary series). Even if it is recognized that IC is possible in AUS implanted patients [92], the risk of traumatic catheterization could be higher on the bulbar urethral site than on the bladder neck. Finally, the bladder neck implantation retains the possibility for patients to recover antegrade ejaculation [93, 94] (LOE4).

On the other hand, inserting an AUS cuff around the bladder neck is more difficult in adults in comparison with peri-bulbar implantation (LOE4), and the rate of erosion in the published series is higher than in the post-prostatectomy incontinent population [46-59, 95] (which is always implanted around the bulbar urethra). As previously stated, a thorough urodynamic evaluation of the bladder is mandatory to evaluate the possible degradation of bladder reservoir compliance following AUS implantation, which has been reported in several retrospective series (LOE3) [46-59, 95]. The reasons for this change in bladder behaviour are not known, and it has been observed particularly in populations of patients with myelomeningocele [51, 55, 56, 58, 96]. In the event of any doubt on the quality of the bladder reservoir, bladder augmentation should be performed. This may change in the future, with the development of intra-detrusor injection of botulinum toxin, to control incontinence in certain patients [97].

The main results of the recently published series are summarized in Table 9. The continence rate is high, especially when a bladder augmentation has been performed (59 to 100% of the patients) [46-59, 95]. The older series comprise patients with the previous version of the AMS 800 (AMS 792). Therefore, long-term results could be even better as AMS 800 is considered as a better device than AMS 792. The bladder neck or urethral erosion is the main risk with AUS and appears to be higher in these series than it is in the general population (approximately 5 to 15%). These erosions seem to happen more frequently in the first two years after the procedure. However long-term erosions are still possible [50] (LOE3). The average "survival" for AUS exceeds rarely ten years. This particular point has to be explained to the patient, especially when they are very young. However, the majority of the authors consider AUS to be the "gold standard procedure to treat sphincter deficiency, even in patients with a neurological bladder dysfunction [41].

RECOMMENDATIONS

• Suspected neurological bladder requires careful investigation before implanting suburethral tape. Tests must include: a micturition diary, a detailed interview using validated questionnaires, and urodynamic tests to provide the patient with optimum information on post-operative risk of complications and failure (C).

• The clinical assessment must also evaluate the degree of patient handicap to determine whether they may perform self-catheterization. Sub-urethral tape can be used in patients with a neurological bladder. However, it is contraindicated where patients cannot perform self-catheterization (D).

• Autologous slings can be proposed to patients with a neurological bladder dysfunction after careful assessment of their general handicap and if the patient accepts...

5. SURGICAL ALTERNATIVES EXCLUDING DENERVATION PROCEDURES TO TREAT REFLEX INCONTINENCE DUE TO NEUROGENIC DETERUSOR OVERACTIVITY

**Keywords**
- neurogenic bladder; spinal cord injury; spina bifida; myelomeningocèle; multiple sclerosis; bladder augmentation; enterocystoplasty; gastrocystoplasty; sigmoidocystoplasty; colocystoplasty; ureterocystoplasty; autoaugmentation; detrusorectomy

### a) Bladder augmentation using intestinal segments

The aim of bladder augmentation is to provide long-term protection to the upper urinary tract by reducing the risk of impairment due to high bladder pressure, as well as to improve micturition comfort [1].

First performed in man in 1889 by Von Mickulicz [2] who used a segment of small intestine, the technique has regained popularity since the 1970s after the introduction of intermittent catheterization [3].

Unlike complete bladder replacement, enterocystoplasty preserves the integrity of the trigone of the bladder with the urethra and ureters and reimplantation is not necessary. A segment of the gastrointestinal tract is then removed and sutured onto the bladder.

Various augmentation techniques using different segments of the gastrointestinal tract (caecum, colon, and ileum) have been described.

1. **INDICATIONS**

Bladder augmentation is indicated wherever bladder capacity and compliance is reduced, or in the event of detrusor overactivity, when all conservative treatments (medical treatments, detrusor injections of botulinum toxin and/or neuromodulation of the posterior sacral roots) have failed [1, 4].

Before performing bladder augmentation, it is essential to ensure that:

- There is no malignant disease or lithiasis in the bladder.
- Renal function is normal and the upper urinary tract is unimpaired (screen particularly for lithiasis).
- There is no gastrointestinal tract disease (Crohn’s disease, hemorrhagic rectocolitis, short gut syndrome, etc.).
- The patient is capable of, and willing to, perform self-catheterization. This can be combined with continent cystostomy, a topic to be dealt with in a separate chapter.

2. **TECHNICAL PRINCIPLES**

There are two stages to the surgical procedure: first bladder preparation and then augmentation. Usually open surgery is performed, but recently laparoscopy has been reported [5, 6](LOE3). At present, except for technical articles on laparoscopy, there are no publications comparing this technique with open surgery.

The bladder can be prepared either by clam cystoplasty or by supratrigonal cystectomy. The preferred preparation depends on the quality of the detrusor, and more particularly on whether the bladder has retained its visco-elastic properties. Where the detrusor is very fibrous and thick, supratrigonal cystectomy should be envisaged, since exclusion of the ileal patch may occur. Nowadays, supratrigonal cystectomy is often performed because compliance disorders in a bladder that has retained its visco-elastic properties can be treated effectively by detrusor injections of botulinum toxin [7].

a. **Bladder preparation**

• **CLAM CYSTOSTOMY**

Clam cystoplasty involves freeing the anterior/posterior surfaces and dome of the bladder and then sectioning from front to back in the sagittal plane. The bladder can be opened either in the transverse plane or sagittal plane, the incision starting and ending about 2 cm above the bladder neck. The lateral surfaces are not freed. The umbilical arteries are preserved to maintain vascularization of the bladder dome.
Supratrigonal cystectomy involves resection of the bladder tegument and sparing the trigone. The bladder is freed under the peritoneum and the right and left umbilical arteries ligated and sectioned. The bladder tegument is completely freed and the bladder pedicles ligated and sectioned laterally up to the trigone, which is preserved. During the bladder dissection, care must be taken to spare the ureteral vascularization. Supratrigonal cystectomy is performed by making a circular incision with an electric scalpel into the tegument 1 to 2 cm above the trigone.

Ureteral reimplantation must be carefully discussed in the event of vesicoureteral reflux. Several authors have reported that improved bladder compliance precludes the need for vesicoureteral reimplantation (LOE 3) [8-11]. They have reported a resolution rate of about 85% for vesicoureteral reflux, classified below grade IV. For grade V reflux, improvement was observed in 2/3 of patients. It is important to point out that, except for the work of Simforoosh [8], these consistent results were obtained in small heterogeneous series of children (neurogenic bladders and congenital anomalies). The results were published after relatively short mean follow-up times (1 to 5 years).

Recently, Hayashi et al. [12] reported on 22 patients treated by ureteral reimplantation during bladder augmentation (LOE 3). Their work was original in that it gave detailed account of renal function after long-term follow-up (mean: 12 years). In the hands of this experienced team, ureteral reimplantation during bladder augmentation did not result in greater morbidity and 97% of patients recovered. Renal function was preserved and satisfactory.

It is therefore too early to rule out the need for ureteral reimplantation during bladder augmentation, especially for cases of grade V reflux. However, it is clear that improved compliance will reduce some vesicoureteral reflux.

b. Intestinal segments

The choice of intestinal segment depends on patient’s history and the local conditions. All segments of the gastrointestinal tract may be used, except the jejunum because of the risk of water-electrolyte disorders. The most frequently used segment in adults is the ileum because it is easy to remove, is close to the bladder and may be shaped easily into a reservoir. Colon segments are used more often in children.

The removed intestinal segment must always be detubularized to reduce peristalsis to a minimum and to obtain a reservoir with low pressure. The segment is then placed and sutured onto the bladder in the form of a patch. For supratrigonal cystectomy, the intestinal segment needs to be longer and fashioned into a neo-bladder [4].

The main objective is to reduce mucus secretion and prevent the reabsorption of urine by the intestinal mucosa that leads to metabolic acidosis. Two variant techniques have been proposed but not developed extensively, probably because they involve relatively major surgery for the benefits they bring.

The first is seromuscular colocystoplasty lined with urothelium. This involves removing the detrusor, leaving the bladder mucosa intact, and then covering it with a demucosalized sigmoid patch [13].

The second technique is seromuscular enterocystoplasty. After preparing the bladder, a segment of the ileum or the sigmoid is removed and detubularized. The mucosal membrane of the intestinal segment is surgically removed, or destroyed by argon beam [14] and the segment is then placed on the prepared bladder [15].

c. Results of enterocystoplasty

The main published series for patients undergoing surgery for neurogenic bladder are summarized in Table 10.

Early morbidity and mortality

Peri-operative mortality is estimated between 0 and 3.2% (LOE 2-3). The most frequently reported early morbidity (LOE 2-3) is prolonged post-operative ileus. It occurs in up to 11.7% of cases [16-18]. However, it should be noted that systematic and prolonged use of a nasogastric catheter is no more justified in neurological patients than in the general population (LOE3) [19]. Other common complications include episodes of febrile urinary infection (4.8 to 9%), urinary fistula (0.4 to 4%) that usually resolve and thrombo-embolic complications (1 to 3%). When the pelvis has been irradiated, the patient must be warned of the increased risk of enteric- or colovesicular fistula.

Late morbidity

Chronic bacteriuria always occurs with intermittent catheterization and should not be considered a complication [20](LOE4).

The risk of calculus in the enlarged reservoir ranges from 10 to 50% [21-24] (LOE 2-3). It would appear that there is a higher risk of developing upper urinary tract lithiasis than in the general population [25-27] (LOE3).

After bladder augmentation, intestinal transit disorders are frequent and probably underestimated (0 to 30% of cases [17, 28-30]). Several explanations have been proposed (ileocecal valve not preserved, biliary salt malabsorption, etc.). Somani et al. recently conducted

</table>
a cohort study (LOE2) focusing on this particular problem [31]. They report a high rate of intestinal transit disorders, affecting almost 50% of patients treated for neurogenic bladder. These complications distressed patients and nearly 10% regretted having undergone surgery. Although transit disorders cannot be imputed to surgery alone (patients with neurogenic bladder may have intestinal transit disorders unrelated to surgery), patients should be informed of this risk.

Since the gastrointestinal tract mucosa resorbs urine, water-electrolyte disorders may occur. Hyperchloremic acidosis is reported in up to 15% of cases (LOE 2-3). These water-electrolyte disorders may be accompanied by anomalies of calcium metabolism that do not appear to have any significant long-term effect, particularly on child growth, but the subject is still under debate (LOE 3) [32-35]. However, care must be taken when treating patients with a marked decrease in creatinine clearance, since metabolic acidosis is no longer compensated [4](LOE4).

In theory, diversions performed using the ileocaecal junction and the end segment of the ileum would expose patients to a risk of vitamin B12 deficiency (with possible onset of megaloblastic anemia). The fact that the intestinal segments measure less than 50 cm would explain why very few patients suffer vitamin B12 deficiency.

The risk of cancer development of the newly formed reservoir is particularly feared since neuro-urological surgery is often indicated in patients with long life expectancy, many being children. The general consensus today is that patients with a bladder reservoir are at higher risk of developing a tumour than is the general population, but this risk has not as yet been clearly defined. The figures usually given for the risk of tumour development range from 1 to 3% [36, 37]. (LOE 4). Most of the published cases concern adenocarcinoma at the junction of the intestinal mucosa with the urothelium. These usually developed long after the initial surgery (over 10 years in most cases). Some patients developed urothelial tumours with the typical risk factors. Two facts should be emphasised with regard to neurogenic bladder (augmented or not):

- The sensitivity and specificity of the routine bladder tumour diagnostic and monitoring tools (urinary cytology, BTA test, simple cystoscopy, etc.) are reduced. Patient monitoring can only be envisaged by regular cystoscopy with biopsy of suspect areas.
- Monitoring is essential, since many patients develop tumours without symptoms and may be not be diagnosed until late.
- The most serious and possibly life-threatening complication is cystoplasty perforation (LOE3). This can happen whichever gastrointestinal segment is used, but occurs more often after ileocystoplasty [38](LOE3). It is estimated to occur in 5 to 13% of cases [16](LOE3). Perforation usually occurs on the graft or at the junction of the bladder with the enterocystoplasty and often results from high pressure within the enterocystoplasty, or more rarely from traumatic catheterization or urodynamic investigations [39](LOE4).

**FUNCTIONAL OUTCOME**

The functional outcome of bladder augmentation by enterocystoplasty is given in Table 10-Table 10 ctd. Only series of patients undergoing bladder augmentation for neurogenic bladder were retained in our analysis. Given the wide range of indications, surgical techniques and enteric segments used, it is difficult to draw any clear conclusions from these studies. Furthermore, most were retrospective studies; however certain points should be noted.

All authors reported an improvement in bladder capacity and compliance (LOE2-3) [17, 18, 40-42]. Improved vesicorenal reflux has already been mentioned. More than 90% of patients achieved nocturnal continence, and between 91 and 100% achieved diurnal continence [17, 18, 40-42] (LOE2-3).

Two quality-of-life studies (LOE2) reported improvement rates exceeding 90% [18, 43]. However, we would draw attention to one potential bias due to the heterogeneous population in these studies. Some patients underwent augmentation for detrusor overactivity of neurological origin, and others for idiopathic overactive bladder. We may conclude that these results can be applied to the sub-population of neurogenic patients, since they have already accepted intermittent catheterization before surgery.

If the bladder compliance defect persists, exclusion or ischemia of the intestinal patch must be investigated [37, 42]. Sometimes urinary leakage is related to sphincter deficiency and may be treated by an artificial urinary sphincter [44] or other means of urethral pressure reinforcement [37, 45]. However most authors consider that this type of adjunctive treatment should not be performed routinely since most patients have a good functional outcome after bladder augmentation, and only those with marked sphincter deficiency prior to surgery require these measures.

**b) Possible alternatives to enterocystoplasty**

1. **GASTROCYSTOPLASTY AND URETEROCYSTOPLASTY**

The use of a pediculated segment of stomach (gastrocystoplasty) or ureter (ureterocystoplasty) as an alternative to enterocystoplasty has been reported mainly for children with a neurogenic bladder. In theory, its advantage lies in the absence of metabolic acidosis, but in adults this is very theoretical. Moreover, both these intestinal segments secrete less mucus than the small and large intestines [46-50]. Abdel-Azim et al.
utomation technique in adults (LOE3). In the light of their experience with children, they decided to use this technique in a set of young adults (mean age: 23 years, range: 4-32 years). Their paper records that the short-term results (3 years mean follow-up) of gastrocystoplasty were satisfactory, with increased functional bladder capacity and no impairment of the upper urinary tract (LOE3). However, two disadvantages are reported. First, a hematuria-dysuria syndrome requiring occasional use of antacids sometimes accompanied gastrocystoplasty. Second, the maximum bladder capacity was slightly lower than that observed in patients having undergone enterocystoplasty. This may have a benefit for easier bladder voiding but a negative effect due to the fear that in the long-term, the bladder may lose its capacity and further surgery will be required. The outcome in the very long-term for patients who have undergone laparotomy, can be performed by simple video-assisted gastrointestinal tract surgery (intra or extra peritoneal celioscopy) and/or perforation is poorly documented. An experimental animal study concluded that the bladder rupture pressure was slightly lower after enterocystoplasty, thus exposing the patient to an increased risk of rupture (LOE4). A retrospective study (LOE4) reported 20% complications for enterocystoplasty (infectious digestive and parietal complications) against only 3% for detrusorectomy [62]. The rate of secondary rupture and/or perforation is poorly documented. An experimental animal study concluded that the bladder rupture pressure was slightly lower after detrusorectomy than after enterocystoplasty, thus exposing the patient to an increased risk of rupture [68] (LOE4).

Bladder autoaugmentation without any associated gastrointestinal tract surgery as an alternative to enterocystoplasty was proposed as early as 1972 by Mahony and Laferte [51] who performed detrusorotomies (detrusor incision without resection) to increase bladder capacity and reduce incontinence. With Cartwright and Snow [52], the technique then evolved to detrusorectomy. This involves excising a thick segment of muscle from the dome of the bladder, leaving only the mucosal membrane in place. Bladder pressure gradually dilates the “demuscularized” area resulting in bladder augmentation.

The intervention, initially described by extra peritoneal laparotomy, can be performed by simple video-assisted surgery [53, 54] (intra or extra peritoneal celioscopy) or by robot-assisted surgery [55](LOE4). The detrusor can be dissected by laser [56](LOE3). The area around the detrusorectomy can be protected using the omentum [57] or a striated muscle [58] (rectus abdominus muscle) to prevent perforation and retraction(LOE4).

Techniques using free-graft or pediculated de-epithelialized gastric patches [59, 60] require gastrointestinal tract surgery and were therefore not included in the present work. Furthermore, most of the previously published studies concerned children. All the studies are retrospective and with few patients. For children, most authors [57, 61-65] report poor results after surgery, both symptomatic and urodynamic, together with a risk of upper urinary tract impairment(LOE4). Two authors recently reported better results with certain technical artefacts, namely an extensive detrusorectomy [66](LOE4) and rectus muscle hitch and backing [58](LOE4). The last technique supposes a large dissection of the rectus muscle. Urothelium is the sutured to this muscle in the theoretical objective to prevent its retraction and shrinkage.

Only three series are available for adults and all are retrospective studies. The first, published by Stöhrer et al in 1997 [67] (LOE3), reports interesting results for efficacy, with increased functional bladder capacity. However, the authors did not report mean follow-up and described a mixed population with 39 patients with neurogenic bladder and 11 patients without. The two other published series concerning adults [61, 62] did not confirm these findings but did confirm the marked superiority of enterocystoplasty with respect to both urinary symptoms and upper urinary tract impairment (LOE3). An analysis of the paper by Kumar [61] shows that the results of enterocystoplasty may differ according to the type of detrusor overactivity (DO). He reported good results for patients presenting idiopathic DO. Conversely, with a mean follow-up of 79 months, nearly all patients (5 of 6) with neurogenic detrusor overactivity were not improved (LOE3).

There is little information on specific complications, but detrusorectomy is simpler and seems to present less risk than enterocystoplasty. A comparative retrospective study (LOE4) reported 20% complications for enterocystoplasty (infectious digestive and parietal complications) against only 3% for detrusorectomy [62]. The rate of secondary rupture and/or perforation is poorly documented. An experimental animal study concluded that the bladder rupture pressure was slightly lower after detrusorectomy than after enterocystoplasty, thus exposing the patient to an increased risk of rupture [68] (LOE4).

It is not yet possible to use artificial bladders. However, bladder augmentation using porcine intestinal submucosa (SIS, Cook®) [69](LOE4) or an acellular matrix of porcine dermal collagen and elastin fibres (Pelvicol, Bard®) [70](LOE4) have been described. These biomaterials can only be used after performing clam cystotomy since the area to be colonized should not be too large. It also appears that the use of biomaterials is associated with higher incidence of bladder lithiasis. To date, the number of reported cases remains limited. Larger trials are necessary to evaluate routine use of biomaterials. The use of autologous tissue may also be envisaged. In 2006, Atala [71] has published promising preliminary results on a small prospective study of 7 young patient with a neurogenic bladder (LOE 2). In this article he describes his technique, which consists in seeding patient’s urothelial and muscle cells on a biodegradable scaffold. After 7 weeks, this engineered artificial bladder could be implanted in patients. Although the small number of patients doesn’t allow definitive conclusion, a trend to a better bladder capacity and compliance was observed. Future studies will have to confirm these very exciting results.
RECOMMENDATIONS

- Any segment of the gastrointestinal tract may be used for bladder augmentation, but the ileum seems to give the best results in terms of ease of use, risk of complications and efficacy (B). Few data are available concerning gastrecystoplasty and ureterocystoplasty in adults (D).
- When the bladder suffers a significant compliance defect, supratrigonal cystectomy is preferable to clam cystoplasty (B).
- Bladder augmentation may solve low-grade vesicorenal reflux. In the event of grade IV or V reflux, ureteral reimplantation may be necessary (C).
- Patient should be informed that the most frequent and serious complications are bladder calculi and perforation at the bladder/bowel junction, usually caused by the abdominal pressure (B).
- Bladder augmentation may have sequelae such as intestinal transit disorder, and patients should be informed of this before surgery (C).
- The body of evidence concerning detrusor myomectomy in neurological patients is controversial. Therefore, detrusor myomectomy should not be recommended in these patients with impaired bladder function (D).
- Bladder augmentation using biomaterials or tissue engineering is promising, but the preliminary results need to be confirmed by larger studies (D).
- Due to risk of complications regular follow up is needed (B).

6. CUTANEOUS CONTINENT URINARY DIVERSION

Keywords used for the medline research

Continent urinary diversion; vesicostomy; cystostomy; neurogenic bladder; spinal cord injury; spina bifida; myelomeningocele; multiple sclerosis

a) Introduction

For certain patients, urethral catheterization can be or become, unacceptable or even impossible. The following list is not exhaustive, but describes the more frequent reasons:

- Functional limitations of the upper limbs (Tetraplegia [1] unilateral or bilateral plexus problems, musculoskeletal trauma problems)
- Cognitive disorders (forgetfulness, lack of comprehension, refusal)
- Difficulties in terms of mobility and/or undressing (spasticity, upper spinal cord injury resulting in difficulty in maintaining the equilibrium of the trunk and or limited control of the upper limbs, obesity).
- Failure to reach the urethra independently (more common in women, compounded by the tilted pelvis and all other factors that cause mobility difficulties.)
- Urethral injuries (stenosis, fistulas, hyperesthesia), urethral pain.

In these situations, the realization of a continent cystostomy may be an option. The general principle is to permit the emptying of a full bladder, independently and easily, by intermittent catheterization through an efferent tube attached to the wall of the lower half of the abdomen. The absence of any leakage from the cystostomy is controlled by its own watertight system associated with the return process of a capacitive and compliant reservoir.

This will require careful selection of patient candidates especially when there is any function impairment of the upper limbs (trauma to the spinal cord) [2-4](LOE3).

A pre-operative assessment is indispensable and must include the motivation of the patient, capabilities for dressing and undressing, capability of catheterization in the planned stoma area, tolerance for the time and potential discomfort involved.

In the case of cognitive difficulties that are too significant, if a severe upper limb dysfunction exists [1] or if compliance of the patient remains an impossible obstacle, continent diversion is not indicated. Contraindication can also be a deteriorated renal function [5].

In neuro-urology, techniques for heterotopic continent neo-reservoir (derivation supra-bladder such as Koch pocket, Benckenhoun, Mainz, Miami…) are seldom used initially. They can be offered to patients with vesico-renal reflux, with incontinence through the native urethra despite bladder enlargement or when closure of the bladder neck will be needed (e.g. urethro-vaginal fistula).

b) Results of the different types of cystostomy:

The series are in the vast majority, retrospective (LOE 3) and frequently combine several techniques. This makes the analysis of the results difficult, but some major facts can be gleaned from them.

The catheterizable tube must be able to penetrate the intact or enlarged bladder and it must be able to reach the abdominal wall through a direct pathway with easy access for the patient that has already been predetermined by pre-operative research. The pathway...
of the tube must be direct in order to facilitate self-
catheterization. Two major families of techniques can
be used: simple tubes implanted with an anti-reflux
system and intestinal loop invaginations.

1. SIMPLE TUBES:
   a. Technique:

   Virtually any anatomical structure that is tubular or
   that can be tubularized and that is vascularized can
   be used to make a continent catheterizable tube
   [4](LOE4).

   The two structures that are the simplest to use are:

   The appendix: Transappendicular cystostomy
   according to Mitrofanoff's procedure [6] has long been
   the most used technique(LOE3). Different
   modifications have been proposed, especially to gain
   more length by removing a cecal cuff.

   A short, remodeled intestinal segment (small intestine,
   less frequently the sigmoid or right colon). Yang and
   Monti simple [7] (LOE3) or double technique and the
   Yang-Monti technique modified according to Casale
   in order to gain length by avoiding a double tube [8]
   (LOE3).

   Other structures that have been used in a more anecdotal
   manner, primarily in children: cecum and appendix
   monobloc [9] (LOE4), bladder [10](LOE4), stomach
   diverticulum [2, 13](LOE4), or the preputial or clitoral
   skin [14] (LOE4).

   For most authors, continence of the tube was
   guaranteed by implantation in the native bladder or
   in the augmentation via a submucosal path similar to
   that used in ureteral reimplantation for vesicorenal
   reflux. (LOE4). The submucosal path length must be
   at least 2cm, and is adapted to the bore of the tube
   (two to three times the diameter) [4] (LOE4). A posterior
   or posterolateral bladder flap (kept in case of a
   supratrigonal cystectomy) should allow a more solid
   implantation of the tube in the bladder [15](LOE2).
   Direct implantation into the digestive plasty has also
   been reported.

   The stoma's cutaneous anastomosis is made in the
   lower half of the abdomen, at the umbilicus, most
   frequently by principle, or in the right or left iliac fossa.
   Most authors recommend the interposition of a skin
   flap in the distal end of the tube in order to avoid
   frequent stenosis on the circular orifice scars. Several
   techniques have been proposed: flap in V, VOZ [16]
   (LOE3), and VR [17](LOE3). However, at present,
   the results published do not confirm that the risk of
   stenosis is avoided by any of the techniques.

   It seems essential that the site of the stoma would be
determined preoperatively in patients with functional
limitations of the upper limbs. The site is chosen based
on the patient's capabilities and the position during self-
catheterization (seated in a chair, supine, other). The
surgical technique used in this particular case must
allow access to any point on the lower half of the
abdominal wall [3, 18, 19].

b. Results:

Table 11 summarizes the results in terms of stoma
continence, utilization of the DUCC (carrying out ASPI
across the DUCC), and complications. We retained
only points specifically related to the continent stoma
in the articles. The necessity of reservoir augmentation
(80% of published cases) and techniques allowing
reinforcement of ureteral continence are addressed
in another chapter. Similarly, complications of the
upper apparatus were not detailed. They are in
essence found in the oldest series, in which bladder
augmentation was seldom proposed, and/or during a
ureteral reimplantation procedures (reflux treatment).

In adults as in children, techniques especially of
Mitrofanoff (or variations using the appendix) and of
Yang-Monti allow functional, continent stomas to be
obtained in 75 to 100% of cases (LOE3).

Seven studies indicate significant improvement in
quality of life after the procedure related to improved
autonomy in bladder evacuation, to continence, and
to improved sex life [3, 15, 19-23] (LOE2-3).

The rate of stoma complications (16 to 60%) is
dominated by the risk of stenosis, which is most often
treatable by a simple dilation [24] (LOE3). Many authors
emphasize the fact that this complication occurs most
often in the year following surgery. However, Liard's [25,
16] results (LOE3), which reported an elevated (65%)
intervention rate at 20 years of monitoring, must be
emphasized. For most authors the rate of complications
related to the tube continent was lower when the
segment used was the appendix or intestines remodeled
according to Yang-Monti (LOE3). However, these two
plasties seem to have equivalent complication rates.
Only Narayanaswamy et al [26] (LOE3) reported higher
rates for catheterization difficulty and reinvention
with the Yang-Monti tube in comparison to the appendix.
The Monti tubes in this study were double tubes in
68% (17/25) of cases, and the majority of the
complications were related to the junction area for the
two semi-tubes and not to stoma stenosis. Therefore
it seems that this lengthening method should be used
with caution. If there is a problem with tube length, the
method proposed by Casale [8] (LOE4) has the
theoretical advantage of avoiding an anastomosis on
the tube or a bent pathway at the junction of the two
tubes.

The umbilical anastomosis site for the stoma may be
related to an increased frequency of stoma stenosis
[10, 27] (LOE3). The poorer vascularization of the
umbilicus has been proposed as an explanation [27].
However, results on this point are contradictory with
more recent studies [15].
c. Other types of continent urinary stoma:

Techniques are extremely varied and are better described in the series on bladder cancer. Two technical approaches can be broadly outlined here:

Invaginated valves (Koch pocket, Benchekroun, Mainz) in which the continence mechanism is tied to the flattening of the invaginated valve by urine accumulated in the neo-reservoir;

Ileal-caecal reservoirs in which a portion of the ileum and the ileal-caecal valve are used as a continence mechanism (Indiana pouch, Charleston pouch, Miami pouch).

Data in the literature do not allow a determination to be made as to the superiority of one type of stoma over the others. However, the catheterization difficulties seem to be lower with stomas that use the appendix; the risk of lithiasis seems to be higher with the stomas which require the use of metal staples [28] (LOE4). Several authors have also specifically reported results in neurological patients [20, 29-34] (LOE3).

Continence rates for the stoma vary between 63 and 100%. Complication rates for the stoma are between 10 and 23%. The need to proceed systematically to ureteral reimplantation is aggravated to a certain degree by short term stenosis (0 to 18%), but, as in “simple” tube techniques, few long term follow ups of patients are available.

7. NON-CONTINENT CUTANEOUS URINARY DIVERSION IN NEUROUROLOGY

a) Introduction

Non-continent cutaneous diversion refers to all methods used to divert urine, and where incontinence remains or where a system of extra-physiological continence is created, i.e. urine flow is continuous and requires a means of collecting urine attached to the skin.

In the context of neurogenic bladder, these diversions make it possible to obtain low bladder pressure and to preserve the upper urinary tract.

This type of surgery is a last resort for the many complications related to neurogenic bladder (and congenital anomalies of the lower urinary tract), in patients for whom other therapies have failed to help.

Four techniques are described for non-continent urinary diversions for patients with neurological vesico-sphincter disorders. In order of frequency these are: ileal conduit urinary diversion, ileovesicostomy, cystostomy and cutaneous ureterostomy.

b) Ileal conduit urinary diversion

Ileal conduit urinary diversion is the type of diversion most frequently performed on neurological patients with bladder dysfunction. It differs only slightly from the cystectomy performed for bladder cancer [1]. Pre-operative location of the intended stoma site is crucial and must be adapted to the patient’s main position (wheelchair or bed); the stoma site must be easy to access for management. The ileal segment must be as short as possible to prevent stasis [2](LOE3). There is a variant to this technique whereby a segment of jejunal loop is removed and a stoma made on the left hemi-abdomen. This technique can be proposed after irradiation of the pelvis minor, if the ileum has been impaired and a short loop must be used (about 10 cm) to avoid metabolic disorder (jejunal conduit syndrome: hyperkaliemia, hyponatremia, hypochloremia, acidosis) [3](LOE3).

In neurological patients, ileal conduit urinary diversion by laparoscopy and by robot-assisted laparoscopy have been described [4-7](LOE4). Patients seem to benefit from the procedure, though this remains to be confirmed in the medium and long-term [8] (LOE 2).

1. RESULTS IN NEUROLOGICAL PATIENTS WITH BLADDER DYSFUNCTION

Some series of neurological patients were evaluated to determine the onset of early and late complications [8-14](LOE2-3). Early series of children can be evaluated to determine the morphology of the upper urinary tract and renal function after urinary diversion over a long period (up to 20 years) [15-20](LOE3).

2. EARLY COMPLICATIONS

Mortality is estimated between 0 and 3.4% (LOE2-3) [8-14].

The commonest early complication is intestinal occlusion (4 to 12.6%), usually reversible after prolonged intestinal drainage [8-14](LOE2-3). The risk of gastrointestinal fistula should also be taken into account (0 to 3.3%). As for enterocystoplasty, the current trend is to try to reduce nasogastric tube drainage time to a few hours [21](LOE3).

The most frequent medical complications encountered (3 to 8%) are febrile urinary infections and thromboembolism (2 to 3%)[8-14](LOE2-3).

Other major complications include: urinary fistula in 0.3 to 3.4% of patients which may be prevented by placing a ureteral catheter for about ten days [8-14](LOE3). This complication could be a risk factor for later uretero-ileal anastomosis (LOE4).

3. LATE COMPLICATIONS

a. Gastrointestinal risk

The risk of long-term intestinal occlusion is difficult to evaluate. It ranges between 5 and 7% (LOE3) [9-14]. Even when a short intestinal segment is used, some patients can experiment transient constipation or diarrhoea, which could adversely affect their quality of life[22](LOE2).

b. Complications affecting the bladder left in situ
For the particular indication of neurological patients with bladder dysfunction, several authors have proposed not carrying out cystectomy so as to avoid potentially morbid surgery. At present, this is debatable for several reasons:

- First, there is a risk of pyocyst formation in the unused bladder (21-50%) [9, 10, 14, 23] (LOE3). Even where conservative treatments have been attempted (combining vesical irrigation with antibiotherapy) [24] (LOE3), secondary cystectomy is then necessary in 50 to 100% of cases [10, 15, 17]. For women, a surgical alternative is vaginovesicostomy, which appears to be effective [11, 17] (LOE4).

- Furthermore, the unused bladder is frequently infected and may become an "irritative thorn", especially in patients with spinal injury or multiple sclerosis (LOE4) [10, 25].

- A final argument in favour of cystectomy is that the risk of bladder neoplasia is higher in neurogenic patients, the principal risk factors being long-term indwelling catheterization (more than 8 years), bladder calculi and smoking [26-28] (LOE3). Moreover, screening by cystoscopy-biopsy is not effective [29, 30] (LOE3).

- Finally, improvement of the cystectomy technique (noticeably laparoscopic cystectomy) has considerably reduced related morbidity [8] [31] (LOE2-3). Supratrigonal cystectomy can be performed in men, preserving the prostate and preventing any genital and sexual sequelae.

c. Upper urinary tract complications

Stenosis of the uretero-ileal anastomosis may occur in the medium and long term. This is very damaging to the upper urinary tract and requires regular monitoring of the morphology. In contemporary series of neurological patients with bladder dysfunction, it occurs in 2 to 7.8% of cases within 10 years [9-14] (LOE3). For cases followed for more than 10 years, the finding of 16.5 to 50% stenosis is essentially that of early paediatric series [15-20] (LOE3). Impairment of the upper urinary tract and renal function seems to be correlated mainly with stenosis of the uretero-ileal anastomosis, but also with a long ileal graft and stomal stenosis leading to poor voiding and pyelonephritis [16] (LOE4). In the event of poor functioning of the uretero-ileal anastomosis, some authors suggest endoscopic dilation before further surgical repair of the anastomosis (LOE3) [13, 32-34]. Surgery however remains the reference treatment [32] (LOE3).

The risk of upper urinary tract lithiasis (3 to 31%) is always present in these patients (even without stenosis of the uretero-ileal anastomosis) [9, 10, 13, 14] (LOE3). Patient monitoring should include regular screening of the upper urinary tract to detect any lithiasis and to implement timely treatment (LOE 4).

Chronic bacteriuria is frequent but should not be treated if asymptomatic. Both patients and attending physicians must be informed so as to avoid the administration of unnecessary antibiotics. However, the risk of febrile infection persists over the long term and is logically favoured by uretero-ileal stenosis (12 to 34%) [9, 10, 13, 14].

d. Stoma complications

These are relatively frequent (18.6 to 30%) and varied [10, 13, 14]. The risk of peristomal eventration is the most frequently reported (between 7.7 and 10%). Stomal stenosis may also occur. Stoma complications appear to occur more often in obese patients (LOE3) [35].

Finally, it should be noted that some patient could ask for undiversion. These mainly concern adults who underwent surgery as children and who later wished to recover a continent system, or who have had complications with their non-continent urinary diversion [36-40] (LOE3-4).

\[\textit{c) Ileovesicostomy [41-50]}\]

This technique was first described by Cordonnier in 1957 for treatment of three children suffering from myelomeningocele [48] (LOE4). Its theoretical advantages are relative simplicity, the absence of dissection and suture of the ureter, thus preventing ureteral complications and the potential of "\textit{restitutio ad integrum}" of the bladder (only one case described) [47] (LOE4).

The surgery consists in removing a 10 cm ileal segment from about 15 to 20 cm above the ileocecal valve. One side of the segment is anastomosed to the dome of the bladder and the other to the skin halfway between the iliac spine and the umbilicus. A partial cystectomy is performed to reduce reservoir volume and possible urine stagnation. Surgical variants have been described with simple partial detubularization of the ileum before vesico-ileal suture [50], or the creation of a modified Boari flap on the bladder associated with partial detubularization of the ileum [42, 45-47, 49] (LOE3). These improve drainage by reducing the ileal segment. Laparoscopic ileovesicostomy seems to be feasible [41, 44] (LOE4).

One of the problems with this type of surgery, particularly in women, is the need for further surgery to prevent residual urinary leakage. All authors agree that this significantly prolongs surgery time. This further surgery may consist in closing the bladder neck or placing a suburethral tape [47, 49, 51, 52] (LOE3). Some authors propose performing this surgery later, where necessary [50] (LOE3).

1. \textbf{Early complications}

Early complications are related to the underlying condition of these patients, which is often poor. No case
of post-operative mortality has been reported in the published series [42, 43, 45-47, 49, 50, 52](LOE3). In some cases of poor drainage through the stoma, the drainage was prolonged to six weeks (instead of the usual three). Other early complications were related to poor results of the surgery performed to render patients continent (Table 12). Patients with this type of problem are the most likely to resort to cystectomy with ileal diversion (3 to 6%) [47, 51](LOE3).

2. Late complications

These are summarized in Table 10. No reported series to date has more than five years of follow-up. The most frequent problems appear to be poor voiding related to stenosis of the stoma or the ileovesical anastomosis. Only one report specifically mentions problems related to stoma equipment that occur in about 28% of patients [51](LOE3). The incidence of renal or vesicular lithiasis appears to be low, and several authors report that affected patients had history of lithiasis.

Renal function appears to be preserved with this procedure at least with a mean follow-up of five years (LOE 3) [16, 42, 43, 45-47, 49-51, 53]. No case of impaired renal function, or even post-operative ureterohydronephrosis was reported.

Finally, it should be underline that two patients in the series with the longest follow-up who developed a bladder tumor [45](LOE4).

d) Vesicostomy

Vesicostomy was described by Blocksom in 1957 [54] and detailed more recently by Lapides [55, 56].

The technique consists in constructing a bladder tube anastomosed to the skin by making a transverse suprapubic incision to reach the space of Retzius. The stoma is located half way between the umbilicus and the incision.

The principal benefits of vesicostomy are its simplicity and reversibility, particularly in children [57-63], making it possible to envisage temporary surgery to treat an acute urological problem. In pediatric series, an improvement in the symptoms of infection was reported, with 6 to 20% of patients suffering bladder calculi and 6 to 18% stomal stenosis. Hydronephrosis improved or stabilized in most cases. The rate of end-stage renal failure varied between 6 and 18% for mean follow-ups of 6-7 years.

Nowadays, it is rare to conserve a vesicostomy long term. The results of Lapides are therefore all the more interesting: after two years of follow-up, no urinary infection, 16% poor drainage and 12% calculi [56] (LOE3). Renal function was preserved. At 10 years of age, however, 9.6% of deaths due to end-stage renal failure, mainly due to calculi and repeated infection of the upper urinary tract, were reported [56] [64](LOE3). At 20 years, the rate of chronic renal failure is around 16.6%[54-65](LOE3).

e) Cutaneous ureterostomy

During this procedure, the ureters are placed in direct contact with the skin without using the gastrointestinal tract. There is no gastrointestinal resection/anastomosis which is a marked source of morbidity and mortality. Surgery via the retroperitoneal route is quick and simple.

The main inconveniences are: cutaneous stenosis if the stoma is left without catheter, upper urinary tract infections and calcification around catheters if stoma is equipped. Moreover, it is frequently necessary to construct a double stoma.

It is used in adults, usually in the context of palliative urinary diversion for those with obstructive pelvic cancer (bladder, uterus, rectum), and rarely in neurological patients [66-71].

Surgery is simple: in the absence of cystectomy, two short lateral incisions are made in the iliac fossa, at approximately 3-4 cm from the anterosuperior iliac

860
spine. Direct retroperitoneal access is made and the two ureters located on the internal border of the psoas muscle or above the iliac vessels.

It is important that the peri-ureteral region be spared and the ureter sectioned as low as possible. The ureter is then catheterized and raised to the skin. The stoma is formed by attaching the ureter to the skin, or by spatulating the sutured ureter on a V-shaped cutaneous incision (separate sutures with fine resorbable thread).

Variants are described so as to obtain only one stoma: Y-transuretero-ureterostomy, implantation of both ureters in a single stoma, implantation of a single ureter (ureter ligated to the least functional kidney, or even nephrectomy). The use of cutaneous plasties may remove the need for ureteral catheterization [72].

Cutaneous ureterostomy was first performed in the 1960s, to treat children with spina bifida and severe upper urinary tract impairment [68, 71]. The technique was also developed to treat malformative uropathies (extrophy of the bladder and the posterior urethral valves) [66, 68-70].

Long-term results with a mean follow-up of 8 years are given hereafter: rates of stenosis between 8.7 to 11%, infections from 6.6 to 10% and calculi from 10 to 15.5%) [67, 70](LOE3).

Renal function was preserved for short follow-up times, but fatal end-stage renal failure occurred in up to 26.6% of children during long-term follow-up [69](LOE3).

This technique is almost never used for neurological patients with bladder dysfunction anymore because conservative treatments (intermittent catheterization, urological endoscopy) have improved and the number of children suffering from spina bifida or presenting with complex malformation of the lower urinary tract has gradually lowered. Moreover, new urinary diversion techniques have been developed.

RECOMMENDATIONS

- Utilization of a short intestinal segment (10 cm maximum).
- Minimal dissection of the ureters.
- There are several reports of good results for ileovesicostomy, but the medium-term results need to be confirmed in the long term. Quality-of-life studies should also be performed (C).
- Vescicostomy may be a useful transient solution, particularly for children (D)
- Cutaneous ureterostomy shouldn’t be used for non-continent urinary diversion in adult patients because of the rate of long term complications (B).

D. NEUROLOGICAL FAECAL INCONTINENCE

I. EPIDEMIOLOGY

• Summary from the previous edition [1]

There have been limited numbers of references giving data on prevalence of faecal incontinence (FI) following neurological diseases. Searching from Pubmed from 1964 to 2004, 36 papers were included and the prevalence and incidence of FI varied due to different definitions, severity and also causes/diseases.

The incidence of FI among spinal cord injury (SCI) patients after discharge from rehabilitation was reported between 11% and 75%; the prevalence of constipation and/or FI among multiple sclerosis (MS) ranged from 20% to 73%; and 30% to 50% of Parkinson’s disease (PD) patients reported bowel incontinent.

Regarding stroke patients, during acute admission 32% to 79% of the patients reported FI; the prevalence dropped to 25% to 28% at discharge and 12% to 19% at 6 months. New-onset FI in stroke survivors was transient. Modified risk factors for FI at 3 month after stroke onset were anticholinergic drug use and difficulty with toilet access. It was recommended that bowel dysfunction should be evaluated jointly with bladder dysfunction.

• Search strategy

To add new information to the previous edition, we searched from Pubmed from 2004 to 2008 with search words neurogenic bowel, faecal incontinence, prevalence, incidence, epidemiology, stroke, SCI, MS, PD. Relevant papers from Pubmed, non-Pubmed,
and also other relevant papers that were not cited in the previous edition were recruited and summarized as follows:

1. SPINAL CORD INJURY

During rehabilitation phase, Aya? et al (2006)[2] studied 24 traumatic SCI patients before applying abdominal massage and found that 45.8% had abdominal distention, 41.7% had FI and 25% had difficult intestinal evacuation. New PW (2007) [3] retrospectively reviewed 70 non-traumatic SCI consecutively admitted for initial rehabilitation, 5% of the patients (excluded who died) reported having FI, incontinent at least once per week before discharge.

According to the survey of the impact of secondary conditions after SCI reported in 2007 [4], 13.8% of 65 chronic SCI patients (mean current age 43.8 years, mean years since injury 13.7) rated bowel dysfunction (FI, constipation, diarrhea) as significant or chronic problem, equal to bladder dysfunction and circulatory problem.

Regarding chronic SCI, Tongprasert and Kovindha (2006) [5] studied 100 chronic traumatic SCI patients (duration from onset > 6 months, average 6 years) in Chiang Mai, Thailand and compared with 55 normal persons; 86% of the SCI patients reported constipation, 35% reported FI and 16% had hemorrhoids. The prevalence of constipation and FI were significantly different (P<0.0013) from the normal population (constipation 5%, FI 1.8%). However, prevalence of hemorrhoid between SCI and normal persons was not different (16% vs. 20%, p = 0.338). According to the study of Ng et al (2005)[6] done in 110 established traumatic SCI persons (> 12 months after injury, median 17 years) in Sydney, Australia, the prevalence, based on the Rome II Integrative Questionnaire, was as follows: 41% of FI, 22% abdominal bloating, and 46% constipation (including laxative use). Another prospective, multicentre follow-up observational study was reported in 2007 by the Italian Group for the Epidemiological Study of SCI [7], only 2.7% of 403 traumatic SCI persons (mean duration from discharge to follow-up 3.0+/−0.68 years) reported no bowel continence (= FI), 20.1% had partial, 77.2% had full bowel ‘continence’ (absence of unplanned bowel evacuations) and 70.5% had bowel autonomy (patient’s ability to perform bowel management without assistance). According to the survey in Canada reported in 2004 by Liem et al [8], the most common complication among 352 SCI volunteers for more than 20 years was bowel problems: 47.9% constipation and 41.8% diarrhea/bowel accidents.

FI was found to associate with higher level of anxiety (odds ratio, OR = 2.4, p =0.05) [6] and severity of injury [5] but not with the level of injury [5,6]. According to the study of Vallé et al (2006)[9], they found that in 54 patients with motor complete SCI (mean duration from onset 6 years), 67% presented with constipation (according to Rome II criteria) and 85% some degree of FI. They also found associations between bowel abnormalities i.e., constipation and FI and different neuropathophysiologic patterns. Those with SCI above T7 had frequent constipation (86%) and not severe FI; those with SCI below T7 with preserved sacral reflexes had not so frequent constipation (50%) and not severe FI; and those with SCI below T7 with no sacral reflexes had not very frequent constipation (56%) and greater severity of FI. When compared with those with spinal sacral reflexes, those with no such reflexes had significantly more severe FI (p < 0.005)[9].

According to Krog et al (2006)[10] who did a study in 424 SCI patients to develop and validate a symptom-based score for NBoD, those with daily FI had 10 times more impact on QOL than those with no FI (OR 10.0, p <0.05). Moreover, studies showed that NBoD had significant impact on QOL of chronic SCI patients [10] and they had significantly lower Gastrointestinal QOL score as compared with the normal persons (92.51 +/- 16.21 vs 118.33 +/- 14.17, p <0.001)[5]. From the Italian study [7], loss of bowel/bladder autonomy was correlated significantly with complications (OR 2.202; 1.357-3.574; p <0.001), re-admission (OR 2.097; 1.306-3.366; p < 0.002) and death (OR 5.457; 2.350-12.670; p <0.0001).

Regarding constipation, its association with level of injury was supported by many studies [5,6,9] i.e., upper motor neuron NBoD vs lower motor neuron NBoD (p =0.0013)[5]; cervical injury had more than 5 times more frequent constipation than lumbar injury (OR =5.6, p =0.02)[6]; lesion above T7 had more constipation than lesion below T7 (p <0.05)[9]. In addition, constipation was also associated with severity of injury [4] and taking bladder relaxants [5]. Moreover, it was associated with a 97% increase in the likelihood of needing more help with activities of daily living (ADL) [8].

2. STROKE

In 2006, Brittain et al [11] reported prevalence of isolate UI, FI and double incontinence (DI) in stroke survivors living in community of Leicestershire, United Kingdom. Those living in institutional care were excluded. Of 1,483 stroke survivors, the prevalence was as follows: 6.9% any FI, 4.7% major FI, 2.2% minor FI, 4.3% FI and UI (or DI) and 0.8% isolated FI. Major FI (soiling of underwear or more on a monthly basis) was 4.5 times as prevalent in stroke survivors as in the non-stroke population. DI (major FI and monthly urine leakage) was more than 4 times as high in stroke survivors than in the non-stroke population (4.3% was 0.9%, P < 0.001). Isolated FI as well as isolated UI was also significantly higher in the stroke population. According to the epidemiologic multi-centre study of the Thai Stroke Rehabilitation Registry [12], on admission to rehabilitation, 31.5% of 327 stroke patients (median 24 days; about 5%
admitted one year after onset) reported of bladder and bowel problems: 24.5% UI, 8.6% urinary difficulty and 11.9% FI.

Regarding factors related to FI in stroke, urinary incontinence (adjusted OR 8.1; 95% CI 6.62-9.69) and functional limitation (adjusted OR 4.02; 95% CI 3.27-4.95) were significantly related to major FI in stroke living in community [11].

3. MYELOMENINGOCELE

According to the Dutch study on the prevalence of incontinence in young adult spina bifida reported in 2007[13], of 179 participants (142 with spina bifida aperta and 37 with spina bifida occulta), 60.9% had UI and 34.1% had FI (defined as having accident once a month or more); 109 were diagnosed as having myelomeningocele, 13 as having meningomeningocele and 119 suffered from hydrocephalus. When classified by type of lesions, 40.8% of spina bifida aperta and 8.1% of spina bifida occulta; 46.2% of those with hydrocephalus and 10% of those with no hydrocephalus; and 39.7% of those having lesion at L5 or above and 13.2% of those having lesion below L5 reported FI (P <0.05). Moreover, about 2/3 of those with spina bifida aperta, hydrocephalus and lesion at L5 or above had UI as well; and most of them perceived FI and UI as problem.

4. PARKINSON’S DISEASE

Recently Krogh et al (2008) [14] did a study to compare bowel symptoms in PD with normal control subjects. Most of the cases had minor constipation-related symptom. However 7% of 416 PD but 0% of normal controls reported severe constipation; 27% and 23% with PD had bowel movements less than every second day and incomplete emptying every week, respectively. The severity of PD was associated with assisted defecation (p < 0.001) and unsuccessful attempts at defecation (p < 0.001). Regarding incontinence, 6% of PD patients reported incontinence to solid stool at least one per month, 6% to liquid stool at least one per month; 32% of PD patients had flatus incontinence at least one per week; these were no statistically significant difference to normal control group. They believed that the increase in obstructed defecation symptom but the less prevalence of FI are due to dystonia of the external anal sphincter but intact internal anal sphincter with normal anorectal sensibility.

5. TRAUMATIC BRAIN INJURY (TBI)

According to the report from the Traumatic Brain Injury Model Systems national database [15], the incidence of FI among TBI patients was 68% at admission to inpatient rehabilitation, 12.4% at rehabilitation discharge and 5.2% at 1-year follow-up; and FI was significantly associated with admission Glasgow Coma Scale score, length of coma and post-traumatic amnesia (PTA), length of stay (LOS), frontal contusion, functional independence measure (FIM) scores and urinary tract infection.

6. MULTIPLE SYSTEM ATROPHY (MSA)

Wenning et al (1994) [16] described the clinical features and natural history of 100 patients diagnosed as probable MSA. The most frequent autonomic symptom in men was impotence, and in women was UI. Moreover, Parkinsonism was the initial feature in 46%, but had subsequently developed in 91% of subjects at latest follow-up. According to the North American Multiple System Atrophy Study Group (2005) [17], UI occurred commonly. According to Sakakibara et al. (2004) [18], 93% of MSA patients showed neurogenic motor unit potentials in anal sphincter EMG and concluded that FI resulted from weak anal sphincter due to denervation.

CONCLUSIONS

- Faecal incontinence is prevalent among neurological patients, but less prevalent than urinary incontinence. (LOE 3)
- In spinal cord injured patients, constipation is more frequent than faecal incontinence; faecal incontinence is more severe in those without external anal sphincter responses/reflexes; and constipation is more frequent in those with higher level of injury. (LOE 3)
- The prevalence of faecal incontinence in stroke and traumatic brain injury survivors in community was lower than in hospital-based patients; and urinary incontinence, anticholinergic drug use and functional limitations were associated with faecal incontinence. (LOE 3)
- Faecal incontinence is commoner in spinal cord injured than in stroke patients. (LOE 3)
- Faecal incontinence is a significant problem of chronic neurological patients but not of multiple system atrophy patients. (LOE 3)

RECOMMENDATIONS

- Variation of definition of faecal incontinence as well as constipation should be minimized.
- More epidemiologic study on neurogenic bowel dysfunctions and its consequences in other neurologic diseases.
II. SPECIAL DIAGNOSIS OF FAECAL INCONTINENCE IN NEUROPATHIC PATIENTS

1. SEARCH STRATEGY

To add new information to the previous edition, we searched from Pubmed from 2004 to 2007 with search words of neurogenic bowel and faecal incontinence. There have been only 9 relevant papers and they are summarized as follows:

2. GENERAL PRINCIPLES

According to the previous section D2 in the chapter 17 of the 3\textsuperscript{rd} ICI on Neurologic Urinary and Faecal incontinence [1], 22 papers published from 1996 to 2004 were reviewed. Specific diagnostic tests for faecal incontinence (FI) are tests to assess anal sphincter including levator ani complex functions and structures, anal sensation, rectal sensation and rectal accommodation/compliance.

For neuropathic patients, comprehensive neurophysiologic or electrodagnostic tests – rectal mucosal electrical sensory threshold, thermal sensation, pudendal nerve latency, and needle EMG of the anal sphincter or puborectalis muscle, may be helpful to distinguish non-neurogenic from neurogenic causes of FI especially in those with lower motor neuron lesions (LMNL) including conus medullaris, cauda equina and peripheral nerve damage. For those with suprasacral or upper motor neuron lesions, electromyography (EMG) during straining and balloon expulsion test may show dyssynergic pattern. In addition, saline enema test has been suggested as patients with tethered cord lesion showed hyperactive rectum, diminished rectal saline retention ability and diminished maximal flow.

In spinal cord injured (SCI) patients, FI was not a common problem like constipation. However one should be reminded that constipation is one of the main causes of FI in SCI patients; and anal manometer and colonic transit time (CTT) were frequently selected to assess constipation. In addition endoanal ultrasound (US) or magnetic resonance imaging (MRI), and puborectalis and pelvic floor motion, assessed by dynamic MRI may be helpful to determine myopathic damage that may coexist in neuropathic patients. Moreover as FI has a strong impact on quality of life, QOL. Therefore QOL as well as patients' environment, physical disabilities and co-morbidity should be assessed in order to plan a comprehensive and appropriate management.

3. CLINICAL ASSESSMENT

Vallès et al. (2006)[2] studied and identified a comprehensive neurogenic bowel (NBo) pattern in 54 patients with motor complete SCI based on clinical assessment, total and segmental CTT quantification, anorectal function evaluation by manometry, intrarectal balloon distension, and surface EMG. They revealed 3 patterns: Pattern A, present in above T7 injuries, characterized by very frequent constipation (86%) with significant defecatory difficulty and not very severe incontinence (mean Wexner score 4.5); it was related to moderate delay in CTT (mainly in the left colon and recto-sigma), incapacity to increase the intra-abdominal pressure, and the absence of anal relaxation during the defecatory maneuver; Pattern B, present in below T7 injuries with preserved sacral reflexes, characterized by not so frequent constipation (50%) but very significant defecatory difficulty and not very severe incontinence (Wexner 4.8); the pathophysiological counterpart was a moderate delay in CTT, capacity to increase intra-abdominal pressure, increased anal resistance during the defecatory maneuver, and presence of external anal sphincter (EAS) contraction when intra-abdominal pressure increased and during rectal distension; Pattern C, present in below T7 injuries without sacral reflexes, characterized by not very frequent constipation (56%) with less defecation difficulty and greater severity of incontinence (Wexner 7.2); this was associated with severe delay in CTT (mainly in the left colon), capacity to increase intra-abdominal pressure, absence of anal resistance during the defecatory maneuver, and absence of EAS contraction when intra-abdominal pressure increased and during rectal distension.

Krogh et al. (2005)[3] did a cross-sectional questionnaire study to develop and validate a symptom-based score for neurogenic bowel dysfunction (NBoD). It included 39 questions about background parameters, FI, constipation, obstructed defecation, and impact on quality of life (QOL – no, little, some and major). Based on odds ratios for associations between items and impact on QOL, each item was given a corresponding number of points in the NBoD score; and 10 items met the criteria: frequency of bowel movements (0-6 points), headache, perspiration or discomfort before or during defecation (0-2 points), and drops against constipation (0-2 points each), time used for each defecation (0-7 points), frequency of digital stimulation or evacuation (0-6 points), frequency of FI (0-13 points), medication against FI (0-4 points), flatus incontinence (0-2 points) and perianal skin problems (0-3 points); and if the score is $>14$, NBoD is severe; if the score is 10-13, NBoD is moderate; if the score is 7-9, NBoD is minor and if the score is 0-6, NBoD is very minor.

4. ANORECTAL MANOMETRY

According to the study of Ito et al. (2006)[4], (Table 13) normal physiology of the lower urinary tract (LUT) and the caudal part of the lower gastrointestinal tract (LGIT) in 15 normal healthy volunteers by using the same videomanometry method revealing fluoroscopic images, subtracted bladder/rectal pressures, urethral/
anal sphincter pressures, sphincter electromyography, and urinary/fecal flow. Spontaneous phasic rectal contractions (SPRC) and abdominal strain are features of the LGIT, whereas micturition bladder contraction is a feature of the LUT. These features can aid in understanding the possible rectal ‘artifacts’ of videourodynamics and neurogenic pelvic organ dysfunction.

Li and Xiao (2006)[5] investigated the anorectal status by anorectal manometry in 26 patients with lumbosacral (LS) cord injury (2 AIS: A and 24 AIS: B-D; median age 43.7 years; median time since injury 59.1 months) with mixed symptoms of constipation and/or FI and 13 normal volunteers. The maximum anal resting pressure in the patients group was slightly lower than that in the control group (P=0.939). During defecation maneuvers, 23 of 26 (88.5%) patients and 1 of 13 (7.7%) normal volunteers showed pelvic floor dysfunction (PFD) (P<0.0001). Rectoanal inhibitory reflex was identified in both patients and the controls. The rectal volume for sustained relaxation of the anal sphincter tone in the patient group was significantly higher than that in the control group (P<0.0001). The mean rectal volume to generate the first sensation was 92.7 ml+/-57.1 ml in the patient group, and 41.5 ml+/-13.4 ml in the control group (P<0.0001).

According to the study of Sakakibara et al. (2004)[6], at the resting state, patients with multiple system atrophy (MSA) had a lower anal squeeze pressure (external sphincter weakness) and a smaller increase in abdominal pressure on coughing; during rectal filling, they showed smaller amplitude in phasic rectal contraction, which was accompanied by an increase in anal pressure that normally decreased, together with leaking in 3 patients; during defecation, most of them could not defecate completely and had larger post defecation residuals due to weak abdominal strain, smaller rectal contraction on defecation, and larger anal contraction on defecation (paradoxical sphincter contraction on defecation). They concluded that the responsible sites for these dysfunctions (constipation and FI) seem to be both central and peripheral nervous systems that regulate the lower gastrointestinal tract [6].

5. PELVIC FLOOR IMAGING

Adding fluoroscopy, Ito et al. (2006)[4] used the same videomanometry to reveal fluoroscopic images of the caudal part of the LGIT to help understand the possible rectal ‘artifacts’ of videourodynamics and neurogenic pelvic organ dysfunction in normal volunteers. During the last three years, there was no such study in neuropathic patients.

6. ELECTRODIAGNOSTIC TESTS

In 2006, there were two review articles. One was the study of Craggs et al. [7] who reviewed details of the interactions of somatic and autonomic lumbosacral pathways responsible for coordinating the bladder and sphincters, the nature of their aberration post-injury and those aspects of neural control of the pelvic organs that are amenable to neurophysiological examination in man; and the other was the study of Lefaucheur [8] who reviewed the neurophysiological techniques (Table 14) currently available to evaluate anorectal disorders.

To determine risk factors for development of FI, Dubravica and Demarin (2004)[9] examined the anal sphincters in 110 women with SCI and 91 women with spinal cord lesion (SCL) by means of standardized

Table 13. Shows normal values from manometry of the lower urinary tract (LUT) and the caudal part of the lower gastrointestinal tract (LGIT) derived from the study of Ito et al. (2006) [4] with 15 normal healthy persons

865
EMG technique with concentric needle electrode. The results demonstrated predominantly neurogenic lesion of the anal sphincters in SCL women and predominantly normal findings in SCI women. Sakakibara et al. (2004) [6] also studied anal sphincter EMG and showed neurogenic motor unit potentials in none of control subjects but in 93% of multiple system atrophy (MSA) patients; and FI resulted from weak anal sphincter due to denervation.

7. COLONIC TRANSIT TIME (CTT)

According to Sakakibara et al. (2004)[6], MSA patients had significantly prolonged CTT in the rectosigmoid segment and total colon. Constipation in MSA most probably results from slow colonic transit, decreased phasic rectal contraction, and weak abdominal strain.

8. QUALITY OF LIFE ASSESSMENT

According to the study of Krogh et al. (2005)[3], differences in NBoD score representing very minor, minor, moderate and severe NBoD groups of SCI patients reporting no, little, some or major impact on QOL were statistically significant (all P<0.001). In addition, frequency of FI, medication against FI and flatus incontinence were significantly associated with impact on QOL (OR 13.1, p < 0.0001; OR 3.6, p <0.01; OR 1.8, p < 0.05, respectively).

9. COMPREHENSIVE ASSESSMENTS

Bharucha (2006)[10] reviewed and summarized the indications, methods, strengths, and limitations of anorectal testing in clinical practice (Table 15). In patients with FI, diagnostic testing complements the clinical assessment for evaluating the pathophysiology and guiding management. When neurogenic sphincter weakness is suspected, anal sphincter EMG is recommended as the measurement of pudendal nerve latencies has several limitations [6,9,10].

CONCLUSIONS

- Greater severity of faecal incontinence was found in SCI individuals with no sacral reflexes due to absence of external anal sphincter contraction when intra-abdominal pressure increased and during rectal distension. (LOE 3)
- Anorectal manometry could show pelvic floor dysfunction during defecatory manoeuvres, impaired rectal sensation functions and abnormal cough reflex in those with lumbosacral cord injury. (LOE 3)
- Electrodiagnostic tests are complementary to other methods of investigation to establish the diagnosis and guide therapeutic management of neurogenic anorectal disorders. (LOE 3)
- Faecal incontinence in SCI individuals shows correlation to impact on QOL. (LOE 3)

RECOMMENDATIONS

- Perform electrodiagnostic tests, especially external anal sphincter needle EMG, in addition to anorectal manometry, to identify or confirm neurogenic cause of faecal incontinence. (C)
1. SUMMARY FROM THE PREVIOUS EDITION[1]

Bowel care is a procedure devised to initiate defecation and accomplish faecal evacuation. This can be achieved by bowel training with scheduled and stimulated defecation program consisting of cleansing the colon, normalizing of stool consistency with adequate fluid and fiber intake, and stimulating evacuation of stool on a regularly scheduled basis. Timing a bowel movement to take advantage of the gastro-colic reflex may be useful to achieve complete evacuation with the rectum free of stool, thus decrease the chance of faecal incontinence (FI).

Reflex-triggered bowel evacuation with mechanical stimulation – digital rectal stimulation and/or chemical stimulation – suppositories, enemas, can be helpful. In addition, Valsalva or manually-generated external pressure, oral medications – stool softeners, stimulant laxatives and prokinetic agents; diet modification; biofeedback; electrical stimulation and functional magnetic stimulations may be useful. However successful bowel care needs intensive patient education and training. If conservative bowel management fails, surgical management may be necessary.

2. SEARCH STRATEGY

Search from Pubmed 2004-2008 by using key words of faecal incontinence, neurogenic, neuropathic, neurologic, neurogenic bowel, bowel care, conservative treatment, and practice guideline. From such searches, there are 17 relevant papers of various levels of evidence as follows:

### 3. BOWEL PROGRAMME / BOWEL CARE

In 1998, the Consortium for Spinal Cord Medicine [2] published the “Neurogenic Bowel (NBo) Management in Adults with Spinal Cord Injury (SCI)” Clinical Practice Guideline (CPG). Later in 2005, to improve an adherence to the CPG recommendations through a targeted implementation strategy, Goetz et al [3] did a multi-site clinical trial study at 6 Veterans Affairs SCI centers. The CPG adherence was determined from medical record review for 3 time periods: before guideline publication (T1), after guideline publication but before CPG implementation (T2), and after targeted CPG implementation (T3). In focus groups before the intervention, the barriers were identified by SCI providers and then, two specific implementation strategies were chosen to address: the development and dissemination of a standardized documentation template and the development of a patient-mediated intervention to enhance guideline adherence. Because of the effective chart-based reminders, there was significant increase in overall adherence to recommendations related to NBo between T2 and T3 (P < 0.001) for 3 of 6 guideline recommendations: patient history, physical examination and documentation but the overall adherence of documentation was still low (40%). Moreover, it was found that other 3 recommendations i.e., functional assessment, education and competency, had high-rate of adherence in all 3 phases.

#### a) Mechanical stimulations for bowel movements

##### 1. DIGITAL RECTAL STIMULATION

Digital rectal stimulation (DRS), a gentle and slow rotation or circular movement of finger, is recom-
mended for reflex bowel as an adjunctive to facilitate bowel evacuation [2]. It dilates an anal canal and relaxes puborectalis muscle, thus decreases the ano-rectal angle and reduces outflow resistance to the passage of stool. Korsten et al (2007) [4] applied DRS, with a gloved finger fully inserted into the anal canal and distal rectum and contacted with the anal mucosa; each lasted for 1 minute with a 2-minute interval between successive DRS, to measure colonic motility by using a manometric catheter affixed endoscopically to the spleen flexure. In addition, evacuation of barium oatmeal paste was assessed simultaneously using fluoroscopic techniques. In 6 SCI patients, the results showed that the mean number (+/- SEM) of peristaltic waves per minute increased from 0 at baseline to 1.9 (+/- 0.5/min) during DRS and 1.5 (+/- 0.3/min) during the period immediately after cessation of DRS (P < 0.05). The frequency of contractions, as well as amplitude of contractions, during or immediately after DRS was not significantly different; peristaltic contractions disappeared 5 minutes after the cessation of DRS; and the manometric changes in response to DRS were accompanied by expulsion of barium oatmeal paste in every subject by the fifth DRS. This proved that DRS contributes to bowel evacuation in individuals with SCI in part by increasing left-side colonic motility.

However, mechanical stimulation may cause local trauma and induce autonomic dysreflexia (AD) in SCI individuals. Furusawa et al (2007)[5] studied the relationship between bowel manoeuvres and AD in cervical SCI patients and demonstrated that insertion of rectal medication induced a significant increase in systolic BP, which persisted during additional DRS; furthermore, the manual removal of stool induced AD, with maximal increases of systolic BP. However, after the end of stool flow the insertion of a finger into the anus did not cause a further increase in systolic BP which recovered to pre-program values within 5 min after defaecation. The combined effects of rectal and/or anal sphincter distension and uninhibited rectal contraction in response to the manual removal of stool are assumed to induce AD. According to the CPG [6], if the elevated systolic blood pressure is less than 150 mmHg, gently instill a topical anaesthetic agent into the rectum, wait for 2 minutes, gently remove the stool; if AD becomes worse, stop manual evacuation, instill additional topical anesthetic and recheck the rectum for the presence of the stool after 20 minutes

b) Chemical stimulants

According to the meta-analysis review done by Coggrave et al (2006)[7] to determine the effects of management strategies for faecal incontinence (FI) and constipation in people with neurological diseases affecting the central nervous system. Most of the ten trials were identified were small and of poor quality. Oral medications for constipation were the subject of four trials. Cisapride does not seem to have clinically useful effects in people with SCI (three trials). Psyllium was associated with increased stool frequency in people with Parkinson’s disease but did not alter colonic transit time (CTT) (one trial). Prucalopride, an enteroendocrine did not demonstrate obvious benefits in this patient group (one study). Some rectal preparations to initiate defaecation produced faster results than others (one trial). Different time schedules for administration of rectal medication may produce different bowel responses (one trial). Mechanical evacuation may be more effective than oral or rectal medication (one trial). The clinical significance of any of these results is difficult to interpret.

During the last 3 years there has been no research study on the effectiveness of such medications in patients with neurogenic bowel dysfunction (NBoD).

c) Assistive techniques for defecation

1. Abdominal massage

Another assistive technique usually applied to enhance bowel movement is abdominal massage in a clockwise motion up the ascending colon, across the transverse colon, and down the descending colon [2]. To investigate its effect on clinical aspects of NBoD and CTT, Aya? et al (2006)[8] did an uncontrolled clinical trial in 24 SCI patients whom were placed on a standard bowel program (phase I), after which abdominal massage was added to the regimen (phase II). In phase I, 45.8% had abdominal distention and 41.7% had FI; corresponding results for phase II were 12.5% and 16.7% (P = 0.008 and 0.031, respectively) and no significant differences between the proportions of patients with difficult intestinal evacuation or abdominal pain or in mean time required for bowel evacuation in phase I vs. phase II. The mean frequencies of defecation in phases I and II were 3.79 +/- 2.15 (2.75-4.55) and 4.61 +/- 2.17 (3.67-5.54) bowel movements per week, respectively (P = 0.006). Mean total CTT decreased from 90.60 +/- 32.67 (75.87-110.47) hrs in phase I to 72 +/- 34.10 (58.49-94.40) hrs in phase II (P = 0.035). According to this study, abdominal massage is an effective technique in enhancing bowel movement and defecation and thus reducing bowel accident, FI in SCI persons.

2. Anal stimulation with water streams (LOE 3)

In 2007, Uchikawa et al (2007)[9] reported the effectiveness of a newly modified washing toilet seat equipped with a CCD camera monitor and an electronic bidet to facilitate precise hitting of the anal area with water streams to stimulate bowel movement in patients SCI who were at least 5 months post acute injury, and could change their position on the toilet seat while watching the monitor. The stimulation was provided for a maximum of 30 minutes. Bowel movement was successfully induced in 15 of the 20 patients (75%) and success was not related
To evaluate the outcome of transrectal irrigation (TRI) significantly to injury level, ASIA impairment scale, or ability to voluntarily squeeze. Moreover, no complications were observed and time needed for successful bowel movement was shortened in 11 of 13 patients as they usually spent more than 30 minutes before stimulation.

3. TRANSCANAL / TRANSECTAL IRRIGATION

Christensen et al (2006)[10] did a prospective, multicenter, randomized controlled trial (RCT) involving 5 specialized European SCI centers, and 87 SCI patients with NBoD were randomly assigned to either transanal irrigation (TAI) using the Peristeen Anal Irrigation system with 750-1,500 ml of tepid water in 42 patients and conservative bowel management, scheduled bowel care at least every 2 days, at the same time of the day and after ingestion of food and liquid, diet modification, adequate fluid, regular physical activity; and laxatives or constipating medicine when necessary as recommended in the American CPG (2) in 45 patients for a 10-week trial period. Results showed that the TAI improved constipation, FI, and symptom-related QOL much better than conservative bowel management. In addition, urinary tract infection (UTI) was less in the TAI group than in the conservative group (5.9% versus 15.5%, P = .0052); AD tended to be less in the TAI group because the underlying faecal impaction was tested; and wheelchair users and those confined to be seem to have the highest benefit of the TAI. However, half from the TAI group discontinued due to failure of the TAI.

Later in 2008, Del Popolo et al (2008) [11] did a multi-center study in Italy to evaluate the effect of the Peristeen Anal Irrigation[10]. Twenty-four of 36 SCI patients with NBoD became less dependent on their caregiver; 28.6% of 32 who completed the study was able to perform it independently. All children were free of constipation; most (35/40) were also anal continent. Rectal volume and anal sphincter pressure improved, while plasma sodium values remained within the normal range. They concluded that TRI with tap water was a safe method to resolve constipation and FI in children with MMC and NBoD, but it did not help children to independence at the toilet.

4. APPLIANCE/ASSISTIVE TECHNIQUES FOR FAECAL INCONTINENCE

a) Anal plug (LOE 2)

Previous studies of an anal plug have yielded conflicting results. Bond et al (2007)[13] did a multi-centre RCT to evaluate the Conveen anal plug (Coloplast Limited) for the management of FI in congenital, acquired and neurogenic children and adults. It was used for 12 months. The main outcome measure was a condition-specific score on a 0 to 100 scale. Thirty-one intervention and 17 control patients were recruited. At baseline, patients managed their condition preemptively or protectively. Intervention patients used the plug as a complete management substitute or as an adjunct to existing management and majority retained the plug most of the time. Compared with control group, there was greater improvement from baseline in mean condition-specific score in intervention group but this difference was not statistically significant (t test p=0.053). Complete data analysis using analysis of covariance showed the mean difference between the intervention groups in condition-specific score of 9.9 (95% confidence interval-1.4, 21.1). Intention to treat analyses using imputation showed similar results.

b) Neuromodulation

According to Fowler’s review (2004)[14] on treatment related research in faecal and urinary incontinence, afferent innervation is important in sensing the degree of bladder fullness and in forming the input limb to involuntary detrusor contractions in neurogenic detrusor overactivity (NDO). It is likely that homologous mechanisms are involved in control of the bowel. Experimental evidence suggests that the “procontinence” reaction consists of an inhibitory effect on the detrusor and presumably the lower rectum resulting from contraction of the pelvic floor and the anal or urethral sphincter. Development of methods of enhancing the inhibitory reflex effect could lead to improved voluntary control of micturition and defaecation for patients with SCL.

1. INTRAVESICAL ELECTRICAL STIMULATION (IVES)

Han et al (2004)[15] retrospectively reviewed the effect of IVES on NBoD – controlling FI, in 9 boys and 15 girls (mean age 8.1 years) who completed a mean of 30.3 daily sessions of IVES. After IVES, the mean number of overall FI episodes decreased
significantly from 7.36 to 4.8 a week (p <0.05). Greater than 50% decrease in the episodes of FI was observed in 75% of the children but there was no significant change in the number of daily bowel movements before (1.8 daily) and after (1.55 daily) IVES.

5. QUALITY OF LIFE (LOE 3)

In 2005, there was one study of Luther et al [16] that compared patient outcomes and QOL for people with NBoD using either a standard bowel care program or colostomy. This study was part of a larger study that evaluated CPG implementation in SCI. The sample included 1,503 SCI veterans with the response rate of 58.4%. For comparison, a total of 74 veterans with SCI and colostomies were matched with 296 controls, using propensity scores. Seven items were designed to elicit information about the respondent’s satisfaction with their bowel care program, whereas 7 other items were designed to measure bowel-related QOL. No statistically significant differences in satisfaction or QOL were found between the responses from those with colostomies and those with traditional bowel care programs. Both groups had received training for their bowel care program, experienced relatively few complications, such as falls as a result of their bowel care program, and that their QOL related to bowel care was generally good. However, 55.7% of respondents with colostomies and 41.7% of those without colostomies reported that they were very unsatisfied with their bowel care program.

Zickler and Richardson (2004)[17] did a review on MMC and other neural tube defects children with NBoD and NBD, who had a physical inability to attain continence. However, they can attain continence when the appropriate modifications to the traditional routines are made. Enabling the child to attain continence would improve parental relationships and self-concept.

CONCLUSIONS

- Apart from relaxing the external anal sphincter, digital rectal stimulation increases peristaltic contractions by facilitating excitatory ano-colonic reflex and enhances bowel movement and evacuation in reflex bowel. (LOE 3)
- Abdominal massage has positive effects on some clinical aspects of neurogenic bowel dysfunction including defecation function and faecal incontinence. (LOE 3)
- Transanal irrigation seems to be a safe method to improve constipation and faecal incontinence in individuals with neurogenic bowel dysfunction. (LOE 3)
- An anal plug seems to benefit in controlling faecal incontinence in neurological patients but not better than control (without anal plug). (LOE 2)

- To increase adherence rate with bowel care programme/clinical practice guideline, implementation strategies should be addressed to care providers. (LOE 3)

RECOMMENDATIONS

- Apply appropriate mechanical stimulation - digital rectal stimulation, and/or assitive techniques – abdominal massage, transanal/transrectal irrigation to improve defecation and reduce faecal incontinence in neurological patients with neurogenic bowel dysfunction. (B)
- Be aware of autonomic dysreflexia when using mechanical stimulation and assitive techniques with neurologic patients with a high cord lesion. (B/C)
- Provide appropriate modifications to the bowel care program to improve bowel functions including defecation and continence. (B/C)

RECOMMENDATIONS FOR RESEARCH

- Further study to prove the existence of the excitatory ano-colonic reflex in response to digital rectal stimulation in individuals with lower motor neuron lesions.
- Further study to confirm that the newly anal stimulation with water stream is an appropriate method to facilitate bowel movements without complications.
- Well-designed controlled trials with adequate numbers and clinically relevant outcome measures of bowel management are needed.
- Larger and good quality randomized crossover trials are needed to confirm the effects of neuromodulation for controlling faecal incontinence and reducing constipation in neuropathic people.

IV. SURGICAL TREATMENT

- Methods

Using MEDLINE we identified English-language journal articles and reviews published from 2000 to April 2008, looking for the keywords neurogenic constipation and faecal incontinence, surgery, sacral nerve stimulation, ante grade, continent enema procedure, dynamic graciloplasty, artificial anal sphincter and colostomy.
Surgical treatment of faecal incontinence in the general population is overviewed in the Chapter on the Surgery for Faecal Incontinence. Therefore, this section focuses on specific aspects in neurogenic patients. Although traumatic lesion of external sphincter is treated by reconstruction of the external sphincter, functional impairment of anal sphincter without mechanical defect of the sphincter in neurogenic patients can not be treated by this simple surgical repair, and thus options for surgical treatment of neurogenic bowel dysfunction are limited. However, they consist of 1) sacral nerve stimulation, 2) ante grade continent enema procedure, 3) dynamic graciloplasty, 4) artificial anal sphincter, and 5) elective colostomy.

1. SACRAL NERVE STIMULATION (SNS)

Electrical stimulation of sacral nerve roots has been reported to restore continence in patients with intact muscle structure. The procedure is divided in three steps: acute percutaneous testing, temporary percutaneous nerve evaluation and permanent electro stimulation phase with an implantable neurostimulation device. An electrode inserted into the S3 sacral foramen provides low grade stimulation. Only when patients respond to acute and temporary percutaneous sacral nerve stimulation tested for 2 to 3 weeks, permanent stimulation via a chronic stimulator implanted under the anterior abdominal wall is applied or subcutaneously in the gluteal region. The first case report with this technique was published by Matzel et al [1] in 1995 who described a successful outcome in three patients with faecal incontinence. Since then, ten articles have been published [2-11] (Table 16).

Recently, Matzel et al [2] reported a multi centre, prospective trial with chronic sacral nerve stimulation in a series of 34 patients at a median follow-up of 23.9 months. At least 83 % of patients had a 50 % or greater improvement in total number of incontinent episodes per week and at least 71 % of patients a 50 % or greater improvement in total number of days per week with continence during the course of follow-up. Continence was fully restored in at least 12 (37%) patients. Quality of life improved in all four ASCRS (American Society of Colon and Rectal Surgeons) scales (p<0.0001) and in seven of eight SF-36 scales, though only social functioning was significantly improved (p=0.0002).

Although 12 patients had 19 device-related adverse events including pain (ten episodes in 9 patients), lead breakage in one patient, recurrent infection needing device removal in one patient and deterioration of bowel symptoms in three patients, resolution rate was 63.2 % and 100 % for all and severe complications, respectively. However, this study excluded patients with neurological diseases. Similar success rates (73-100 %) with this technique have been reported from other centres [3-5, 7-11]. Among these reports, only one case-series by Rosen et al [12] targeted mainly on faecal incontinence in patients with neurological lesions. In that study, 20 patients (15 neurogenic, 5 idiopathic) with severe faecal incontinence were initially treated by temporary external stimulation over a period of 10-14 days. Sixteen patients (11 patients with neurogenic causes including 5 spinal cord injuries, 4 post spinal cord surgeries, 1 myelomeningocele, 1 multiple sclerosis, and 1 Friedreich ataxia, and 5 idiopathic patients) who had shown a positive response to the temporary stimulation subsequently underwent permanent implantation. The median follow-up was 15 months (range, 3-26 months). All patients who had received a permanent implant revealed a marked reduction in their incontinent episodes as well as an increase in retention time. In the neurogenic subpopulation, the median numbers of incontinence episodes decreased significantly (p<0.01) from 7 (4-15) to 2 (0-5), and a median retention time significantly (p<0.01) increased from 2 minutes (0-5) to 7 minutes (2-15) after chronic stimulation. Assessment of QOL scales using ASCS questionnaire after 6 months treatment showed significant improvement on all scales. Three patients (2 neurogenic and 1 idiopathic) had severe infections needing explantation of devices and wound drainage 0-3 months after implantation. Another one patient had dislocation of the permanent electrode.

No complications were observed in the remaining 12 patients (60 % of total series). All of those patients with functioning systems have showed improved incontinence during the follow-up period. Although the mechanism of SNS to improve faecal incontinence is uncertain, rises in anal resting and squeezing pressures and changes in rectal sensitivity and motility have been proposed. Particularly in neurogenic patients, neuromodulation of sacral reflexes and regulation of rectal sensitivity appear to be the major reasons for the functional improvement [7].

Alternatively, the diagnostic stage can be performed as a staged implant, with a quadripolar foramen electrode (tined lead, Medtronic model 3886). This technique improves the results of the test period in the urological literature from a 50 % success rate with the wire electrodes up to 80 % using already the quadripolar foramen electrodes in the test phase Kessler et al., 2005 [13]. The tined lead has four active electrodes (compared with a single electrode used in PNE) and has self-retaining flanges, which prevent lead migration. Usage of the tined lead has the benefit of minimizing false-negative results. Recently, Jarrett et al (2005) [14] reported on their experience with sacral nerve stimulation for faecal incontinence in patients with previous partial spinal injury including disc prolapse; the spinal insults were disc prolapse (six), trauma (four), spinal stenosis (one) or occurred during neurosurgery (two).
Temporary SNS was performed in thirteen patients (median age 58, range 39-73 years). Twelve patients had successful temporary stimulation and proceeded to permanent implantation. The median follow-up time was 12 (range 6-24) months, the mean number of episodes of incontinence decreased from 9.33 (7.64 per week at baseline) to 2.39 (3.39) at last follow-up (p = 0.012). The number of days per week with incontinence and staining decreased significantly (p < 0.001). The ability to defer defecation improved from a median of not being able to defer (range 0-1 min.) to being able to defer 5-15 (range 0->15) mean (p = 0.022). The authors conclude that SNS can benefit patients with faecal incontinence following partial spinal cord injury.

Holzer et al (2007) [15] report on 36 patients included in a trial of SNS, 29 subsequently had a permanent implant. After a median follow-up of 35 (range 3-71) months, 28 patients showed a marked improvement: Incontinence to solid or liquid stool decreased from a median of 7 (range 4-15) to 2 (range 0-5) episodes in 21 days (p = 0.002). Saline retention time increased from a median of 2 (range 0.5-1) to 7 (range 2.1-19) min. (p = 0.002). The quality of life on all scales among patients who received the permanent implant increased at 12 and 24 months after operation. Also Holzer et al stated that SNS is of value in selected patients with neurogenic faecal incontinence.

CONCLUSIONS

RECOMMENDATIONS

2. ANTEGRADE CONTINENCE ENEMA (MACE)
has been applied mainly to paediatric population with neuropathic bowel dysfunction and anorectal anomaly, and successful outcome was achieved in 70-100 % [2-22] (Table 17). Overall, stoma stenosis is the most common complication, affecting 10-41 %. In a study of 62 children with median follow-up of 5.4 (3.25 to 8.25) years, 84 percent were completely continent or had soiling less than once a month [4]. There was a significant correlation between the level of continence and satisfaction with the procedure [4] Improvement of self-esteem and psychosocial function after the ACE procedure in children with myelomeningocele has been reported [6]. Several modifications have been reported including laparoscopic technique, left colonic continence stoma, etc [7-9, 11-13]. This procedure was also applied to adult neurogenic patients with faecal incontinence [3,12,14], and similar success rates (83-100 %) were reported. Casale et al (2006) [23] compared total continence reconstruction to staged-reconstruction of neuropathic bowel and bladder: In this retrospective chart review of all patients with Myelomeningocele who underwent went reconstruction with a cutaneous catheterisable urinary channel or Malone ante grade continence enema. The authors were unable to find any differences in the continence rate or stoma complications between total continence reconstruction or/and staged reconstruc- tion. However, because of shared pathology the authors believe that most patients benefit from intervention in the gastrointestinal and the genitourinary tract. Therefore, a major advantage of total continence reconstruction is avoidance of the morbidity of a second major surgical procedure (LOE 3).Recently, Herndon et al 2004 [24] reported on in situ Malone ante grade continence enema in 127 patients reflecting a 6-year experience: ACE in situ technique was performed in 76 females and 51 males, average patient age at the time of surgery was 9.6 years, diagnosis included myelomeningocele in 116 cases, lipomeningocele in 6, spinal cord injury in 2, posterior urethra walls in 1, sacral agenesis in 1 and functional constipation in 1. The mean follow-up was 26.9 months. Faecal continence was reported by 91 % of the patients, 13 stoma revisions (stenosis 10, prolapse 2 and leakage 1) were required in 11 patients. Major complications included a caecal volvulus requiring a right hemicolectomy in one patient, small bowel obstruction in two and a shunt infection and or malfunction in two. The authors conclude that the in situ MACE procedure has reliable long-term results for treating faecal incontinence associated with neuropathic bowel.

CONCLUSIONS AND RECOMMENDATIONS

• This procedure is effective for controlling faecal incontinence and constipation associated with neurogenic bowel dysfunction especially in neuropathic children (LoE 3; Grade B). Patients should be properly selected to determine appropriate motivation.

3. DYNAMIC GRACILOPLASTY

This procedure consists of transposition of the gracilis muscle around the anal canal and subsequent implantation of a pulse generator to stimulate the gracilis muscle. Before continuous stimulation is applied, the muscle is trained for 4 to 8 weeks according to a protocol. During a stimulation program the fatigable type 2 skeletal fibres are replaced by slow type 1 fibres, which are able to sustain a long lasting contraction. Satisfactory continence has been reported in 56% to 81% of patients [1–13] (Table 18). Recently, a prospective study of 200 consecutive patients with a follow-up of at least two years showed a 72% overall success rate [6]. Complication rate is rather high (42%-92%), especially infectious complications which occur in about one fourth of the patients. Impaired rectal emptying has occurred in 16% to 29%. A prospective controlled comparative study of single stage with the conventional two-stage procedure showed no significant difference in infection rates, continence rates, morbidity or quality of life between the two groups after a mean 521-day follow up [11]. A prospective controlled study comparing dynamic graciloplasty with artificial anal sphincter in 16 patients (8 in each group) showed that both of the two procedures had a high incidence of technical failures and complication requiring reoperation [12]. Chapman et al [13] reported a systematic review article of this procedure, where they searched articles published until November 1999, and found 40 articles met the inclusion criteria. Mortality rates were around 2% for both graciloplasty and colostomy. However, morbidity rates reported for graciloplasty appear to be higher than those for colostomy.

Rorgen et al [11] reported an 80% success rate with this procedure in 16 patients with neurogenic faecal incontinence. However, all studies presently available expect this report include quite small number of neurogenic patients, and there is no information on the outcome in neurogenic subgroup of patients.

CONCLUSIONS AND RECOMMENDATIONS

• Since dynamic graciloplasty seems to be associated with high complication rates, and outcome appears to correlate to surgeon’s experience, this procedure should only be carried out in specialist centres with a reasonably large number of patients, and should be reserved only for carefully selected patients with intractable faecal incontinence where other methods have failed (C).

• Further studies are needed to determine its role in the neurogenic subpopulation.

</table>
ARTIFICIAL ANAL SPHINCTER

Implantation of an artificial anal sphincter was first reported in 1987 [1]. The sphincter used was originally designed for treatment of urinary incontinence, but subsequently the device has been modified. The system consists of an inflatable cuff placed around the upper anal canal, a pressure-regulating balloon to maintain closure of the cuff placed in the subperitoneal space lateral to the bladder and a control pump accessible to the patient to empty the cuff for defaecation placed in the scrotum or labium. The system is left deactivated for 4 to 6 weeks. A multi centre prospective, non-randomized trial in 112 patients with one year follow-up showed 73 revision operations were required in 51 (46 %), and the infection rate necessitating surgical revision was 25 %. Forty-one patients (37 %) have had their devices completely explanted [4]. The reported success rates obtaining acceptable continence range were 41 % to 90 % [4-14] (Table 19). Explantation rates in the reported series were 20-40 %. One series with long-term follow-up (more than 5 years) showed that 7 of 17 patients had the system removed due to infection, malfunction or obstructed defaecation [13]. Technical complications like rupture of the cuff, which occurred frequently with the earlier modification of the device, are now rare. Emptying problems, without anatomical stenosis, as described for dynamic graciloplasty, have also occurred frequently (13 % to 45 %) in most series and have in some patients required explantation. Other complications leading to explantation have been erosion of the cuff through the skin or into the anal canal.

As shown in the Table, most studies have a small number of neurogenic patients or do not indicate the number of neurogenic patients included. In the study reported by Christiansen et al [10], 10 (59 %) out of 17 patients had neurological disorders, and the overall success rate was 47 %, which seems to be lower than the others. The authors mentioned that the result in neurogenic subgroup was clearly poorer than that in non-neurogenic subgroup.

In a prospective, randomized controlled clinical trial of placement of the artificial bowel sphincter for the control of faecal incontinence O’Brien et al (2004) [8] compared its effects to a program of supportive care and patients were followed for six months from operation or entry into the study.

The principal outcome measure was the level of continence, measured with the Cleveland Continence Score, representing perfect control through a total incontinence. Secondary outcome measures were peri-operative and late complications in the artificial bowel sphincter group and the changes in quality of life in both groups. In the control group (N = 7) the Cleveland Continence Score was not significantly altered. The artificial bowel sphincter group (N = 7)

showed a highly significant improvement. One patient in the artificial bowel sphincter group had failure of healing and implantation of the device. There were major improvements in the quality of life for all measures in the artificial bowel sphincter group. The authors conclude that the placement of an artificial bowel sphincter is safe and effective when compared with supportive care alone. Peri-operative and late problems are likely to continue to occur and between 15% and 30% of patients may require permanent explantation. For the authors the device is easy and discrete to use, highly effective in achieving continence and able to generate a major improvement in the quality of life (LoE 3).

CONCLUSIONS AND RECOMMENDATIONS

- Implantation of the artificial anal sphincter may be done for the same indications as for dynamic graciloplasty except in patients with previous perianal infections or with a thin and scarred perineum where a muscle transplant is preferable. It should be emphasized that due to the relatively high risk of treatment failure and of complications requiring re-operation patient selection for both procedures should be very strict (C).

5. COLOSTOMY

Spinal cord injury (SCI) has a significant effect on bowel dysfunction, in terms of faecal incontinence, urgency, and toileting methods.

This results in a marked impact on quality of life [1-2]. Several retrospective studies on the effect of colostomy formation on bowel care and QOL in SCI patients showed a significant decrease in the average time spent on bowel care per week and improvement on QOL [3-13].

The early and long-term complication rates reported are 6 to 15%, and 15 to 37, 5%, respectively. The commonest long-term complication is mucus discharge per rectum. It should be noted that one of the frequent, persistent, problematic complication is diversion colitis [9-10]. Symptoms include hemorrhagic purulent rectal discharge, abdominal pain and tenesmus. This condition is thought to result from a deficiency of luminal short-chain fatty acids [11]. Steroid enemas, 5-aminosalicylic acid enemas or suppositories, or short-chain fatty acid enemas have been reported to be helpful [12].

CONCLUSIONS AND RECOMMENDATIONS

- Elective colostomy may be an option for some SCI patients with severe uncontrolled faecal incontinence (C).

E. SPECIFIC NEUROLOGIC DISEASES

I. DEMENTIA

1. DEMENTIA AND URINARY INCONTINENCE

- Methods

Using MEDLINE we identified English-language journal articles and reviews published from 2000 to April 2008, looking for the keywords Alzheimer’s disease, vascular dementia, Lewy bodies dementia, frontal-temporal dementia, urinary incontinence, bladder dysfunction, management.

The dementias can be categorized according to clinical presentation, neuropathology and/or etiology into four major dementia groupings, (I) Alzheimer’s dementia; (II) the vascular group (including large and small vessel disease); (III) the Parkinson’s group (including Lewy Body disease, dementia of Parkinson’s and Alzheimer’s dementia with Parkinson’s); (IV) the frontotemporal group (including Pick’s disease and Semantic dementia) [13]

a) Alzheimer’s disease

1. EPIDEMIOLOGY AND PREVALENCE

Alzheimer’s disease (ALD) is the most common type of dementia in clinical and autopsy surveys. AD affects mostly elderly people. The symptoms include worsening of the memory, impairment of language and other cognitive functions (analytical thinking, abstract reasoning). Ultimately, there is loss of self-hygiene, eating, dressing and ambulatory abilities and incontinence and motor dysfunction. The onset of incontinence usually correlates with the disease progression (LOE 3) [1]. The prevalence of incontinence is reported to be between 23% and 48% (LOE 3) [2-3].

2. PATHOLOGY AND DISEASE SPECIFIC LUT PROBLEMS

ALD at the outset was identified by its unique pathology, the plaques and tangles that Alzheimer referred to as “a clotting of fibrils…. in addition an extraordinary number of peculiar patches disseminated throughout the entire cortex.”

The clinical hallmark of Alzheimer’s disease is memory impairment. A sense of memory failure, detected by the patient or a close relative, is usually the presenting symptom. Motor and sensory symptoms are absent until late in the course of the disease. However, other cognitive domains, such as language, praxis and recognition skills, are affected even early in the presentation.
ALD has a gradual and progressive course, typically 10 years from diagnosis to death. The advent of cholinesterase inhibitors has had some effect on the course of disease for individual subjects, though population trends have been harder to demonstrate (10, 11).

In a study by Del Ser et al (LOE 3) urinary incontinence was associated with severe cognitive decline in pure Alzheimer’s disease but usually preceded severe mental failure in patient with dementia due to diffuse Lewy body disease [4]. Nobili et al (LOE 3) performed quantitative EEG in Alzheimer’s patients, finding that incontinence was predicted by alpha power in the right side [5]. In another study by Nobili et al (LOE 3) the value of regional cerebral blood flow from a posterior temporal-inferior parietal area in each hemisphere predicted development of incontinence [6]. Brain computer tomography study done by Sugiyama et al (LOE 3) in Alzheimer’s disease patients showed that the degree of brain atrophy was more severe in those with detrusor overactivity than those without it [9].

Detrusor overactivity was found in 61% of their patients. Haddad et al (LOE 3) described two patients with vesicoureteral reflux, one of them showing buccosalivary, gastroesophageal, vesicoureteral, urethroprostatic and urethrovessicular reflux as a consequence of the neurologic dysfunction [8].

There is no systematic review of type and grade of LUT dysfunctions in Alzheimer’s disease, nor a study about progression of those dysfunctions as the disease progresses.

3. Disease Specific Diagnosis and Treatment

EEG and regional cerebral blood flow might predict when and if incontinence will occur during the course of the disease [5, 6]. Franssen et al (LOE 2) examined the occurrence of following developmental reflexes: the tactile suck reflex, the palmar and plantar grasp reflexes, and the plantar extensor reflex in healthy elderly, cognitively and functionally mildly impaired patients, and patients with Alzheimer’s disease [9].

Prevalence of all five reflexes was more than 6 times higher for those categories that comprised only permanently doubly incontinent patients as compared to those categories that comprised only continent individuals. It is interesting that the frequency of developmental reflexes rose sharply with the onset of progressive incontinence, suggesting its cortical origin. As demonstrated above, the development of incontinence in Alzheimer’s disease patients is associated with cognitive impairment and brain degeneration, suggesting its central nervous system origin. Therefore behavioural therapy, toilet training and prompted voiding would be most useful treatment modalities for this type of incontinence.

Hutchinson et al (LOE 3) suggested that caregivers of patients with Alzheimer’s disease should study the toileting behaviours. This would permit them to provide physical and cognitive assistance while attempting to avoid accidents and catastrophic events [10]. Tariot (LOE 4) stressed the necessity for taking into account different factors (like mobility, cognitive functions, general medical conditions), when planning treatment (also for incontinence) in Alzheimer disease patients [11].

Again the general guidelines should apply for choosing the best management of incontinence in Alzheimer’s disease patients. The treatment should be however tailored to individual patient needs and disease status.

There is still some controversy that the central Acetylcholinesterase (AcHE) inhibitors given by the neurologist might exacerbate urinary incontinence in those patients (18). Donepezil hydrochloride is a selective central acetylcholinesterase (AchE) inhibitor, which decreases degradation of acetylcholine in the brain, then increasing the concentration of acetylcholine in the synaptic cleft [21]. This drug is widely used to ameliorate cognitive decline in patients with Alzheimer’s disease [15; 20] which is thought to be due to a decrease in cholinergic innervation of the cerebral cortex and the basal forebrain [14]. Since the bladder is innervated by the parasympathetic cholinergic nerves [16] neurogenic lower urinary tract (LUT) dysfunction occurs in a subset of patients with AD [19; 22].

Although donepezil may facilitate cholinergic neurotransmission mostly in the central nervous system, common adverse effects of donepezil, such as nausea and abdominal discomfort, have been attributed to the peripheral nervous system (PNS) [15; 21]. Therefore, the increased bladder contraction is reasonably attributed to the PNS effects as seen with other cholinergic drugs. However, according to Sakakibara et al (2005) [12] the patients with AD showed a slight increase in the bladder capacity, which can not be explained by the PNS effects alone. Although it is unknown to what extent central cholinergic circuit may participate in the regulation of micturition, recent experimental studies showed that lesions in the nucleus basalis Meynert in the basal forebrain (central cholinergic nucleus projecting fibres to the frontoparietal cortex) give rise to decreased bladder capacity [19]. In addition, improved cognitive status and alertness may well lead to proper initiative to hold urine in the patients. Central AchE inhibitors including donepezil hydrochloride, therefore, may have complex effects on the LUT function. Although the number of the patients was small, it seems possible that donepezil could ameliorate cognitive function without serious adverse effects on the LUT function in patients with AD. This should be true also for other selective central AchE inhibitors.
4. Guidelines for further research

There is still no cure for Alzheimer's disease, which is progressive and a type of dementia associated disease. We are still lacking studies evaluating LUT disorders in Alzheimer's disease. No systematic review has been performed regarding the possibilities of medical management (both pharmalogical and behavioural) of incontinence.

An open issue also remains the question of aggressive surgery for LUT problems in these patients. Should we offer a surgical therapy for incontinence in female patients with stress incontinence and progressive Alzheimer’s disease? This is a question so far unanswered.

Conclusions

2. Diagnosis

Vascular dementia may be the result of a single strategic infarct, multiple cortical or lacunar infarcts, or a microvascular insult in which neither clinical symptoms of stroke nor infarcts by imaging are evident. There is an elevated risk for subsequent dementia in patients who have had a stroke in comparison to controls without any evidence of a stroke (LOE 2)[2]. Diabetes and hypertension are stronger risk factors for vascular dementia than for Alzheimer’s disease (LOE 3)[3]. The apolipoprotein e4 genotype is a risk factor for vascular dementia as well as AD (LOE 3) [4].

3. Pathology and disease specific LUT problems

Sakakibara et al (LOE 2) found that mainly the medial frontal lobe is responsible for urinary dysfunction in patients after stroke [5]. Griffiths (LOE 2) in his PET studies, shows that cognitive function was slightly more impaired in patients with genuine urge incontinence. But the strongest and most specific association was with impaired temporal orientation [6]. Genuine urge incontinence with reduced bladder filling sensation was associated with global under-perfusion of the cerebral cortex and more specifically, with underperfusion of the frontal areas of the brain, especially on the right. Jirovec et al (LOE 3) found that cognitive ability and mobility differ significantly between continent and incontinent patients [7]. When the variables were examined together, mobility emerged as the best predictor of the patient’s urine control, followed by cognitive impairment.

In a study by Resnick et al (LOE 2) performed in institutionalized elderly, detailed urodynamic studies in 94 of the 245 incontinent patients showed that detrusor overactivity was the predominant cause in 61 percent, with concomitant impaired detrusor contraction present in half these patients. Other causes among women were stress incontinence (21 %), underactive detrusor (8 %), and outlet obstruction (4 %) [11]. Among the relatively few men in this sample, outlet obstruction accounted for 29 % of the cases. Yoshimura et al (LOE 3) found a 47 % prevalence of detrusor overactivity which correlated with the prevalence of dementia [9].

4. Disease specific diagnosis and treatment

No specific diagnostic tests to evaluate dementia related incontinence were described. Since patients with dementia and incontinence usually have one or more concomitant diseases, the evaluation of the LUT functions should follow the general rules, bearing in mind that this is the population of frail elderly.

The treatment should start with modification of patient’s behaviours and general rehabilitation targeted at making patient more ambulatory, as it was demonstrated that movement limitations are strongly
related with incontinence. No other specific treatment in dementia have been described, however certain issues like prompted voiding, anticholinergic drugs and intermittent catheterization have been studied. In his review of trials where prompted voiding was implemented Eustice et al (LOE 1) found that prompted voiding increased self-initiated voiding and decreased incontinence episodes in the short-term [10]. A single small trial suggested that adding oxybutinin, reduced the number of incontinent episodes in the short-term. In a study by Suzuki et al (LOE 3) the best results were obtained with ambulatory patients with the use of a portable chamber pot and induced urination, while no improvement was seen in bedridden patients treated with anticholinergics [11]. Sugiyama et al (LOE 3) studied the effects of anticholinergics therapy in patients aged 65 years or older with and without dementia. The patients received anticholinergic agents for more than two weeks [12]. Urodynamic studies demonstrated significant increase of maximum bladder capacity in the dementia group and the non-dementia group. There was no significant difference in rate of objective improvement between both groups. On the other hand, rate of subjective improvement was significantly higher in the non-dementia group (40 %) than in the dementia group (15 %). Improvement of functional bladder parameters was not associated however with improvement of subjective symptoms in the demented patients. In case of emptying failure, like in other bladder diseases intermittent catheterization is a treatment of choice. Lieu et al (LOE 3) found that carer-assisted clean intermittent urethral catheterization is an effective and safe treatment option for persistent urinary retention in elderly female patients with cognitive impairment and other disabilities [13]. With this method of treatment, 54 % of the patients were able to void spontaneously and were continent after a median period of 6 weeks with a range of 1 to 40 weeks. Twenty-seven per cent had significant improvement in the symptoms of urinary incontinence and the residual urine volumes became progressively smaller. However, 19 % failed this treatment modality. The recovery of spontaneous voiding was found to be significantly influenced by the age of the patient, the carer performing the intermittent catheterization and the development of catheter-related urinary tract infection. Twenty-five per cent of the study patients developed symptomatic urinary tract infection which was associated with a delay in the recovery of spontaneous voiding. Its development was also found to be significantly associated with the presence of pre-existing diabetes mellitus, the person doing the catheterization, the presence of dementia and with more predisposing common medical conditions.

Another interesting issue is the surgical treatment in patients with dementia. Two major groups of surgical procedures could be identified: prostate surgery and incontinence surgery. Yonou et al (LOE 3) studied a group of 13 patients with dementia who underwent TURP procedure [14]. Six patients reported good urination, 3 reported some improvement in urination after surgery, although requiring intermittent catheterization and 1 developed mild incontinence. No specific study addressing the issue of incontinence surgery in woman with dementia was performed; however it seems that the incontinence surgery in patients with dementia should be reserved only for the cases with good ambulation and without concomitant functional disorders of micturition (overactive bladder, hypocontractile detrusor).

5. GUIDELINES FOR FURTHER RESEARCH
Since dementia is not a homogeneous disease a population study targeted at specific disorder of micturition is urgently needed. Also, a study evaluating different treatment modalities in patients with dementia (especially anticholinergic treatment for overactive bladder and surgical treatment for stress incontinence) is lacking.

CONCLUSIONS

- Dementia associated incontinence occurs in 30-100 % of patients with dementia (LOE 3).
- The degree of incontinence is strongly associated with patient’s general status and ambulation (LOE 3)
- There is no one major cause for incontinence in these patients; however overactive bladder is responsible for a significant portion of incontinence (LOE 3)
- LUT surgery is not contraindicated in this group of patients (LOE 3-4)

RECOMMENDATIONS

- The extensive and aggressive therapy of incontinence in dementia patients should be reserved for patients with good general status and ambulation (C)
- In case of ambulatory patients, prompted voiding, rehabilitation and oral anticholinergics seems to be treatment of choice (C).
- In case of significant post-void residual, intermittent catheterization is the treatment of choice (B); however in elderly non-ambulatory patients the recovery of LUT functions is not so good (C/D).

c) Dementia with lewy bodies

1. EPIDEMIOLOGY AND PREVALENCE
Dementia with Lewy bodies is thought to be the third most common type of dementia in the elderly,
accounting for 10 – 15% of cases at autopsy. In population-based studies of subjects aged 65 and older, the prevalence of dementia with Lewy bodies was found to be 0.7%, which is consistent with its rate of 10 – 15% of hospital-based cases at autopsy [3]. The epidemiology of dementia with Lewy bodies is sparse; age and gender distribution and potential risk factors have yet to be defined.

2. Pathology and Disease Specific LUT Problems

Dementia with Lewy bodies primarily affects the basal ganglia. Lewy bodies and Lewy neuritis are pathologic aggregations of alpha-synuclein, a ubiquitously expressed synaptic protein that has been implicated in vesicle production [1]. Lewy bodies also contain chaperone proteins and elements of the ubiquitin-proteasome system. Immunohistochemical staining for alpha-synuclein has been shown to be the most sensitive and specific method for detecting Lewy bodies and can be used in a semiquantitative grading of severity of Lewy related pathology [2].

In dementia with Lewy bodies (DLB), autonomic dysfunctions can occur and is actually included as a supportive feature for clinical diagnosis [8].

The essential feature for a diagnosis of possible or probable dementia with Lewy bodies is progressive cognitive decline of sufficient magnitude to interfere with normal social or occupational function. Fluctuations (waxing and waning of cognition, functional abilities and arousal from almost normal to markedly confused or hypsomolent) are a core feature of dementia with Lewy bodies.

Horimoto et al (LOE 3) found 97 % incidence of urinary incontinence amongst patients with Levy body dementia.

Many patients with dementia with Lewy bodies also have Alzheimer’s disease pathology, which alters the clinical presentation. Dementia with Lewy bodies’ patients who also have many neurofibrillary tangles display more core clinical features of AD [4]. Conversely, Lewy bodies also occur in more than half of all patients with sporadic and early-onset AD [5].

3. Lower Urinary Tract Symptoms in Dementia with Lewy Bodies, Parkinson and Alzheimer’s Disease – a Comparison

From the urological point of view patients with dementia with Lewy bodies (DLB) tend to develop urgency and urge incontinence more often than do patients with Parkinson (PD) or Alzheimer disease (ALD). Similar bladder capacity, detrusor pressure at maximum voiding, maximum urine flow, mean voided volume and post-void residual volume were found in these diseases, however detrusor overactivity, the major cause of urgency and urge incontinence, was more prevalent in DLB than in PD and in ALD [7]:

Urinary symptoms were recorded in 35 % of patients with DLB, compared to 70 % in MSA and 25 % in PD patients. Detrusor overactivity, the major cause of urge and urge incontinence was more prevalent in DLB and AD. No detrusor-sphincter-dyssynergia was observed. DLB patients with detrusor overactivity had significantly higher Hoehn and Yahr scores than did those without detrusor overactivity. Since the prevalence of frequency, urgency, urge incontinence and detrusor overactivity is markedly lower in AD than in Lewy Body disease, LUTS may contribute to the differential diagnosis of these two entities.

4. Disease Specific Diagnosis and Treatment

Since patients with Lewy Body disease and incontinence usually have one or more concomitant diseases, the evaluation of the LUT functions should follow the general rules, bearing in mind that this is most often the population of frail elderly (LOE3).

5. Guidelines for Further Research

Since dementia is not a homogeneous disease and can be classified in four main categories, further studies should aim whether there is a difference in LUT symptoms between these four groups and if yes, whether they could influence the urological treatment strategy.

RECOMMENDATIONS

- They do not differ from those in ALD and are very much dependent on the general condition of the patient (C).

d) Frontotemporal dementia

1. Epidemiology and Prevalence

Prevalence studies of FTD are inconsistent (LOE 3), giving ranges of 3,6-15,0 per 100,000 [1]. There is a high familial occurrence of FTD [2].

The distribution of FTD is equal between men and women. The mean duration of illness from onset to death is 4-6 years, with a range of 2-20 years. Progression to death in FTD is much more rapid than in ALD (average of 4,2 years and 6,0 years, respectively).

2. Pathology and Disease Specific LUT Problems

Frontotemporal dementia (FTD), also known as Pick’s disease, encompasses a diverse group of clinical and pathological disorders. There are several distinct clinical presentations, most commonly behavioral changes, but a language disorder, usually in form of a progressive non-fluent aphasia, can be the main presenting sign. The most common clinical presentation of FTD is characterized by profound changes in personality and social conduct, including a decline in manners and social skills that are incongruent with the patient’s premorbid behaviour. Affected patients lack emotional warmth, empathy and sympathy and are indifferent to others.
At autopsy markedly gross atrophy of the frontal and temporal lobes is seen in FTD. On histologic examination the salient features include neuronal loss, micro-vacuolization and astrocytic gliosis centered on cortical layer II.

MRI of patients with FTD often shows atrophy in the frontal and temporal lobes (LOE 2), which may be asymmetric [3].

There a no data on LUTS in patients with fronto-temporal dementia, however it is obvious that due to the cognitive state these patients have incontinence, either because they forget to take down clothes when they go into the toilet, or they have difficulty finding the toilet, they may urinate in inappropriate places and pass urine more often than usual. Moreover, they may be effected by constipation, diarrhoea or faecal incontinence.

3. DISEASE SPECIFIC DIAGNOSIS AND TREATMENT

No specific diagnostic tests to evaluate dementia related incontinence were described. There are no studies which show the significance of LUTS in fronto-temporal dementia.

4. GUIDELINES FOR FURTHER RESEARCH

As there are no studies which show the significance of LUTS in fronto-temporal dementia, such studies would be of value.

CONCLUSIONS

- There are no studies available which show the significance of LUTS in patients with fronto-temporal dementia.
- However, from the underlying pathology – gross atrophy of frontal and temporal lobes - autonomic dysfunction including LUTS should be present, but needs further investigation.

RECOMMENDATIONS

- The recommendations do not differ from those with other types of dementia

2. DEMENTIA, CONSTIPATION AND FECAL INCONTINENCE

- Methods

Using MEDLINE we identified English-language journal articles and reviews published from 1990 to April 2008. The key words included constipation, faecal incontinence and dementia. Special attention was given also to data regarding persons aged > 65 years.

- a) Prevalence

MEDLINE research detected only one paper related to the influence of dementia on the prevalence of urinary and faecal incontinence in an age group of 85-year-old men and women[1]. This is surprising, because patients with faecal incontinence experience anxiety, embarrassment, and social isolation.[2]

Hellström et al.[1] investigated the influence of dementia on the prevalence of urinary and faecal incontinence in 85-year-old men and women in the random sample n=485 of the total population of 85-year-olds from the city of Gothenburg, Sweden.

The prevalence of urinary and faecal incontinence and dementia were 38%, 17% and 29% respectively. Demented men (50%) and women (60%) were more often incontinent than non-demented men (18%) and women (36%). Also faecal incontinence was more prevalent in demented (34.8%) than non-demented subjects (6.7%); both urinary and faecal incontinence were more prevalent in demented women (43% and 20% respectively) than in men (27% and 11% respectively). The prevalence of urinary and faecal incontinence and dementia were higher in residents of a nursing home or hospital (74%, 51% and 92% respectively) than in subjects living at home (32%, 9% and 18% respectively): of the demented residents in an institution 78% were incontinent compared with 37% living at home.

- b) Management of faecal incontinence in demented people

No specific paper was found on the management of faecal incontinence in demented people; however it should not be too different from the management in frail elderly. Faecal incontinence in demented people can be negatively influenced by stool impaction, medications and neuro-muscular dysfunction.

Demented patients may benefit especially from a bowel habit training programme, which also includes management of constipation with non-pharmacologic (such as exercise and fibre) and pharmacologic measures.[3]

CONCLUSIONS

- Although the prevalence of faecal incontinence (as well as of urinary incontinence) in demented people is prevalent, no paper was found dealing with the disease specific management of faecal incontinence (LOE3).
- However this management should not be too different from that in frail elderly, focusing on bowel habit training programmes including management of constipation. (LOE 3)
RECOMMENDATIONS

- Studies on the prevalence of faecal incontinence in dementia are needed
- Studies should be undertaken to find out, which management is preferable for constipation and faecal incontinence in demented people.

II. MULTIPLE SYSTEM ATROPHY

Methods

Using MEDLINE we identified English-language journal articles and reviews published from 2000 to April 2008, looking for the keywords Multiple System Atrophy, Urinary Incontinence, Bladder Dysfunction, Bowel problems, Constipation, Faecal Incontinence, Management.

1. URINARY INCONTINENCE

a) Epidemiology and prevalence

Multiple system atrophy (MSA) is a rare, adult-onset degenerative disease of the nervous system of unknown origin. Autonomic failure (postural hypotension and urinary dysfunction) is fundamental to the diagnosis of MSA: it is diagnosed when the criteria of either postural hypotension (systolic blood pressure fall > 30 mmHg or diastolic > 15 mmHg) or urinary dysfunction (persistent, urinary incontinence/ incomplete bladder emptying) or both are fulfilled, along with poorly levodopa-responsive parkinsonism or cerebellar dysfunction.[1] Based on the major motor deficits MSA can be classified as MSA-P (parkinsonism - predominant) or MSA-C (cerebellar-predominant).

Urinary symptoms of incontinence are caused by neurologic detrusor overactivity and external sphincter weakness [3] (LOE 2). Sphincter electromyography (EMG) abnormalities were found in 91% of the patients with MSA [3] (LOE 2). Approximately 60% of patients with MSA develop urinary symptoms either prior to or at the time of presentation with the motor disorder [4] (LOE2). This indicates that many of these patients seek urological advice early in the course of their disease. Although postural hypotension was thought to be a marker for autonomic failure in MSA, Wenning et al [5] (LOE2) noted urinary incontinence in 71%, urinary retention in 27%; postural faintness in 53%, and syncope in 15% of 100 patients with MSA. Sakakibara et al [4] (LOE2) found that urinary symptoms (96%) were more common than orthostatic symptoms (43%) (p < 0.01) among 121 patients with MSA. Kirchhof et al [6] (LOE2), found that bladder symptoms preceeded symptoms of orthostatic hypotension in 76% of their 71 male patients. Sakakibara et al [4] (LOE2) also found that among 53 patients with both urinary and orthostatic symptoms, those who had urinary symptoms first (46%) were more common than those who had orthostatic symptoms first (29%), and some patients developed both symptoms simultaneously (23%).

b) Pathology and disease specific lut problems

Urinary dysfunction is divided to that of storage and voiding, respectively. Sakakibara et al [7] (LOE2) performed an extensive study of the urological symptoms in MSA patients. They found the following prevalence of different symptoms: difficulty of voiding in 79%, nocturia in 74%, sensation of urgency (recently called an overactive bladder) in 63%, urge incontinence in 63%, diurnal urinary frequency in 45%, enuresis in 19% and urinary retention in 8% of the patients. All of MSA patients presented with some kind of LUT symptoms. In addition, many of them had storage and voiding urinary symptoms together; suggesting altered storage and micturition functions in this disorder.

Among 245 urodynamic cases of MSA, Ito et al [8] (LOE2), found that average volume of post-void residuals as a marker of voiding dysfunction was 71ml at the first year, which increased significantly to 170ml at the 5th year (p<0.01) after onset of the disease. Patients were not always aware of their post-void residuals. The frequency of weak detrusor by a pressure-flow analysis was 20% at the first year, which increased to 53% at the 5th year (p<0.05). The frequency of detrusor-external sphincter dyssynergia was 12% at the first year, which increased to 39% at the 5th year (p<0.05). Therefore, detrusor underactivity seemed to contribute to voiding dysfunction in MSA more than detrusor-external sphincter dyssynergia did. The responsible sites of lesion (micturition facilitating area) for voiding difficulty and retention in MSA seem to be the locus coeruleus (pontine micturition center). The work of Bennaroch demonstrated, that in MSA there is severe depletion of catecholaminergic neurons of the CI and Al areas in the ventrolateral medulla, and this may contribute to orthostatic hypotension and endocrine disturbances in this disorder, respectively. Additionally loss of corticotrophin-releasing factor (CRF) neurons in the pontine micturition area may contribute to neurologic bladder dysfunction [9] (LOE 2). In addition, the sacral intermediolateral cell columns, where preganglionic neurons innervating the bladder are located, are affected in post-mortem MSA cases.

Regarding the storage abnormalities, the frequency of detrusor overactivity was 61% at the first year,
which increased to 75% at the 5th year (p<0.05) [8] (LOE2). The frequency of neurogenic pattern in the sphincter EMG was 52% at the first year, which increased to 83% at the 5th year (p<0.05) [10] (LOE2). Abnormalities in the videourodynamic study included open bladder neck at the start of filling in 53% of MSA patients, suggestive of bladder neck denervation [11] (LOE2). Similar results were reported by others [12]. The responsible sites of lesion (storage-facilitating area) for urinary urgency and incontinence in MSA seem to be the basal ganglia, cerebellum [13], lumbar intermediolateral cell columns where preganglionic neurons innervating the bladder neck are located, and sacral Onuf’s nucleus innervating the external sphincter, all of which are affected in post-mortem MSA cases, causing urinary stress incontinence.

Repeated urodynamic studies in MSA patients showed that the cystometrogram changed from detrusor overactivity to low-compliance or acontractile detrusor, and from negative to positive bethanechol supersensitivity [4] (LOE2). In fact, as the disease progresses, symptoms may change from urinary urgency and frequency to those due to incomplete bladder emptying. These findings suggest that the responsible sites of the bladder cholinergic disorder may change from the center to the periphery. Whereas in the midst of disease, the cystometrogram of patients with MSA often show neurogenic detrusor overactivity with impaired contractile function (DHIC), mostly accounting for urinary urgency / frequency and large post-void residuals, respectively. This condition presumably reflects lesions in both storage and voiding-facilitating areas in this disorder. [15]

Beside bladder disorders, patients with MSA may have nocturnal polyuria, which results in nocturia and morning hypotension. In normal children over 7 years and adults, the circadian release of arginine vasopressin from the posterior pituitary gland into plasma peaks at night. This leads to a nocturnal decrease in urine formation. The ratio of nighttime to daytime urine production is usually <1:2, which can be estimated by a bladder diary. A postmortem study of the brains of patients with MSA revealed the degeneration of arginine vasopressin neurons in the suprachiasmatic nucleus [16] (LOE 2), leading to impairment of the circadian rhythm of the plasma arginine vasopressin concentration in MSA [17] (LOE 2).

c) Disease specific diagnosis and treatment

Since LUT functional disturbances precede very often orthostatic hypotension and other autonomic nervous system symptoms in MSA patients, the diagnosis of lower urinary tract (LUT) symptoms is of paramount importance. Further discussion of the differentiation between MSA and Parkinson’s Disease is to be found in the section on PD.

Amongst different tests external sphincter EMG is the most sensitive one. Sphincter motor unit potential analysis showed neurologic motor unit potentials in 93% of those with MSA, suggestive of external sphincter denervation. Palace et al [18] (LOE 2) demonstrated abnormal sphincter EMG in 93% of MSA patients, which can differentiate this disorder from idiopathic Parkinson’s disease. Oertel et al [19] (LOE2) suggested that reduced genital sensation in females could be pathognomonic for MSA (with equal importance as erectile dysfunction in males). A total of 47% of the MSA patients and 4% of the control group had reduced genital sensation. Moreover, the appearance of reduced genital sensitivity in female MSA patients showed a close temporal relation to the onset of the disease. Hahn and Ebersbach [25] (LOE 2) investigated the value of sonography of the bladder to evaluate post-void residual urine (PVR) for the differential diagnosis between idiopathic Parkinson’s disease and Multiple System Atrophy. The positive predictive value of increased residual urine for MSA was 91.6% in the study, the negative predictive value was only 67.8%. They state, that bladder sonography is an objective, simple and safe tool that allows one to screen for urinary retention which is highly suggestive, but incompletely sensitive for MSA. Because sonography is easily accessible and rapidly performed, it is feasible for routine assessment of atypical Parkinson syndromes. Also Takashi et al 2006 (LOE 2) commented that urinary retention can be a major cause of morbidity in Multiple System Atrophy. The grand average volume of PVR was 140 cc in their patients, the average PVR volume increased from the first year from 71 cc to 129 cc in the second year and 270 cc in the 5th year.

When treatment of the voiding disorders in MSA is concerned, again the general principles of urodynamic based therapy should be used. However it is important to observe that aggressive surgical therapy is not recommended in MSA patients. Chandiramani et al [20] (LOE2) found that all MSA patients who underwent transurethral resection of the prostate (TURP) due to voiding problems were incontinent postoperatively, most probably due to pre-existing sphincter weakness. The same observations were done by Beck et al [3] (LOE2), who evaluated the results of TURP and stress incontinence surgery in MSA patients. They concluded that the results of surgery were unfavorable. Patients benefited from clean, intermittent catheterization (CIC), anticholinergic medication and desmopressin spray [21] (LOE 3), which improved continence in 82%.

A nearly half of the MSA patients suffer from voiding difficulties, its management by other means than CIC would be very attractive. Sakakibara et al [22] (LOE 3) compared different non-selective and alpha I A selective alpha blocking agents (prazosin and moxisylyte) in the treatment of LUT dysfunctions in MSA patients. The respective means for reductions in residual urine volume for the prazosin and moxisylyte groups were 38.1% and 35.2% and there was lessening of urinary symptoms. Side effects due to
orthostatic hypotension were seen in 23.8% of the prazosin group but in only 10.7% of the moxisylyte group. A more recent study showed that the effects of alpha blocking agents, as well as those of TUR-bladder neck, for lessening post-void residuals lasted for up to 2 years in MSA, although during that period patients benefited from the therapies [8] (LOE2). On the contrary, administration of amezinium, an adrenergic drug for ameliorating postural hypotension, may increase the risk of retention and post-void residual volume compared to that before treatment [23] (LOE2). Amezinium most probably stimulates the alpha receptors, both in the vascular wall (alpha1B receptors) and the proximal urethra (alpha1A/D adrenergic receptors).

Both postural hypotension and bladder dysfunction are common clinical features in MSA. Pyridostigmine, an acetylcholinesterase inhibitor, can be effective in lessening post-void residual volumes, since it stimulates muscarinic acetylcholine receptors on the bladder (M2/3-muscarinic receptors) that are innervated by parasympathetic cholinergic neurons. Pyridostigmine also lessens post-void residual volumes, since it may increase the risk of retention and post-void residual volume compared to that before treatment [23] (LOE2). Amezinium most probably stimulates the alpha receptors, both in the vascular wall (alpha1B receptors) and the proximal urethra (alpha1A/D adrenergic receptors).

Both postural hypotension and bladder dysfunction are common clinical features in MSA. Pyridostigmine, an acetylcholinesterase inhibitor, can be effective in lessening post-void residual volumes, since it stimulates muscarinic acetylcholine receptors on the bladder (M2/3-muscarinic receptors) that are innervated by parasympathetic cholinergic neurons. Pyridostigmine also lessens post-void hypotension, presumably by enhancing nicotinic acetylcholine receptor transmission in the sympathetic ganglia [24].

**RECOMMENDATIONS**

- The most sensitive test to detect multiple system atrophy associated LUT abnormalities is sphincter EMG (A), and post-voiding residual volume, especially when differencing from Idiopathic Parkinson’s disease.
- Due to progressive nature of the disease aggressive treatment and LUT surgery (e.g. TURP) are not recommended (A).
- Treatment of choice in case of increased post-void residual are alpha blocking agents and IC (B).

**CONCLUSIONS**

- LUT symptoms often precede the clinical manifestation of multiple system atrophy (LOE2).
- The most common LUT disturbances are detrusor overactivity, detrusor-external sphincter dyssynergia, sphincter and detrusor weakness (LOE2).
- Significant post void residual is observed in about half of the multiple system atrophy patients (LOE2).

**RECOMMENDATIONS**

- The most sensitive test to detect multiple system atrophy associated LUT abnormalities is sphincter EMG (A), and post-voiding residual volume, especially when differencing from Idiopathic Parkinson’s disease.
- Due to progressive nature of the disease aggressive treatment and LUT surgery (e.g. TURP) are not recommended (A).
- Treatment of choice in case of increased post-void residual are alpha blocking agents and IC (B).

**2. FECAL INCONTINENCE**

**a) Epidemiology and prevalence**

Lower gastrointestinal tract (LGIT) dysfunction is also common in patients with multiple system atrophy (MSA). Sakakibara et al [1] (LOE2) performed a bowel questionnaire in 15 patients with MSA and in 10 age-matched healthy control subjects. MSA group showed decreased bowel frequency (< 3 times a week) in 9, difficulty in expulsion in 11, and faecal incontinence in 3; whereas control group showed decreased bowel frequency in only 2, mild difficulty in expulsion in 2, fecal incontinence in none. Therefore, constipation is the major bowel dysfunction in this disorder; although in advanced stages faecal incontinence is not uncommon.

**b) Pathology and disease specific LUT problems**

Previous studies on the mechanism of bowel problems in this disorder are scarce. Stocchi et al [2] (LOE2) performed anorectal manometry in 16 patients with MSA; and 13 patients showed paradoxical anal sphincter contraction on fictive straining. Bardoux et al [3] (LOE3-4) reported a case of fecal incontinent patient due to MSA, who showed inability of anal squeezing. More recently, Sakakibara et al [1] (LOE2) performed colonic transit time, sphincter electromyography (EMG) and rectoanal video-manometry in 15 patients with MSA and 10 age-matched healthy control subjects. Compared with the control subjects, MSA patients had significantly prolonged colonic transit time in the rectosigmoid segment (p<0.05) and total colon (p<0.05). Sphincter EMG showed neurogenic motor unit potentials in none of control subjects but in 93% of MSA (p<0.01). At the resting state, MSA patients showed a lower anal squeeze pressure (external sphincter weakness) (p<0.01) and a smaller increase in abdominal pressure on coughing (p<0.01). During rectal filling, MSA patients showed smaller amplitude in phasic rectal contraction (p<0.01), which was accompanied by an increase in anal pressure that normally decreased, together with leaking in 3 patients. During defecation, most MSA patients could not defecate completely with larger post-defecation residuals (p<0.05). MSA patients had weak abdominal straining, smaller rectal contraction on defecation and larger anal contraction on defecation (paradoxical sphincter contraction on defecation, or anismus), though these differences were not statistically significant.

Therefore, constipation in MSA most probably results from slow colonic transit, decreased phasic rectal contraction and weak abdominal straining, whereas fecal incontinence results from weak anal sphincter due to denervation. The responsible sites for these dysfunction are still not entirely clear. However, as described in idiopathic Parkinson’s disease, they most probably reflect lesions of both central and peripheral nervous systems that regulate the LGIT.
**c) Disease specific diagnosis and treatment**

LGIT functional disturbance is often preceded by LUT dysfunction in MSA patients. Abnormalities in colonic transit time and rectoanal videomanometry in MSA were mostly similar to those in idiopathic Parkinson’s disease, except for the sphincter denervation and resultant fecal incontinence in MSA.

When treatment of the bowel disorder in MSA is concerned, use of objective parameters is recommended in order to clarify the action of drugs. A few such studies are available: Eichhorn and Oertel [4] (LOE3) gave polyethylene glycol 3350, an osmotic agent with high water binding capacity, in 2 patients with MSA, and found an improvement in stool frequency and difficult defecation in both patients. Similarly, Sakakibara et al [5] (LOE2) measured colonic transit time in 4 patients with MSA.

After administration of calcium polycarbophil, an osmotic and highly bulking agent, colonic transit time of total and the right segment shortened significantly. Liu et al [6] (LOE2) performed colonic transit time and rectoanal videomanometry in 7 patients with MSA. After administration of mosapride citrate, a novel selective 5-HT4 receptor agonist, the patients showed a shortened total and rectosigmoid segment colonic transit time; lessened first sensation and an augmented amplitude in phasic rectal contraction.

During defecation, mosapride augmented the amplitude in rectal contraction and lessened the volume of post-defecation residuals significantly. Similar results were obtained in a study by Sakakibara et al [7] (LOE2), in which dietary herb extract Dai-Kenchu-To, one active component of which is hydroxy-beta-sanshool (5-HT3 receptor agonistic action), was prescribed.

**d) Guidelines for further research**

MSA is a slowly progressive disease without any cure. More research is needed to evaluate the pathophysiology of LGIT dysfunction, and to evaluate the effects of different drug treatment modalities.

**CONCLUSIONS**

- Patients with multiple system atrophy have often abnormal bowel function (LOE2).
- The most common bowel disturbances are slow colonic transit, decreased phasic rectal contraction and weak abdominal straining, and faecal incontinence results from weak anal sphincter due to denervation (LOE2).
- Bowel dysfunction such as constipation is common and has significant impact on quality of life of patients with multiple system atrophy (LOE3).

**RECOMMENDATIONS**

- More studies on neurologic bowel dysfunction and management in patients with multiple system atrophy are needed before giving any recommendation.

**III. PARKINSONS DISEASE**

1. **URINARY INCONTINENCE**

   a) **Epidemiology and prevalence**

   Parkinson’s disease (PD) is a movement disorder due to degeneration of dopaminergic neurons in the substantia nigra and a loss of dopamine-containing nerve terminals in the basal ganglia. Degeneration of the nigrostriatal pathway is accompanied by decreases in corresponding biochemical markers, including dopamine, tyrosine hydroxylase, dopamine metabolites, and dopamine transporter. These central nervous system changes have also influence on autonomic functions, including voiding in affected patients. The most common are gastrointestinal (constipation), perspiratory (hypohidrosis) and urinary systems.

   Lower urinary tract (LUT) dysfunction in PD was estimated to occur in 37-71% in uncontrolled studies. Among these, in a study of Hattori et al [2] (LOE3) 60% of PD patients had urinary symptoms, which could be divided in the following categories: irritative in 28%, obstructive in 11%, and both symptoms in 21%. The frequency of urinary symptoms statistically correlated with severity of the disease, but not with the duration of illness. Gray et al [3] (LOE3) reported that LUT functional disturbances in PD are not disease specific and only correlated with age. In the more recent, control-based studies [4,5,6,7] (LOE2) the prevalence of LUT symptoms (LUTS) was found to be 27-63,9% using validated questionnaires [4,5,6], or 53% in men and 63% in women using a nonvalidated questionnaire that includes a urinary incontinence category [7], with all of these values being significantly higher than healthy controls. The majority of patients had onset of the bladder dysfunction after appearance of motor disorder. In one study, urinary incontinence in PD frequently occurred in conjunction with fecal incontinence, whereas no significant relation was observed between bladder and sexual dysfunction [7]. Also, it is of particular importance to note that that bladder dysfunction substantially affects the quality of life in patients with PD [7] (LOE2). There has been shown a correlation between bladder dysfunction in patients with PD and neurological disability [4] (LOE2), and a correlation to stage of disease [7] (LOE2), both suggesting a relationship between dopaminergic degeneration and LUTS. LUTS was more common in a group of PD patients with older age than that with...
younger age, as it is seen in healthy populations [7]. Among LUTS, nocturia (nighttime urinary frequency) is the most prevalent symptom reported by patients with PD (>60%) [4,5,6,7] (LOE2). Patients also complain of urinary urgency (33-54%), daytime frequency (16-36%), and urinary incontinence in 26% of their male and 28% of their female patients with PD [7].

Although less common than storage symptoms, PD patients also show voiding symptoms. In the study by Sakakibara et al [7] (LOE2), the PD patients had significantly higher rates of retardation in initiating urination (44% of men only), prolongation/poor stream (70% of men only), and straining (28% of women only) compared with the control group. However, despite the voiding symptoms, PD patients have low post-void residuals.

b) Pathology and disease specific lut problems

The net effect of the basal ganglia on micturition is thought to be inhibitory [8], whereas in PD, in which the basal ganglia is affected, the bladder becomes hyperactive. Functional neuroimaging during bladder filling resulted in activation in the globus pallidus of normal volunteers [9] (LOE2) and in the putamen in PD patients with detrusor overactivity[10] (LOE2). In contrast, dopamine transporter imaging (indicating brain dopamine neurons) was decreased in PD patients with urinary dysfunction than in those without it [11,12] (LOE2). The micturition reflex is under the influences of nigrostriatal dopamine[13] (both inhibitory in D1 and facilitatory in D2) and GABA (inhibitory). Deep brain stimulation in the subthalamic nucleus results in amelioration of motor disorder as well as increased bladder capacity and decreased post-void residuals [14] (LOE2). Therefore, urinary dysfunction in PD could reflect degeneration of the nigrostriatal dopaminergic cells associated with specific motor disorders. In addition to the nigrostriatal dopaminergic projection, the ventral tegmental area (VTA, the A10 cell group)-limbic cortex and the hypothalamic (the A11 cell group)-spinal cord dopaminergic projections are presumably involved in urinary dysfunction in PD.

In a study of PD and multiple system atrophy (MSA) patients, Sakakibara et al [15] (LOE2) found urinary symptoms in 72% of PD patients. They were mostly attributed to detrusor overactivity (81%) and external sphincter relaxation problems (33%). During micturition PD patients did not demonstrated detrusor-sphincter dyssynergia, however detrusor-hypocontractility was observed in 66% of women and 40% of men. In addition, patients with PD had mild outlet obstruction, e.g., mean Abrams-Griffiths number (outflow obstruction > 40) was 40 in women and 43 in men, respectively. Nevertheless, average volume of post-void residuals in PD was only 18 ml. Similar observations were done by Defreitas et al [16] (LOE2). The urge incontinence prevalence was around 54%, however no statistically significant correlation between the duration or severity of PD and urodynamic parameters was found.

c) Disease specific diagnosis and treatment

In voiding dysfunctions associated with presumed PD it is important to differentiate between PD and MSA. Chandiramani et al [17] (LOE2), suggested several criteria for distinguishing LUT symptoms caused by MSA from those caused by PD. Presence of the following features: urinary symptoms preceding or presenting with parkinsonism; urinary incontinence; a significant post-void residual urine volume; erectile failure preceding or presenting with parkinsonism, is strongly suggestive of MSA rather than PD. External urethral sphincter EMG is also helpful to distinguish between these two entities, since detrusor-external sphincter dysynergia was not seen in patients with PD but was present in 47% of those with MSA [15] (LOE2). This is also confirmed by studies of palace et al [18] (LOE2) who demonstrated abnormal sphincter EMG in 82% of MSA patients.

It is possible that levodopa and other antiparkinson medication may affect bladder function in PD. Aranda et al [19] (LOE3) studied the effects of apomorphine in 2 de novo PD patients (patients who have not had antiparkinsonian medication previously), and found that the bladder capacity increased. They gave oral levodopa to one of the patients, and the bladder capacity increased. In another study, after 3 months of treatment with levodopa, the storage urodynamic parameters were improved in de novo PD [20] (LOE3).

In contrast, in non-de novo patients, studies concerning the effect of dopaminergic drugs on micturition have produced conflicting results. Some reports have shown storage-facilitating effects of dopaminergic drugs as follows. A questionnaire study has shown that in non-de novo patients, voiding symptoms (intermittency and sensation of residual urine) were more common in those taking levodopa and bromocriptine (D2-selective agonist) than in those taking levodopa alone [7] (LOE2). In contrast, Kuno et al [21] (LOE3) showed that change of bromocriptine to pergolide (D1<2 agonist) brought lessening of nocturia, and Yamamoto [22] (LOE3) described improvement of detrusor overactivity by pergolide. Others have shown voiding-facilitating effects as follows. Christmas et al [23] (LOE3) have studied the effects of apomorphine in 10 parkinsonian patients, and found that anticholinergic bladder became normal in 2, and post-void residuals was ameliorated in 6 of these patients. More recent studies have shown that in early PD [24] (LOE2) and advanced PD with the on-off phenomenon [25] (LOE2), a single-dose of levodopa exacerbates detrusor overactivity in the filling phase, but also improves bladder emptying through increased detrusor contractility. We still do not know the exact reasons for the discrepancy.
There are several factors underlying the complex bladder behavior in non-de novo PD patients. Post-synaptic dopamine D1 (excitatory) and D2 (inhibitory) receptors have a millimolar affinity to dopamine, whereas dendritic D2 (inhibitory) autoreceptors have a picomolar affinity to dopamine [26]. Therefore, when levodopa is administered externally, it may first stimulate dendritic D2 autoreceptors, which might suppress the nigral cells and facilitate the micturition reflex. In cases of PD under long-term treatment with levodopa, dopamine receptors are down-regulated and potential hypersensitivity might occur [27]. Bladder overactivity might also involve an activation of D2 receptors in the spinal cord [28].

Detrusor overactivity should be treated according to the general knowledge of anticholinergic drugs. There are no specific studies on systematic anticholinergic drugs to treat neurologic detrusor overactivity in PD patients; however since anticholinergics were the first drugs available for the symptomatic treatment of PD and since they are still widely used today there is no reason to believe that they will produce any specific adverse events in these patients. A systematic review of anticholinergic use (centrally acting) to treat PD was recently done by Katschmacher et al [29] (LOE I).

For emptying failure the treatment of choice remains clean, intermittent catheterization (CIC); however PD patients rarely have post-void residual volume > 100ml [15] (LOE2). An interesting treatment option was suggested by Finazzi-Agro et al [30] (LOE3), who implanted subthalamic nucleus electrodes in patients with PD. They observed that during chronic subthalamic nucleus stimulation bladder capacity and reflex volume were increased for and the amplitude of overactive detrusor contractions was decreased (non significantly) in comparison with the studies performed when the stimulator was switched off.

As in MSA a very important issue in PD affected patients is the indication for pelvic surgery. Myers et al [31] (LOE2) found that women with PD and LUT complaints have a lower maximum cystometric capacity and a higher rate of detrusor overactivity at lower bladder volumes in comparison with non-neurologic control. Therefore surgery for stress incontinence in women with PD should be performed only when no significant detrusor overactivity is present, since it is well known that this type of surgery can evoke or aggravate detrusor overactivity and subsequent urge incontinence.

The issue of selecting the right patient for prostate surgery was described above. Staskin et al (LOE3) described the results of TURP in MSA rather than in PD patients. Since external urethral sphincter acontractility is extremely rare in true PD, prostate surgery should not be contraindicated in this group of patients.

d) Guidelines for further research

Despite there is no definite cure for PD, with the current knowledge we can slow down the disease process and bring patients to an almost normal live. Therefore it would be of extreme importance to introduce a validated scheme for LUT dysfunction therapy.

CONCLUSIONS

- LUT symptoms are associated in PD with degeneration of dopaminergic neurotransmission (LOE2).
- The most common LUT disturbances are detrusor overactivity, and detrusor hypocontractility (LOE2).
- The effect of levodopa on LIJT in PD patients remains to be elucidated (LOE3).

RECOMMENDATIONS

- Treatment of choice for detrusor overactivity in PD patients is antimuscarinics (B).
- For voiding failure in case of significant post void residual the treatment of choice remains intermittent catheterization (B).
- LUT surgery for patients with Parkinson's symptoms is an option as long as MSA is excluded. However stress incontinence surgery should not be offered to patients with significant detrusor overactivity (C).

2. FAECAL INCONTINENCE

a) Epidemiology and prevalence

Lower gastrointestinal tract (LGIT) dysfunction is common in Parkinson's disease (PD). It occurs in more than half of PD patients in uncontrolled studies. In the more recent, control-based studies [1,2,3] (LOE2), the incidence rate of decreased stool frequency (< 3 times a week) in PD patients ranges from 20% to 81%, that of difficulty in stool expulsion in 57-67%, and that of diarrhea in 21%. All of these values are significantly higher than in the normal population (range, decreased stool frequency, 0-33%; difficulty in stool expulsion, 26-28%; diarrhea, 10%). Fecal incontinence has been reported to be 10-24% in PD [2,4] (LOE2). Therefore, constipation is the most prominent LGIT symptoms in patients with PD. Indeed, PD is a risk factor for elderly nursing home residents to have constipation. Of particular importance is that bowel dysfunction affects the quality of life in patients with PD. Among three pelvic autonomic dysfunctions, the rate of dissatisfaction for bowel dysfunction (59%) is significantly higher than those for urinary (28%) or sexual dysfunction (29%) in PD, although the prevalence rate of all three dysfunctions
is almost the same (more than 60%). The rate of dissatisfaction for the bowel dysfunction in PD is also significantly higher than in healthy controls (16%) [2] (LOE2).

Difficulty in expulsion, and diarrhea are more common in the higher grade of Hoehn and Yahr staging [2,5] (LOE2), suggesting a relationship between dopaminergic degeneration and LGIT symptoms. Fecal incontinence in PD occurs commonly with urinary incontinence, whereas no significant relation has been seen between bowel and sexual dysfunction [2] (LOE2). Constipation in PD occurs commonly with a low coefficient of variation in electrocardiographic R to R intervals [6] (LOE3). The findings indicate that parasympathetic dysfunction might underlie these abnormalities.

A recent epidemiological study revealed an association between the frequency of bowel movements and the future risk of developing PD [7] (LOE1). This observation is in line with the pathological staging of PD by Braak et al [8] (LOE1), in which disease process in the central nervous system starts earlier in the dorsal motor vagal nucleus than in the substantia nigra in PD. From a clinical perspective, it is of particular importance that patients with PD see gastroenterologists or physicians first because of their bowel dysfunction, before they see neurologists and a correct diagnosis of PD is made. Therefore, constipation as the initial presentation of PD is akin to urinary dysfunction as the initial presentation of multiple system atrophy.

**b) Pathology and disease specific lut problems**

The enteric nervous system contains a program in order to generate the peristaltic reflex that promotes bowel transport within the LGIT [9]. The peristaltic reflex consists of two components: ascending contraction oral to, and descending relaxation caudal to the site of stimulus. Cholinergic receptors have a major role in the ascending contraction reflex. The strength of cholinergic transmission is regulated by opposing receptors; serotonin 5-HT4 receptor-mediating excitation and dopamine D2 receptor-mediating inhibition [10,11]. Postmortem studies of bowel in PD have shown decrease in dopaminergic myenteric neurons and the appearance of Lewy bodies along the proximal-distal axis, e.g., they were most frequent in the lower esophagus, but scarce in the rectum [12,13,14] (LOE2). These findings clearly showed that PD affects not only central, but also peripheral (enteric) nervous system.

LGIT function primarily consists of (1) colonic transport of the bowel content to the anorectum, (2) transient anorectum reservoir, and (3) defecation from the anorectum with the aid of strain. In PD, constipation results primarily from decreased transport and/or disturbed anorectal evacuation. Fecal incontinence may result from disturbed anorectal reservoir, or overflow secondary to constipation. Previous reports have shown that total colonic transit time (CTT) is increased beyond the normal threshold in 80% of PD patients, which translates into an increased average CTT ranging from 44 hours to 130 hours in PD [4,15,16] (LOE2), and in 89 hours in *de novo* PD patients [15] (LOE2), all of which are significantly longer than those of controls (range, 20-39 hours). Prolonged CTT has also been documented in PD patients without subjective constipation [17] (LOE2). Slow colonic transit is the major cause of decreased stool frequency. The slow colonic transit is likely to reflect a decrease in slow waves and spike activities of the colon [9].

In the resting anal manometry, the anal pressure of PD patients is low or normal [16,18] (LOE2). The resting anal pressure may reflect sympathetic innervation in the internal anal sphincter, since lesions or anaesthetic blocks at T12-L3 (where the sympathetic preganglionic neurons are located) substantially lessen the anal pressure [19]. Similarly, most PD patients have normal anal pressure increase on squeezing. This finding corresponds to a lack of neurogenic changes in the external sphincter EMG in this disorder. Nevertheless, the latent anal sphincter dysfunction may explain the fecal incontinence that occurs in most advanced cases.

In the slow-filling rectoanal videomanometry, PD patients had the same rectal volume at first sensation and a maximum desire to defecate, and the same rectal compliance as control subjects [16,18] (LOE2). In contrast to the bladder, the normal rectum shows spontaneous phasic contraction [20]. However, the amplitude of the spontaneous phasic rectal contraction in the PD patients is significantly less than that in control subjects [16,20] (LOE2). The decreased spontaneous phasic rectal contraction may share the same aetiology with the decrease in CTT.

During defecation, the healthy subjects utilized the final wave of spontaneous phasic rectal contractions for defecation [20] (LOE2). However, rectal contraction on defecation in PD patients is smaller than that in controls [16] (LOE2). In addition, in PD patients the abdominal straining is smaller [20] (LOE2). In PD patients paradoxical sphincter contraction on defecation (PSCD), or anismus, is observed in studies using sphincter EMG, radiography, and anal pressure measurement [16,18,21] (LOE2). The mechanism of the impaired straining in PD may include rigidity and reduced contractility of the axial muscles, and a failure of coordinated glottis closure [22] (LOE2). However, neuronal degeneration in the brain of PD patients relevant to straining is yet to be clarified. Mathers et al [21] consider PSCD a focal dystonia. PSCD also occurs in spinal cord-injured patients [23], suggesting that dysfunction in the suprasacral descending pathway to the external sphincter is a contributing factor. Apomorphine is shown to lessen PSCD [21] (LOE2). This effect was not antagonized by
domperidone, which did not penetrate the BBB, suggesting that the central nervous system pathology may produce PSCD.

c) Disease specific diagnosis and treatment

Insoluble dietary fibers produced an improvement in stool consistency and an increase in stool frequency in PD, which paralleled an improvement in levodopa absorption [24] (LOE3). More recently, dietary fibers such as psyllium [25] (LOE2) and polyethylene glycol 3350 [26] (LOE2), or bulking and highly hydrophilic agent polycarbophil [27] (LOE2), improve constipation in neurodegenerative disorders, including PD. Although psyllium does not alter CTT or anorectal parameters in PD patients, polycarbophil shortens the total CTT, particularly in the proximal bowel segments [27] (LOE2).

It is possible that levodopa and other antiparkinson medication may affect bowel function in PD. Endogenous dopamine is thought to inhibit intestinal motility via D2 receptors. However, no reports are available to see whether levodopa might change gut function in de novo PD patients.

Since levodopa is absorbed from the small intestine, bowel dysfunction in PD may interfere with levodopa absorption, worsen the motor disorder, or even lead to malignant syndrome [28] (LOE3/4). Domperidone, a peripheral D2 receptor antagonist that does not cross the blood-brain barrier, causes a mean 12% increase in peak plasma levodopa concentrations that occurs a mean of 10 min earlier than when levodopa is given alone [29].

After cisapride has been withdrawn in many countries due to cardiotoxicity, mosapride, a novel selective 5-HT4 receptor agonist, appeared in clinical use; it shortened total CTT (particularly the caudal segment), and augmented the amplitude in rectal contraction during defecation in patients with PD [30] (LOE2).

It is of particular importance that improvement of parkinsonism is more significant with pergolide-mosapride than with pergolide-domperidone, presumably reflecting better levodopa absorption (LOE3). Similar results were obtained in PD by dietary herb extract Dai-Kenchu-To, one active component of which is hydroxy-beta-sanshool (5-HT3 receptor agonistic action)[32] (LOE2).

d) Guidelines for further research

Despite there is no definite cure for PD, with the current knowledge we can slow down the disease process and bring patients to an almost normal live. Therefore it would be of extreme importance to introduce a validated scheme for LGIT dysfunction therapy.

CONCLUSIONS

- Patients with PD have often abnormal anorectal function (LOE2).
- The most common bowel disturbances in PD are slow colonic transit, decreased phasic rectal contraction and weak abdominal strain, and paradoxical sphincter contraction on defecation (or anismus) (LOE2).
- Bowel dysfunction such as constipation is common and has significant impact on quality of life of PD patients (LOE2).

RECOMMENDATIONS

- It seems possible that constipation in PD is treated by drugs acting on dopamine D2 receptors or 5-HT4 receptors in the bowel. (C)
- However, more studies on management of neurologic bowel dysfunction in PD are needed before giving any recommendation.

IV. CEREBRAL LESIONS AND CEREBRO-VASCULAR ACCIDENTS

Listing of terminology used for the searches: cerebrovascular accident, cerebral lesions, bladder dysfunction, urinary incontinence, faecal incontinence

1. URINARY INCONTINENCE

a) Epidemiology and Prevalence

Cerebro-vascular accidents are the third most frequent cause of death in industrialised countries after myocardial infarction and malignancies. Based on age-dependence of cerebro-vascular accidents (CVA) and the increase of the elderly in our population the importance of this disease enhances: currently one out of 200 inhabitants will suffer from a CVA, 80 to 90% of them above the age of 65. The 5-year-survival rate is 96 % in men and 64 % in women.

At the time of maximal impairment 41.1% of 4499 stroke patients (46.0% of females and 37.3% of males studied) had urinary incontinence [1]. An analysis of the symptoms of 532 patients seen within 7 days of their stroke found that the presence of urinary incontinence appeared to be a more powerful prognostic indicator for poor survival and eventual
functional dependence than a depressed level of consciousness in this period [2, 3]. It was suggested either incontinence was the result of a severe general rather than specific loss of function or that those who were incontinent were less motivated to recover from both continence and more general function. Outcome was so much better in those who remained or became dry that it seems possible that recovery of continence may promote moral and self-esteem which can actually hasten overall recovery. Urinary incontinence with impaired awareness of bladder sensation seem to be associated with poorer outcome than urge urinary incontinence with preserved bladder perception [4]. In Nayhama paper 20 % - 30 % of the patients still suffer from urinary incontinence six months after the CVA if no proper treatment has been instored [5]. Recently, it was shown that six months after stroke 16% of stroke patients experience urine loss, and that urinary loss was perceived as urinary incontinence when it occurred at least monthly [6].

b) Pathology and disease specific LUT problems

1. CEREBRAL LESIONS

Prior to the findings of PET-scan studies [7] all that was known about the cortical control of the bladder was based on clinical studies of patients with brain lesions. The most influential study was that by Andrew and Nathan, 1964 [8]. The typical clinical picture of frontal lobe incontinence they described was of a patient with severe urgency and frequency of micturition and urge incontinence, without dementia, the patient being socially aware and embarrassed by the incontinence. Micturition was normally co-ordinated, indicating that the disturbance was in the higher control of these processes. Nathan concludes his translation notes to the paper with a comment “this paper was written because people did not believe that there was such a thing as cerebral disturbance of the bladder”.

There have been a number of urodynamic studies of groups of patients who have had CVA's and subsequently developed urinary symptoms. The conclusions drawn from these groups of patients with disparate cortical lesions are that, in general, voiding is normally co-ordinated as no patients showed evidence of detrusor sphincter dyssynergia, and that the commonest cystometric finding is detrusor overactivity[9-11].

In 1996 Sakakibara et al. [12] reported on the bladder symptoms of 72 patients who had been admitted with an acute hemispheric stroke. When assessed at 3 months, 53 % were found to have significant urinary complaints. The commonest clinical problem was nocturia which occurred in 36 %, while urge incontinence affected 29 % and difficulty in voiding 25%. Urinary retention was seen in the acute phase of illness in 6 %. A significant positive correlation was found between the occurrence of a urinary disturbance and hemiparesis. Brain imaging techniques confirmed a more anterior location of brain lesions in these groups. Urodynamic studies on 22 symptomatic patients showed detrusor overactivity in 68 %, detrusor-sphincter dyssynergia in 14 % and uninhibited sphincter relaxation in 36 %. If this was really a detrusor-sphincter-dyssynergia, which should not occur in suprapontine lesions, or a hold-on manoeuvre to prevent urinary leakage, can not be clarified from the paper. There was some indication that lesion size was related to the occurrence of urinary symptoms. In contrast to the findings of Maurice-Williams [13] and Kuroiwa et al. [11] who found a correlation of urinary incontinence with lesions of the right brain hemisphere, Sakakibara et al. [12] could not find a preponderance of right sided lesions for incontinence. Their findings suggest that the damage to the antero-medial frontal lobe, its descending pathway and to the basal ganglia is mainly responsible for micturition dysfunction in stroke patients.

Urinary incontinence in stroke patients is usually interpreted as the loss of central inhibition, however also the loss of bladder perception as concomitant factor came recently into the focus of attention. Deficit of bladder sensation seems to be associated with poorer general outcome. Interestingly, those patients had more parietal lobe but less frontal lobe impairment than patients with urge urinary incontinence and preserved bladder sensation [12]. Another paper by Mochizuki and Saito [14], looking at patients with frontal lobe lesions (tumours) concluded the damage to the right superior bifrontal region was associated with temporary incontinence, whereas permanent incontinence was associated with bilateral damage.

Urinary retention has also been described in patients with brain lesions: Three case histories of elderly females with various forms of right frontal lobe pathology were described as urinary retention. In two, one with an abscess and the other with a haematoma, successful treatment brought recovery of bladder function [15, 16].

An experimental model for studying the effect of forebrain lesions and voiding dysfunction was recently developed in the rat by occluding the middle cerebral artery under pentobarbital or halothane anaesthesia. At thirty minutes after recovery from anaesthesia bladder capacity in animals with cerebral infarct was markedly decreased indicating an overactive bladder. The decreasing bladder capacity continued as long as four months after artery occlusion. Based on the effects of two different types of receptor antagonists on OAB induced by left middle cerebral artery occlusion, the authors Yokoyama et al. [17] conclude that the NMDA receptor (N-methyl-D-aspartate) has an essential role in the development of OAB after CVA. Therefore, a glutamate receptor antagonist can
be expected to be beneficial for treating overactivity caused by cerebrovascular disease, as the induced potentiation of bladder reflexes seems to depend on NMDA glutamate transmission (LOE 4).

2. BRAINSTEM LESIONS

Already in 1926 Holman [18] noted that voiding difficulty could be a sign of tumours in the posterior fossa. In a series of patients with brain tumours Ueki et al [19] reported voiding difficulty to occur in 46/152 (30 %) of patients with tumours in the posterior fossa, while urinary incontinence occurred only in 3 (1.9 %).

Renier and Gabreels [20] found urinary retention in 12/17 children with pontine glioma. There are a number of case histories published presenting difficulties with micturition in the presence of various brain stem pathologies [21-24].

Sakakibara et al. [23] reported the urinary symptoms of 39 patients who had brainstem strokes. Almost half the patients had urinary symptoms, nocturia and voiding difficulty in 28 %, urinary retention in 21 % and urinary incontinence in 8 %. The problems were more common following haemorrhage, probably because the damage was usually bilateral. Urinary symptoms did not occur in those with lesions of the midbrain, but they did in 35 % of those with pontine lesions and in 18 % of those with medullar stroke. Urodynamic studies in 11 symptomatic patients showed detrusor overactivity in 8/11, low compliance in 1/11 and detrusor acontractility in 3/11 three months, six months and 3 years after the occurrence respectively. A non-relaxing sphincter on voiding was found in 5/11 and uninhibited sphincter relaxation in 3/11 (LOE 3).

c) Disease specific diagnosis

Basic diagnosis comprises a targeted history and clinical investigation, urine analysis, postvoid residual urine and a bladder diary. In patients with significant residual urine of over 100 cc or more than 50 % of bladder capacity an urodynamic investigation is recommended to differentiate between detrusor weakness and functional or morphological outflow obstruction.

d) Disease specific treatment

Immediately after the stroke accident in the Stroke Unit, an indwelling transurethral or suprapubic catheter allows control of the urinary output. Diuresis should be monitored. Once the stroke situation is stabilised and diuresis is normalised the catheter should be removed and the patient put on intermittent catheterisation if voiding is unbalanced. In the early stage after the stroke, urinary incontinence can be managed by a condom catheter or by pads. Further treatment comprises, as the two main stays of management, behavioural therapy, initially toileting, later on micturition training and anticholinergic therapy, if the voided volumes are below 250 cc. The patient’s ability to squeeze voluntarily the anal sphincter is a good prognostic sign to achieve continence further on.

In the early phase, especially during catheter drainage, special care must be taken to avoid urinary tract infections with secondary complications. In diabetic patients low dose infection prophylaxis is recommended (LOE 4).

A recent systematic review on treatment of urinary incontinence after stroke in adults assessed the available knowledge on behavioural interventions (timed voiding and pelvic floor muscle training), specialised professional input interventions (e.g. continence nursing), compliment therapy and pharmacological/hormonal intervention (e.g. oxybutynin). It was concluded that data from the available trials are insufficient to guide continence care of adults after stroke and that better quality evidence is required concerning interventions for continence care after stroke [25] (LOE C).

e) Guidelines for further research

There is a need for further epidemiologic studies of the true incidence of LUT symptoms incl. incontinence after cerebro-vascular accidents in long term. There is a considerable lack of evidence concerning efficacy and safety of currently used therapeutic interventions. Controlled studies comparing behavioural therapy and anticholinergic medication alone and in combination should show which treatment regime is best.

CONCLUSIONS

- Incontinence after CVA is not only a distressing symptom but also a powerful prognostic indicator for survival and eventually functional dependence. (LOE 2)
- The commonest urological problems after stroke are nocturia (36 %), urge incontinence (29 %) and difficulty in voiding (25 %). (LOE 2/3)
- There is a positive correlation between the occurrence of urinary dysfunction and hemiparesis. (LOE 2/3)
- Urodynamic studies revealed detrusor overactivity in 68 %, sphincter relaxation problems in 36 % (LOE 4).
- Damage to the antero-medial frontal lobe and its descending pathway and the basal ganglia are mainly responsible for voiding dysfunction in stroke patients. With brainstem pathology symptoms of impaired voiding (urinary retention) predominate. (LOE 3)
RECOMMENDATIONS

- As the urological symptoms, especially incontinence are very distressing, urological care is mandatory for these patients (B).
- Prevention of early urinary tract infection, especially when during the acute phase an indwelling (Foley-) catheter is used. Thereafter, management with toileting, later micturition training, combined with anticholinergic therapy are the main stays (C).
- Rarely intermittent catheterisation is necessary due to unbalanced voiding mostly in men with pre-existing infravesical obstruction till general recovery allows surgical measures to relieve obstruction, if alpha-blockers and 5-alpha reductase inhibitors are not effective (C).

2. FECAL INCONTINENCE

a) Epidemiology – (LOE 3)

Brocklehurst et al. [26] observed that 14% of stroke patients with faecal incontinence became so beyond 8 weeks after the acute event, leading to speculation that constipation, immobility and dependence may be primary underlying causes. The incidence of incontinence was 51% (urine) and 23% (faeces) within one year. Faecal incontinence at onset is associated with measures of severity of stroke and of immobility.

In the Copenhagen Stroke Study, Nakayama et al. [5] did a survey of urinary and faecal incontinence using subscores of the Barthel Index during the hospital stay and at 6-month follow-up in 935 acute stroke patients. In the acute state, almost half of an unselected stroke population had urinary and/or faecal incontinence (40%). The proportion declined to one fifth for urinary incontinence and one tenth (9%) for faecal incontinence of the surviving patients at 6 months. By multivariate analysis, significant risk factors for both incontinences were age, severity of stroke, diabetes, and comorbidity of other disabling diseases. According to Harari et al. [27] prevalence of poststroke faecal incontinence was 30% (7 to 10 days), 11% (3 months), 11% (1 year), and 15% (3 years). New-onset faecal incontinence during acute state was associated with urinary incontinence (Odds ratio-OR, 19.96; 95% confidence interval -CI, 8.8 to 36.8), Glasgow Coma Score < 15 (OR, 2.84; 95% CI, 1.6 to 5.0), visual field defect (OR, 2.69; 95% CI, 1.6 to 4.6), dysphagia (OR, 2.16; 95% CI, 1.2 to 3.8) and age 65 years and over (OR, 2.16; 95% CI, 1.0 to 4.8). One third of patients with faecal incontinence at 3 months were continent by 1 year (suggesting the presence of a reversible underlying cause); conversely, 63% continent at 1 year had been continent at 3 months. Urinary incontinence (OR, 87.6; 95% CI, 41.6 to 184.4), anticholinergic drug use (including antipsychotics, tricyclic antidepressants, oxybutynin, or antihypertensives) (OR, 3.1; 95% CI, 1.1 to 10.2) and needing help with toilet use (OR, 3.5; 95% CI, 1.4 to 17.3) were significantly associated with faecal incontinence in stroke survivors at 3 months. Faecal incontinence at 3 months increased the risk of long-term placement (28% vs. 6%) and death within 1 year (20% vs. 8%). Modifiable risk factors for faecal incontinence 3 months after stroke are constipating drug use and difficulty with toilet access.

b) Conservative bowel management (LOE 3)

Venn et al. [28] performed a trial in persons with stroke and compared 4 bowel programmes based on the use of suppositories and scheduled bowel care. 85% of participants successfully achieved effective bowel training within a month. Those assigned to morning suppository schedules were more likely to establish a successful bowel regime than those assigned to evening schedules (P<0.01).

Munchiando and Kendall. [29] compared the effectiveness of two bowel training programs for patients with CVA and determined the length of time required to establish a regulated program. The sample of 48 CVA patients included 23 in the control group who had every-other-day digital stimulation and 25 in the experimental group who had daily digital stimulation. Demographic data showed no significant differences between the two groups. More subjects in the experimental group established regularity. However, the subjects in the control group who did achieve regularity took less time to do it. Subjects with right-side hemiplegia and less mobility required more time to become established. The routine protocol for bowel training in their rehabilitation unit was then changed to include daily digital stimulation.

Recently, a randomized controlled trial evaluated a specialised intervention (structured nurse assessment including history and rectal examination, targeted patient/carer education and treatment recommendations) versus routine treatment of constipation and faecal incontinence in stroke survivors. A single nurse intervention effectively improved symptoms of bowel dysfunction up to 6 months later, changed bowel-modifying lifestyle behaviors up to 12 months later, and influenced patient–GP interaction and physician prescribing patterns [30].

CONCLUSION (LOE2/3)

- Faecal incontinence after stroke is prevalent but declines over time.
- Faecal incontinence is associated with age, severity of stroke, urinary incontinence, co morbidity, using constipating drugs and functional difficulties.
- Suppository and digital stimulation may assist in regulating bowel evacuation.
V. MULTIPLE SCLEROSIS

1. EPIDEMIOLOGY

Even though there are few studies today to confirm it, the impact on the quality of life for patients with vesicourethral (VST) due to multiple sclerosis (MS) is probably significant. Moreover, in a recent cross-sectional study (LOE4), Notvedt et al [1] demonstrated that those patients with VST had distinctly lower quality of life scores on the SF-36 scale in comparison with the population of MS patients that is asymptomatic. The tools for evaluating quality of life that take into account VST in MS have been validated in a retrospective fashion or on a population of patients developing severe follow-on urological problems (LOE4) [15].

The prevalence of VST in the global population of patients who are suffering from MS is in the order of 30 to 96% [6-8, 10, 11, 13, 14, 16-32] (LOE 2b-4). The size of this interval manifests the differences linked to the type of MS, to the duration of the illness, and to the degree of handicap, as well as to a probable under-estimation of the population of MS patients that is asymptomatic. The tools for evaluating quality of life that take into account VST in MS have been validated in a retrospective fashion or on a population of patients developing severe follow-on urological problems (LOE4) [15].

The figures confirm the frequency of urinary disorders in the MS population: urinary frequency (28%), urgency (17%), urge incontinence (14%), and difficulty with bladder emptying (12.5%). Independent of the non-response rate, there are several elements that cause us to think that these figures are in actuality higher. Indeed, 65% of the patients complain of having at least 1 episode of urinary tract infection, and the majority of patients have not been treated or had a specific checkup. One can think of this very elevated rate of episodes, labeled “UTI”, as manifesting the underlying vesicourethral disequilibrium in numerous patients. Problems with emptying the bladder are particularly poorly evaluated by patients, with a large number of patients having a significant post-void residual amount without an evident clinical manifestation. In a cross-sectional study (LOE4) carried out in 2004, Kracht et al had also found a proportion of 16% of patients who had a post-void residual (PVR) greater than 100 ml but without any symptoms that were detected by the questionnaires that are normally used in evaluations of MS (EDSS, GI-Urological disability Scale (GU)).

The estimation of the global incidence of these disorders in the body of patients with MS underlines the frequency of VST in this population. In practice, it is therefore important that the tools that are used to evaluate these problems are the most appropriate ones possible, because, all of the authors agree that the fact that VST is often ignored by the doctors who take care of these patients is due to the fact that the patients under-report their symptoms (LOE5). What is more, a certain number of the patients will suffer from urological problems that develop progressively and slowly.

2. SYMPTOMATOLOGY OF VST IN MS

Urinary symptomatology in MS is polymorphic and, like its incidence, probably subject to change over time. The most frequent urinary symptoms are indisputably overactive bladder (OAB) symptoms: urinary frequency (32 to 99%), urgency (32 to 85%), and urge incontinence (19 to 80%) (LOE2b-4) [7-11, 13-15, 18-22, 24-34].

Obstructive urinary symptoms also exist to a lesser degree: difficulty of voiding and chronic or acute urinary retention. Dysuria was found in 6 to 79% of the patients, and acute episodes of urine retention were reported in 8 to 73% of the patients (LOE2b-4) [8-11, 13, 14, 18-22, 24-35].

All of these studies were carried out most frequently in a retrospective fashion or on a population of patients coming for a consultation for another reason, which can upwardly bias the estimated frequency of the disorders. There was a cross-sectional study from Marrie et al [5] (LOE4) of 16,858 patients. Of those patients, 9688 (57.5%) had responded to the two questionnaires that were posted (Bowel Control Scale (BWCS) and Urogenital Distress Inventory-6 (UDI-6)). The figures confirm the frequency of urinary disorders in the MS population: urinary frequency (28%), urgency (17%), urge incontinence (14%), and difficulty with bladder emptying (12.5%). Independent of the non-response rate, there are several elements that cause us to think that these figures are in actuality higher. Indeed, 65% of the patients complain of having at least 1 episode of urinary tract infection, and the majority of patients have not been treated or had a specific checkup. One can think of this very elevated rate of episodes, labeled “UTI”, as manifesting the underlying vesicourethral disequilibrium in numerous patients. Problems with emptying the bladder are particularly poorly evaluated by patients, with a large number of patients having a significant post-void residual amount without an evident clinical manifestation. In a cross-sectional study (LOE4) carried out in 2004, Kracht et al had also found a proportion of 16% of patients who had a post-void residual (PVR) greater than 100 ml but without any symptoms that were detected by the questionnaires that are normally used in evaluations of MS (EDSS, GI-Urological disability Scale (GU)).

The estimation of the global incidence of these disorders in the body of patients with MS underlines the frequency of VST in this population. In practice, it is therefore important that the tools that are used to evaluate these problems are the most appropriate ones possible, because, all of the authors agree that the fact that VST is often ignored by the doctors who take care of these patients is due to the fact that the patients under-report their symptoms (LOE5). What is more, a certain number of the patients will suffer from urological problems that develop progressively and slowly.

In a systematic review of the literature, De Sèze et al [17] found that the duration of the progression of MS was one of the principal factors that influenced the frequency of VST (LOE 2b-4). Thus, the majority of the studies that were carried out in patients who had a duration of the progression of MS of more than 13 years found a more homogenous frequency for the different symptoms that was in the high range in comparison with the other figures cited up until the present: urinary frequency (38.5 to 99%), urgency (44 to 85%), and urge incontinence (63 to 72%) (LOE2b-4). The frequency of obstructive disorders is
likewise markedly more elevated [36-79.5%] [7-10, 14, 18, 20, 25, 28]. A second important factor that is associated with the frequency of VST is the degree of the patient’s physical handicap as estimated by the EDSS (LOE2b-4) (Expanded Disability Status Scale) [1, 8, 20, 29, 36-40]. It is difficult to confirm from these studies whether this factor has a role in itself, however, on the other hand, clinical practice indicates this common sense observation. A person who can compensate for the urgency by going to the toilet beforehand will see the appearance of urge incontinence following the appearance of a new motor or visual handicap (LOE5). The appropriate management of this problem can allow the improvement of urinary disorders without any specific action on the bladder or the sphincter. As in those patients who have medullar injuries, the clinical examination does not always allow the discovery of the specific neurological insults that are associated with VST. Certain authors have found an association between the pyramidal syndrome and irritable VST [8, 14, 20, 29]. No neurological presentation has been found that is associated in a manifest fashion with bladder voiding disorders [10, 41, 42]. No correlation between radiological insults on the central nervous system (localization and intensity) and clinical VST has actually been found [36, 43-45]. The analysis of a series of autopsies that were done on patients who had a sacral and lumbar insult (autopsy series) did not find any correlation with clinical VST [46] (LOE5).

Other associations have been indicated, but they have all been controversial. The type of progression for the MS (progressive or by crisis), the age at which MS started, and the sex, the age, the geographical location where the patient lives, and the like do not thus appear to be associated with a more elevated frequency of VST [14, 20, 29, 36, 38-40, 47]. The age of the patient does not have impact anymore. On the other hand, older patients will have the same problems as the general population (benign prostate hyperplasia in men and stress urinary incontinence in women), and those problems will of course often be more difficult to treat than they are in the general population.

3. VST COMPLICATIONS IN MS

It is difficult to precisely establish mortality from urological complications. In a recent study of the causes of death in MS patients in the U.S. that was carried out using death certificates (LOE4), a symptomatic urinary tract infection was considered as a contributing cause to the death in 8.4% of the cases, which made it one of the principal causes that were associated with mortality [48]. In that study, terminal renal insufficiency was not found to be a notable cause of mortality.

a) Infectious complications

The reported frequency of lower urinary tract infections is elevated in the literature, ranging from 13 to 80% [7, 9, 10, 18, 21, 25, 29, 30, 38, 49-52] after at least 10 years of progression of the illness. In the study by Marrie et al, 64.6% of the patients indicated at least one annual episode of urinary tract infection. The diagnoses of symptomatic urinary tract infection is therefore very difficult in those patients who have a neurogenic bladder. Indeed, in close to half of these cases the symptoms that are related to neurogenic detrusor overactivity will be complicated by a lower urinary tract infection, as has been well demonstrated by Lisenmeyer et al (LOE 3c) in spinal cord injury patients (SCI) [53]. There is also an incompressible rate of asymptomatic bacteriuria in many neurological patients [54] (LOE4). The occurrence of febrile urinary tract infection (pyelonephritis, orchitis, or prostatitis) is estimated to be between 2 and 23% (9% on average). In addition to the risk of mortality from certain of these infections that has already been underlined, several retrospective studies (LOE5) report an aggravation of MS following an episode of this type [1, 55, 56]. Neurogenic detrusor overactivity is probably a significant factor in the occurrence of upper urinary tract infections. Game et al [57] have also reported a prospective open study in which the injection of botulinum toxin in the detrusor in patients with MS had allowed a significant reduction of symptomatic urinary tract infections to be observed (LOE3c).

b) Alterations of the bladder

Morphological alterations of the trabeculation, thickening of the bladder wall, and diverticulae type were found in 4 to 75% of cases according to the series (30% on average) [9, 10, 14, 19, 21, 25, 27-31, 34, 38, 49, 50, 52, 58, 59]. These alterations did not have pathological consequences that were different from those that are found in the general population (primarily increased risk of symptomatic urinary tract infections). The exact proportion of vesical calculus is difficult to estimate, because the majority of studies do not indicate the precise site of calculi events. It can be estimated to be in the neighborhood of 5%. Several factors are associated with the discovery of morphological alterations of the lower tract: post void residual greater than 100 ml and a progression of MS of more than 10 years in duration [19, 60]. There is no correlation between VST and the morphological anomalies that were found [14].

c) Bladder cancer

The data on the more elevated risk of a vesical tumor in patients with MS are controversial. Indeed, it known that those patients who have a neurogenic bladder have had a more elevated risk of developing a particular bladder tumor: epidermoid carcinoma (LOE2b-4) [61-64]. There are other factors that increase this risk in theory, such as tobacco use, indwelling urinary catheters, untreated vesical calculi, and chronic urinary tract infection. In patients with
of MS, the use of treatment by cyclophosphamide can be an additional risk. The risk is even further elevated in those patients who have an indwelling urinary catheter or who have been exposed to tobacco. The risk of bladder cancer appears to be slightly increased in those patients who suffer from MS, as a result of risk factors related to their neurogenic bladder as well as from medullar trauma: indwelling urinary catheter, vesicoureteral reflux was found in 2 to 15% of the cases (LOE 2b-4) [9, 10, 14, 18, 21, 25, 27-31, 34, 38, 49, 50, 52, 59]. Contrary to the case in medullar traumatization and in spina bifida, the incidence of terminal renal insufficiency is rare in patients with MS, and does not appear to be greater than what it is in the general population [68]. On the other hand, a certain degree of renal insufficiency is indicated in certain articles, and may be as high as 2 to 3% in those patients whose illness has progressed for more than 10 years [19, 25, 27].

e) Risk factors in urological complications

As we have specified previously, the great heterogeneity of the clinical signs of VST in MS leads to delayed diagnosis of urological complications. Simple clinical surveillance therefore exposes one to the risk of overlooking a complication that could significantly increase the risk of urinary tract infection, such as postmictional residue (LOE4) [42]. De Séze et al [17] looked at data based on the literature in an attempt to discern the principal risk factors for urological complications. Those results must be considered with prudence, because the majority of the studies that were used in that analysis were retrospective (LOE4). The duration of the progress of MS is the principal risk factor, with an increase in the frequency of disorders appearing after 6 to 8 years of progression of the illness. These data are consistent with two cross-sectional studies (LOE4) that report a duration of the progress of MS that is significantly more elevated in those patients who have alterations of the upper urinary tract [9, 49].

The second significant risk factor (especially infectious) is the method of urinary drainage. The indwelling catheter (LOE2b-4) [9, 25] has been associated with a number of known infectious complications [69]. The utilization of suprapubic catheters was associated with a reduced risk (LOE3c) [70, 71], however, the series that was published was mid-term [5 to 6 years) and not long term follow up. If one relies on the data that is available for the treatment of patients with SCI, then the best urinary drainage methods are intermittent catheterizations and voluntary voiding (when it can be done without residue) (LOE2) [72].

The third classic risk factor, independent of diagnosis with MS, is the occurrence of post void residual, which is associated with a more elevated risk of urinary tract infection, of vesicular calculus, and, over time, of the distention of the upper urinary tract.

The other risk factors, suggested by many authors, are more rarely reported and do not allow for a group analysis. The urodynamic risk factors will be addressed in the following chapter. The progression of MS and the patient’s sex are not associated with particular alterations of the upper urinary tract. Men were more disposed to have febrile urinary tract infections (LOE4) [8, 9, 25, 35]. Older patients were more susceptible to presentation with urological complications, due on the one hand to the occurrence of urological pathologies at their age, but also probably due to the longer progression since the start of MS [17]. The same factor could explain the data of certain authors who report more frequent urological complications in those patients who have a more severe handicap (LOE4) [9, 14, 15, 51].

4. THE ROLE OF THE URODYNAMIC EXAMINATION IN MULTIPLE SCLEROSIS

The clinical manifestation of vesicosphincteric disorder in MS is heterogeneous, and urodynamic examination is indicated in two situations. The first is in cases in which the patient requests treatment for urinary symptoms that bother him or her. The purpose of the examination is to understand the vesicosphincteric disorder that is causing the clinical symptom and to propose an appropriate treatment. The second situation is one in which the patient is considered at risk and for whom a search for additional urodynamic risk factors is to be carried out.

a) Urodynamic examination before the treatment of urinary symptoms

The most frequently found anomaly is detrusor overactivity, which is found in 34 to 99% of cases. It is defined by the presence of detrusor contractions outside of the bladder filling phase. The second anomaly was detrusor underactivity, which was found in 5 to 37% of the cases [6, 9-11, 18, 20, 22, 24-26, 28-30, 32-36, 38, 50, 52, 59, 73, 74]. In those patients who have urinary symptoms, a normal cystoma-
nometry was found in at the most 30% of the cases [21, 25, 33].

Regarding the sphincter, a vesicosphincteric dyssynergy (VSD) was found in 6 to 82% of the cases (35% on average). It is defined by the absence of relaxation or by the reinforcement of the electrical activity of the external sphincter during vesicular contraction miction, and is the object of needle electromyography of the anal sphincter [58, 75]. VSD is associated indifferently with detrusor overactivity or detrusor underactivity, although the association of detrusor overactivity with VSD (43 to 80% of cases [7, 18, 34, 50, 51]) is more frequent than that of detrusor underactivity with VSD (less than 10% [9, 73]). OAB syndrome seems to more often be the result of DO, especially urgency incontinence [20, 52] (one of the incontinence risk factors that was found was the female sex and the existence of low closure pressure [25]). Obstructive VST was as often associated with DO as it was with detrusor underactivity, and there is also often an associated VSD [10, 20]. VSD does not appear to correlate to the type of urinary symptom [20].

The urodynamic presentations progress through time in a manner that cannot be predicted, especially from the detrusor component. However, VSD, when it is demonstrated in a patient, most often persists without change [26, 59, 73, 76].

b) The urodynamic examination (UDE) in a patient who is considered at risk for urological complications

The role of UDE in this case is much more debated. Certainly, UDE is indicated because of the association of certain UDE anomalies with the possible occurrence of urological complications. The purpose of UDE is therefore the exclusion of an area of risk for the occurrence of complications. Even though this approach is today the most agreed upon, it is useful here to remember that, at least in the case of MS, it has never been evaluated in a strict fashion as part of a prospective protocol. This is explained in part by the fact that sometimes many years will pass before the urological complications occur, which makes the task of evaluation very difficult. The adversaries of preceding in this fashion propose a more pragmatic approach, with regular surveillance of simple criteria (postmictional residue, renal echography) and they propose a therapeutic approach only in those patients who present with a complication. This approach has the advantage of simplicity for the patient and for the doctor. The theoretical risk is that of the late diagnoses of a future complication (indeed, close to 50% of asymptomatic patients have urodynamic anomalies (LOE4)) [21] and of having to therefore propose a therapy to the patient that is more intensive than what could have been proposed had an earlier diagnosis been made.

The three elements of UDE that were strongly associated with urological complications were detrusor overactivity, bladder compliance failure, and VSD [9, 77]. The relationship between DO, bladder compliance failure, and the alteration of the upper urinary tract are classic in neurogenic bladders. The advent of the use of intradetrusor botulinum toxin reinforced the notion of causality between an elevated intravesicular pressure regime and the risk of alteration of the upper urinary tract, because certain authors indicated a disappearance of vesicorenal reflux after injection of botulinum toxin, at which time the intravesicular pressure regime normalized [57]. The relationship between urological complications and VSD is more debated [15, 29, 35]. The practical difficulties of researching this anomaly, the invasive nature of the electromyogram that is necessary for confirmation, and the absence of targeted therapeutic efficacy for VSD mitigate against this systematic search.

5. DIGESTIVE DISORDERS (BOWEL SYMPTOMS) IN MS

a) Epidemiology

Digestive disorders are very frequent in patients who have MS, and, like the urinary disorders that are to blame, when they are significant they have a significant impact on patients’ quality of life (LOE4) [1, 5, 78]. What is more, the patients seem to tend to be ashamed of these problems and seldom report them. The clinicians, for their part, have few tools at their disposal for evaluating this impairment. The het effect of these two observations is that it is the patients’ digestive disorders that are the most often hidden (LOE-4) [27, 34].

Taking into account the great diversity of definitions in the several studies that are concerned with this problem, one is obliged to regroup the digestive symptoms into two large groups: those symptoms that can be defined as “retentive”, including abdominal pain, flatulence, and constipation on the one hand, and those symptoms that can be defined as “irritant”, including false urges to defecate, diarrhea, and/or incontinence of stool and/or gas on the other hand. Digestive disorders of both types were found in 45 to 68% of the cases (LOE 4) [27, 78-82]. The frequency of the “retentive” symptoms was clearly the more elevated, ranging from 31% to 54% [27, 78, 80-82] [79]. The frequency of the irritant symptoms ranged from 6 to 20% [78, 80] [27, 79, 81, 82]. The authors who had sought to flush out the more exceptional episodes of incontinence found a frequency of at least one episode of that type in the months that preceded the interview in 29 to 30% of the cases [27, 79]. Finally, a proportion of about 20% of the symptomatic patients had a combination of irritant and retentive disorders [78, 80] [27, 79, 81, 82]. The figures were clearly more significant than in the general population, where the “retentive” disorders have a frequency that is
estimated to be around 2 to 20% and the “irritant” disorders have a frequency of 2% [83].

b) Risk factors for digestive disorders in MS

There was no factor that allowed the identification of a scalable type of MS that would be at greater risk of developing digestive disorders [78, 80] [27, 79, 81, 82]. Similarly, the duration of the progress of MS does not appear to be a factor that influences the frequency of digestive disorders.

The factor that seems to be the most important is the estimated degree of disability (LOE 3c-4) [82, 84]. Thus, Munteis et al [84] found in a case control study (LOE 3c) a frequency of digestive disorders that exceeded 21.2% if the patients had an EDSS between 0 and 1. This frequency exceeded 78% in those patients who had an EDSS that was greater than 4.5.

Other risk factors were suggested (LOE4), but they seemed to have an influence that was less clear, such as being of the female sex, the existence of related urinary disorders, age, and taking anticholinergic treatments [82, 84] [78, 80] [27, 79, 81].

c) Pathophysiology of the digestive disorders of MS

Few studies have been carried out specifically in patients who have multiple sclerosis. One of the difficulties is the frequent existence of related treatments that can themselves bring about the specific symptoms. The colic transit times can be extended or shortened in those patients who present with digestive disorders [85-87]. Several anorectal manometry anomalies were in evidence: reduced tone and compliance, a reduced sensation of filling and incoordination of the external anal sphincter during expulsion, with an onset of the phenomenon known as paradoxical anal sphincter contraction. In patients with faecal incontinence, a decrease in anal canal pressures and hyper-reactivity of the rectal wall have been shown manometrically. In the most recent of these studies, Munteis et al [84] has found that the anomalies that are found the most often are those of maximal sphincter pressure, of anal inhibitory reflex (which occurred later than in the control population), and the presence of paradoxical contraction of the puborectal musculature during straining. These anomalies might be able to allow the proposal of biofeedback reeducation in the concerned patients, however, at present the benefit of this approach has not yet been proven.

VI. SPINAL CORD LESION

1. URINARY INCONTINENCE
   a) Epidemiology and prevalence

Spinal cord injury (SCI) including cauda equina injury usually causes impairments of urinary functions such as urinary incontinence (UI) and/or difficulty in urination. During the past 3–4 years, there was no report on epidemiology of urinary dysfunction in acute or post-acute SCI but there were three studies on prevalence of bladder management in chronic SCI persons [1-3] (Table 20) and one study in patients with chronic cauda equina lesions [4]. About 8%–11% of chronic SCI persons had normal voiding [1,2], not different from the time after initial rehabilitation [2]; and more normal voiding in tetraplegics then paraplegics [2].

According to the study from Denmark [2], at discharge from the initial rehabilitation period of 233 traumatic SCI patients, bladder-emptying methods were as follows: 12% normal voiding, 57% suprapubic tapping, 19% abdominal pressure, 5% Crédé manoeuvre, 11% CIC, 2% SIC, 8% urethral indwelling catheter (IDC), 0.4% suprapubic catheter (SPC), 0.4% sacral-anterior-root-stimulation (SARS), and 5% use of condom-catheter or diaper. When dividing the patients by years of injury (before 1981 and after 1980), there was a decreasing trend of using suprapubic tapping (drop from over 60% to 45%), abdominal pressure (from over 20% to 15%) and Crédé manoeuvre (drop from over 12% to 1%) but there was an increasing trend of using CIC (rise from 0% to 26%). Over times, 37.5% to 46% of SCI persons changed their bladder-emptying management [2,3]; 28% found their bladder-emptying methods to be a problem; of these 58% were tetraplegic [2]; and the biggest bother bladder management to the subjects was in the compression or straining group (over 50% of the subjects)[1].

There was a statistically significant difference in the frequency of urinary tract infection (UTI) between the bladder management (P< 0.001) [1]; the frequency of UTI was high (about 70%) in the mixed group (65% used CIC with other methods) and the CIC group and less (less than 50%) in the groups with catheter free [1]. According to the study financed by Medicon Valley Academy and Coloplast A/S and done in Denmark, of those using CIC, 92% reported using hydrophilic-coated catheters [2] but there was no report about frequency of UTI. However there was a report of reused silicone catheter for CIC in 28 SCI men done in Thailand [5] with the average time of usage of each catheter of 3 years, 36% reported fever with cloudy urine and 64% of foul smell urine; however, where the frequency of CIC is higher, the abnormality of the urethra was lower (P, 0.05) [5].

In 2006, Podnar et al [4] studied 55 patients with chronic cauda equina or conus medullaris injury: 76% of the patients reported LUT dysfunction, 70% had urinary incontinence (UI) (56% of men and 71% of women); and a post void residual (>100 ml) was found in 40% of men and 17% of women. Perianal sensation was abnormal in 96%, electromyography (EMG) of the external anal sphincter (EAS) muscle in 88%, and sacral reflex in 84% of patients; using multiple linear
regression analysis, perianal sensory loss (P=0.0001) and female gender (P<0.02) had a significant positive effect on urinary incontinence score [4].

b) Pathology and disease specific LUT problems

1. Neuro- and bio-chemical regulation of the LUT

Pontari MA et al (2004)[6] analyzed 7 bladder specimens from 6 cervical SCI patients and 1 L1 congenital myelomeningocele (MMC); and compared with results from bladder specimens obtained from 8 organ transplant donors to determine whether the muscarinic receptor subtype mediating contraction shifts from M3 to the M2 subtype as in the denervated, hypertrophied rat bladder; and found that whereas normal detrusor contractions are mediated by the M3 receptor subtype, in patients with NBD, contractions can be mediated by the M2 muscarinic receptor subtype [6]. Haferkamp et al (2006)[7] evaluated the role of neuropeptide Y in 31 patients with NDO and 7 patients with stress urinary incontinence (SUI) and concluded that the reduction of neuropeptide Y-containing nerves, inhibiting the contractile response of the detrusor, may play a role in the development and persistence of NDO in SCI patients. Oner-Iyido?an et al (2004) [8] found that urine 8-iso PGF2alpha concentrations were significantly increased in SCI with hyperreflexic group (median value 0.89 pg/mg creatinine) compared to both normal control (0.52 pg/mg creatinine) and SCI with areflexic groups (P < 0.001); and the lowest concentrations of urinary 8-iso PGF2alpha were observed in the areflexic group (0.22 pg/mg creatinine) [8].

2. Neurophysiology of LUT

In patients with cauda equina lesion, on filling cystometry DO was found in 21% of men and 0% of women, reduced detrusor capacity in 9% of men and 15% of women, and during voiding phase an acontractile detrusor or detrusor underactivity were found in 59% of men and 85% of women [4].

According to the study of viscerosensory pathway of the lower urinary tract (LUT) by Schmid et al (2004)[9], after electrical stimulation (ES) of the posterior urethral mucosa (single square pulses of 0.2 ms, 2 to 3-fold sensory threshold, 60 mA in complete SCI patients), evoked skin sympathetic responses (SSRs) of the hand could be recorded in 14 of 15 sensory incomplete SCI patients with disturbed urethral sensation but not in 13 sensory complete SCI patients with loss of any urethral sensation. Electrically evoked urethral sensations resembled the subjective desire to void at full bladder reported by controls and patients [9].

Later in 2005, Schmid et al [10] did a comparative study of motor evoked potentials (MEP) and evoked pressure curves (EPC) from the urethral compressive musculature (UCM) in 9 healthy persons and 33 patients with neurogenic UI (15 SCL, 14 cauda equina lesion, and 4 multiple sclerosis). In healthy subjects the central latency was 19.0 msec, the peripheral latency was 4.25 msec, and the ratio between central and peripheral latencies was 4.4. In patients with

incomplete SCL, the central latency was significantly delayed (22.7 msec), whereas the peripheral responses were normal; and the ratio (5.5) was increased. Those with a complete SCL showed no UCM reaction after transcranial stimulation, whereas peripheral responses were normal. The increased ratio of 6.0 indicated a SCL. Ten patients with complete cauda equina lesions and UI had normal central latencies but prolonged peripheral latencies of 6.7 msec; the ratio of 3.4 indicated a lesion of the sacral caudal roots. In patients with complete cauda equina injury neither central nor peripheral responses could be evoked [10].

According to Dai and Xiao (2005) [11], the thresholds of stimulation on ventral root were 0.02 ms duration, 0.2-0.4 mA, (mean 0.3 mA+/−0.07 mA), compared with 0.2-0.4 ms duration, 1.5-3 mA (mean 2.3 mA+/−0.5 mA) for dorsal root (P<0.01) to cause evoked potentials and EMG. The continuous stimulation for about 3-5 seconds on S2 or S3 ventral root (0.02 ms, 20 Hz, and 0.4 mA) could resulted in bladder detrusor contraction, but the strongest bladder contraction over 50 cm H2O was usually caused by stimulation on S3 ventral root in 7 of the 10 patients [11].

3. URODYNAMIC STUDIES

Ockrim et al (2005) [12] found that in men with SCI, cystometric variables and detrusor overactivity (DO) remained consistent over sequential studies while in those with LUT symptom of urge, a significant decrease in the number and pressure of involuntary detrusor contractions (IDCs) in consecutive cystometries resulted in a reduction of observed DO from 72% to 63% and 48%, in the three studies. Chou et al (2006)[13] did a retrospective study on urodynamic studies to provide reference ranges for “normal” variability in urodynamic parameters that can be considered as “no real change” from one study to the next. Fifty consecutive individuals with SCI had 2 trials (trial 1 and trial 2) of urodynamic studies done 5 minutes apart, and the following data were collected:

- maximum cystometric capacity, opening pressure, maximum detrusor pressure, volume voided, and postvoid residual (Table 21).

Generao et al (2004)[14] did a retrospective review of SCI cases with 1-year minimum follow up to determine the effect of SCI on the developing bladder and kidneys using video-urodynamics, sonograms. In 42 children (average age at injury of 5.3 years and mean follow up of 5.5 years), 40 used CIC and 37 took antispasmodics. No patient had reflux, hydronephrosis or renal scarring. Safe bladder capacity, the pressure specific volume at 40 cm water or less, was less than the expected capacity in 80%, 58% and 50% of cervical, thoracic and lumbar injured patients but 100%, 76% and 67% of the respectively groups undergoing multiple urodynamics had increasing capacity with time.

Apart from the above-mentioned urodynamic/cystometric parameters, Ersöz and Akyuz (2004) [15] investigated bladder-filling sensation in 73 consecutive traumatic SCI patients to determine the quality of the preserved sensation and to determine the potential for sensation-dependent bladder emptying in this patient group. Bladder-filling sensation was present to some degree in all incomplete SCI patients, in 82.4% of the patients with complete lesions below T10, and 38.9% of the patients with complete lesions above T11. There were statistically significant differences between three groups with respect to bladder sensation category (P<0.001). About 86% of the patients with incomplete lesions, 53% of the patients with complete lesions below T10 and 22% of those with lesions above T11 had bladder-filling sensation before Pves reached 25 cmH2O and simultaneous bladder capacity of more than 150 ml was present in 61.2, 41.2 and 22.2% of the patients in the groups, respectively. Bladder-filling sensation investigations were reliable in terms of bladder filling sensation category in 36 SCI patients who had second cystometric examination.

To quantitatively measure bladder mucosal sensory function, Ukimura et al (2004) [16] used neuroselective Current Perception Threshold (CPT) tests in 8 healthy volunteers and 38 patients with NBD. Standardized neuroselective CPT measures were obtained from the left index finger and the mucosa of the posterior bladder wall. The CPT values in the bladder could be determined using the neuroselective measures in all patients but three who had no sensory response (absence of sensation) caused by complete SCI. In the 8 patients with NDO due to incomplete supra-sacral SCI, the bladder CPT value (4.0+/-1.9) at 5Hz was significantly lower (p<0.01) than that in the controls (26.2+/-17.7). In the NBD determined to be underactive (n=11, including post pelvic surgery, post infra-sacral level SCI and diabetes patients), the higher CPT values of bladder mucosal sensory functions were found at 5Hz (p<0.05), 250Hz (p=0.07), and 2000Hz (p<0.05) compared to the controls. As described in the section diagnosis of neurogenic urinary incontinence, no fibre specificity has so far been found depending on frequency of current used or current type.

4. DETRUSOR (EXTERNAL) SPHINCTER DYSSYNERGY, D (E)SD

Schurch et al (2005) [17] assessed types of DSD (according to the Blavas classification during urodynamic examinations) in 105 chronic SCI males and evaluated the change in the DSD pattern over time. Results showed that those with an incomplete sensory and motor SCL presented with DSD type 1 whereas those with complete sensory and motor SCI lesion had DSD type 2 to type 3. A correlation was also found between the AIS and the DSD type but not between the DSD type and the level of lesion; and at medium to long-term follow-up, a significant change was found in the DSD type [17]. Generally, presence of DSD was determined by increased wire needle EMG activity and/or by dilated bladder neck and proximal urethra during detrusor contraction, in the absence of valsalva or attempt to inhibit voiding.

De et al (2005) [18] did a comparative study to explore the diagnostic congruence for DSD between needle EMG and voiding cystourethrogram (VCUG) in the neurogenic population. They found 60% agreement and 40% disagreement between EMG and VCUG for diagnosis of DSD. Binomial testing demonstrated significant disagreement (P < 0.000) in observed proportions [18]. By retrospectively analyzing clinical data consisting bladder and EAS EMG from 41 SCI individuals with NDO, Wenzel et al (2006) [19] found that the onset of bladder contractions was detected within 1 sec of the start of the EAS contraction for both synergic and dysynergic human subjects; and they concluded that this detection could be used as a control signal to deliver inhibitory ES to arrest nascent bladder contractions and maintain continence [19].

5. COMPLICATIONS RELATED TO URETHRAL INDWELLING CATHETERIZATION (IDC)

During 2004-2006, at least three papers reporting urinary complications related to prolonged urethral IDC such as follows: the catheter balloon of a Foley catheter inserted only half-way was inflated in the urethra distal to the stricture and a long-term IDC caused urethral erosion and a severe degree of hypospadias (Vaidyanathan et al, 2004) [20]; contracted bladder followed by autonomic dysreflexia (AD), gross hematuria and extravasation of contrast media due to improper technique of voiding cystourethrography (Kovindha et al, 2005) [21]; and continuously incontinent despite a catheter and low bladder compliance leading to a urinary diversion to achieve continence (Stoffel and McGuire, 2006) [22]. In chronic SCI, IDC was associated with higher mean levels of C-reactive protein (CRP) while intermittent catheterization was associated with lower levels of CRP when compared with other methods of bladder management (Frost et al, 2005) [23].

6. VESICOURETERAL REFUX (VUR)

VUR seems common among SCI patients with upper motor neuron (UMN) neurogenic bladder. According to the study of Linsenmeyer et al (2004) [24], there was an association of posterior position of ureteral orifices and reflux (p = 0.004) but no differences were found with regard to bladder capacity, bladder wall compliance, or voiding pressures between the reflux and nonreflux group.

7. STONE FORMATION

Linsenmeyer and Linsenmeyer (2004) [25] found that the majority of bladder stones were calcium phosphate (46.8%) or struvite (26.7%). According to the retrospective study in 32 patients with NBD, Matlaga et al (2006) [26] found renal stones were infectious in etiology in 37.5% (12 struvite/carbonate apatite) and metabolic in 62.5%. All with struvite calculi were infected with urea-splitting bacteria.

Stone formation is usually related to IDC. In 2006, there were five papers reporting on such. Ke et al [27] found bladder calculi with a nidus of hair that could have been introduced into the bladder accidently during the cystostomy catheter replacement. According to the retrospective study of Ku et al [28], over the 17 years 28% and 15% of 140 men were diagnosed with bladder and renal stones for a total of 59 and 25 episodes, respectively; bladder stone was more common in patients injured when aged > or = 24 years than in those injured when aged <24 years (OR 2.5; 95% CI 1.1-5.7; P = 0.03); patients with complete injury had a greater risk of renal stone formation than those with incomplete injury (OR 4.1, 95% CI 1.3-12.9; P = 0.016); renal stone was more common for patients with urethral catheterization than for those voiding spontaneously (OR 5.7, 95% CI 1.3-
individuals had no catheter encrustation; of these, for bladder stones 85% of the time. Thirty-six and 11 of them also had bladder stones i.e., a positive stones. Catheter encrustation was noted in 13 patients encrustation at the time of removal for cystoscopy prospective cohort study by examination of IDC for grew at concentrations of 10^5-10^8 cfu/L, but only a spp (19%), and Escherichia coli (12%); and bacteria incidence of bladder stone than CIC-dry (p<0.05). Linsenmeyer and Linsenmeyer (2006) [31] did a prospective cohort study by examination of IDC for encrustation at the time of removal for cystoscopy and found that 35% of 49 SCI individuals had bladder catheters. Catheter encrustation was noted in 13 patients and 11 of them also had bladder stones i.e., a positive result for catheter encrustation had a positive result for bladder stones 85% of the time. Thirty-six individuals had no catheter encrustation; of these, 16% were found to have bladder stones.

8. BACTERIURIA

According to the retrospective study, Jayawardena and Midha (2004) [32] suggested that healthy asymptomatic SCI patients who came for annual evaluations should not have routine urine cultures if they are at low risk for UTIs; that is, <6 WBC/HPF in the urine and/or nitrite negative [32]. Svensson et al (2004) [33] studied the occurrence of bacteriuria in SCI patients with NBD who used CIC. Of 344 cultured samples, there were 285 isolates: coagulase-negative Staphylococci (27%), Enterococci (25%), Klebsiella spp (19%), and Escherichia coli (12%); and bacteria grew at concentrations of 10^5-10^8 cfu/L, but only a few at 10^4 cfu/L. Levendoglu et al (2004) [34] prospectively studied in 27 SCI patients who applied CIC during the initial rehabilitation and 40 controls. E. coli was predominantly isolated from the urine and the urethral cultures of both female and male patients; there was concordance between urethra and urine cultures concerning the growth of E. coli (P=0.82); and Pseudomonas was colonized more in male patients [34]. Waites et al (2004) [35] found that among 77.1% of men with bacteriuria, uropathogens were shown to be present in the perineum in 57.4% and in the urethra in 85.2%; differences in the occurrence of uropathogens in men with and without bacteriuria were statistically significant, and organisms were present in higher numbers in men with bacteriuria.

9. EPIDIDYMO-ORCHITIS AND OTHER COMPLICATIONS

Over the 17-year follow-up study of Ku et al (2006) [36], of 140 male patients (24.3% complete, the average age at onset of 24.8 years old, the average time since SCI of 16.9 years), 27.9% were diagnosed with epididymo-orchitis; and in multivariate analysis, patients on CIC had a 7.0-fold higher risk (OR, 6.96; 95%CI, 1.26-38.53; P=0.026); however, a history of urethral stricture lost statistical significance (P=0.074). Nambiar et al (2005) [37] reported a C4 tetraplegia man presenting with a necrotic ulceration on the ventral aspect of the penis and scrotum of 2 days duration and diagnosed with fulminant Fournier gangrene. Vaidyanathan et al (2004) [38] reported cases of a perirenal haematoma due to warfarin and a tumor like of necrotic slough and debris in the bladder.

10. QUALITY OF LIFE (QoL)

Oh et al (2005) [39] conducted a prospective trial involving 132 SCI patients and 150 controls matched to age and sex to determine the psychological and social status of patients using CIC. According to health-related quality of life (HRQOL), the Medical Outcomes Study 36-Item Short-Form General Health Survey (SF-36) scores did not reveal any significant differences between the men and women in the patient group. When patients and controls were divided into two groups according to sex and age, the SF-36 scores of the patients were significantly lower than the controls across both sex and all age groups, other than the energy and vitality scale, the differences for which were not statistically significant in women and those younger than 50 years. Later Oh et al (2006) [40] used the Beck Depression Inventory (BDI) with SCI patients on CIC and control group and found that, the average total BDI scores were 20.3±1.0 in the patient group and 11.4/0.5 in the control group, respectively (P<0.001); 69.6% of 102 the patients reported severe depression; female patients had a 3.8-fold higher risk (OR 13.83; 95%CI 1.42-10.31; P=0.008) of depression than male patients; and those who were unable to perform catheterization independently had a 4.6-fold higher risk (OR 4.62; 95% CI 1.67-12.81, P=0.003) of depression than those who were able to perform self-catheterization.

c) Disease specific treatments

1. UROLOGICAL FOLLOW-UP PRACTICE

According to retrospective reviews [4,41], there was evolution of bladder management by time, outcomes and complications in both pediatric onset and adult onset SCI; and treatment was not modified during the entire follow-up in very few patients. Regular urodynamic follow-up is warranted for protection of the upper urinary tract (UUT) and maintenance of continence, however, urological follow-up practice varied: in Bochum, Germany, follow-up included urodynamic evaluation, sonography of the UUT and LUT, urine examination, and evaluation of renal function and treatment modifications were based on the urodynamic findings (Nosseir et al, 2007)[42]; in the Spinal Injuries Units of U.K., all units performed routine upper tract screening, ranging from annually to every 3 years (Bycroft et al, 2004)[43].
According to the retrospective chart review of Sepahpanah (2006) [44], the 24-hour creatinine clearance (CCr) was highly variable from one evaluation to the next and the within-subject standard deviation (SD) for CCr was 25.9 mL/min; for all comparisons of repeatability, variability, and reliability, serum creatinine was superior to CCr; and renal ultrasound results and post-void residuals were the major factors in changing medical management with regard to renal function preservation. To determine the accuracy of bladder stone detection by abdominal x-rays of individuals with SCI, 13/62 (20.97%) of stones found during cystoscopy were detected by the x-ray; the detection by x-ray was 33% for stones 1.0 cm to 1.49 cm, 33% for stones 1.5 cm to 1.9 cm, and 54% for stones > or = 2.0 cm; and 57% for volumes > or = 1.0 cm³ [25]. In addition, long-term SCI individual with aged 50 to 60 or more should be screened for prostate and bladder cancer [45,46]; however, PSA cannot be used in patients with IDC and diagnosis should be based on prostatic biopsies [28].

2. **INTERMITTENT CATHETERIZATION (IC)**

IC is recommended as the safest method of bladder emptying for SCI persons with NBD [47], especially for those who have sufficient hand skills or a willing caregiver to perform the catheterization [48]. Mizuno et al (2004) [49] reported a paraplegic woman using CSIC for 27 years who had no complications and absence of UI due to underactive and normal capacity bladder. However SCI men on CIC, according to the retrospective comparative study of patients on CIC had a 7.0-fold higher risk of epididymo-orchitis [28].

**• Techniques**

Previously, recommended bladder training with CIC was time-dependent, however; some experienced bladder over-distention, especially in those with polyuria that made an IC programme unmanageable [50]. Polliack et al (2005) [51] compared volume-dependent IC (VDIC) following bladder volume measurement by a portable ultrasound device in SCL patients with time-dependent IC (TDIC). After 12-30 days follow-up, the number of IC per patient per day, the time required to perform volume measurements and IC, and their total cost, were approximately 44, 49, and 46% lower in the VDIC group than in the TDIC group. UTI was found in three patients in the TDIC group and in none in the VDIC group.

**• Type of catheter**

In developed countries, there is a variety of urethral catheters available for SCI individuals.

However, by reviewing all controlled trials comparing methods of using catheters in people with NB, Jamison et al (2004) [52] could not draw any conclusions regarding the use of different types of catheter in managing the NB.

According to the multi-centre RCT of De Ridder et al (2005) [53], 57 SCI male patients completed the 12-month study; 64% of those using the SpeediCath hydrophilic-coated catheter experienced 1 or more UTIs compared to 82% of those using the uncoated polyvinyl chloride (PVC) catheter (p = 0.02); and twice as many patients in the SpeediCath group were free of UTI. According to another multi-centre study of Bjerklund Johansen et al (2007) [54], of 378 SCL (the mean duration of IC was 4.6 yr) who completed a 12-d trial of the novel hydrophilic catheter: LoFric Primo, 55.2% of the patients were happy to continue with the novel device, which was 74% of patients using standard PVC catheters and 36% of those using prelubricated PVC (p=0.04).

In a developing country, such as Thailand, Japanese reusable silicone catheters were reused and median duration of usage for each catheter was 2 years. Electron microscopic findings of the reused catheters for 2 years revealed encrustation but no obstruction in the lumens and 20% increase in stiffness. Demographic data, urinary management and complications did not have significant relation to the abnormality of the urethrogram or UTI [21].

3. **INDWELLING CATHETERIZATION**

As mentioned above, the long-term IDC caused significant complications in SCI patients and some applying CIC experienced incontinence in between catheterization. Therefore, Ozawa et al (2005) [30] applied a contemporary (reusable) balloon catheter at night time only. After a mean follow up of 41 months, the incidence of febrile episode was as follows: CIC-wet 3.36 times/100 months, IDC 2.96, cystostomy 1.11, the contemporary catheter 0.57, and CIC-dry 0.42. The incidence of febrile episode in CIC-wet and IDC were significantly higher than in CIC-dry (p<0.05). The incidence of bladder stone was as follows: IDC 1.11 times/100 months, cystostomy 1.05, the contemporary catheter 0.96, CIC-wet 0.61, and CIC-dry 0.21.

4. **BLADDER RELAXANTS**

Many SCI individuals with NDO experienced high detrusor pressure with incontinence and post-voiding residual, bladder relaxants – antimuscarinic drugs, usually are prescribed for those applying CIC as well as IDC. Tolterodine, 2 mg twice daily [55], controlled release oxybutynin (OXY-XL) [56], doubled dosage of tolterodine ER or Trospium [57] and self-selected dosages (SSD) of tolterodine and oxybutynin [55] showed reduction in degree of UI and increase in IC volumes, and cystometric capacity; but the side effect of dry mouth was differed significantly when comparing tolterodine SSD with oxybutynin SSD (P < 0.05) [55].

5. **INTRAVESICAL VANILLOIDS INSTILLATION**

According to a review article [58], currently available
intravesical treatment options either act on the afferent arc of the reflex such as local anaesthetics or vanilloids or on the efferent cholinergic transmission to the detrusor muscle such as intravesical oxybutynin or botulinum toxin. Later there were many clinical trials and case series done in SCI with NDO proved the efficacy of intravesical instillations of various concentrations of resiniferatoxin (RTX) by cystometric/urodynamic parameters and degree of UI [59-64]; intravesical capsaicin (CAP) also improved in symptoms and urodynamic parameters [57,61], without a significant difference between the CAP and the RTX groups [61]. When compared RTX with injection of 300 units botulinum A-toxin diluted in 30 ml normal saline, both treatments provided significant reduction in mean catheterization and episodes of incontinence, and a significant increase in mean first involuntary detrusor contraction and in mean maximum bladder capacity at 6, 12 and 24 months after therapy; while botulinum-A toxin significantly reduced also the maximum pressure of uninhibited detrusor contractions more than RTX at all follow-up time points [59].

6. Treatment of DSD

In those using reflex voiding to empty bladder, it is recommended to use non-surgical methods – alpha-blocker and botulinum toxin injection into urethral sphincter [48]. According to the study of Reitz et al (2004) [65], 12 male SCI patients with NDO and DSD received 10 mg of isosorbide dinitrate sublingually and found that nitric oxide significantly reduced external urethral sphincter pressures at rest (p < 0.05) and during dysynergic contraction (p < 0.05); and the mean post triggering residual volume was significantly reduced (p < 0.05).

7. Prevention of UTI

According to 2 double-blinded, placebo-controlled RCTs [66,67], to determine the effectiveness of cranberry supplement (400-mg cranberry 3 times a day for 4 weeks [66] and 2 g per day for 6 months [67]), at preventing UTIs in SCI individuals with NBD, bacterial count, white blood cell (WBC) count, bacterial counts in urine, urinary pH or episodes of symptomatic UTI did not differ between the placebo and cranberry groups. According to another RCT to determine the effectiveness of methenamine hippurate (MH) (1 g twice-daily) and of cranberry (800 mg twice-daily). MH as well as cranberry did not have a significantly longer UTI-free period compared to placebo Lee et al (2007) [68]. In addition, when taking phosphorus supplementation, there was no significant change in urine pH during the 2-week period compared to when the patient was off supplementation Schlager et al (2005) [69].

• Antibiotic prophylaxis

Some advocated antibiotic prophylaxis for recurrent UTI [43]. To determine the safety and efficacy of a weekly oral cyclic antibiotic (WOCA) regimen consisting of the alternate antibiotic administration of an antibiotic once per week over a period of at least 2 years to prevent UTI in SCI adult patients, symptomatic UTI dropped from 9.4 to 1.8 per patient-year; and no severe adverse events and no new cases of colonization with multiple drug resistant bacteria were reported (Salomon et al, 2006) [70].

• Bladder irrigation

Waites et al (2006) [71] conducted a randomized, double-blind comparison of twice daily bladder irrigation using 1 of 3 different solutions for 8 weeks with 30 mL of (a) sterile saline, (b) acetic acid, or (c) neomycin-polymyxin solution in community-residing persons with NBD who used IDC. Results showed that the 3 irrigants had no detectable effect on the degree of bacteriuria or pyuria; no significant development of resistance to oral antimicrobials beyond what was observed at baseline; but all groups had a significant increase in urinary pH.

8. Treatment of UTI

Bycroft et al (2004)[43] found few routinely treating asymptomatic UTI in SCI individuals using catheters; and the range of recommended duration of treatment for symptomatic UTI was 3-14 days (mean 6.3).

9. Electrical stimulation

Lavano et al (2004) [72] reported improvement in bladder emptying and continence in 6 neuropathic patients treated with sacral nerve stimulation (SNS) and results were unchanged during the follow-up (maximum 26 months) in all except 1 patient. Kutzenberger et al (2005) [73] reported a 17-years experience with sacral deafferentation (SDAF) and implantation of sacral anterior root stimulator (SARS). Of 464 paraplegics receiving a SDAF-SARS, complete deafferentation was successful in 94.1% and continence was achieved in 83%. With a mean follow-up of 6.6 years, 420 out of 440 paraplegics used the SARS for voiding (frequency 4.7 per day) and 401 used it for defecation (frequency 4.9 per week); UTI declined from 6.3 per year preoperatively to 1.2 per year postoperatively and kidney function presented stable. Hansen et al (2005) [74] applied automatic event driven ES of the dorsal penile/clitoral nerve triggered by Pdet exceed 10 cmH2O and reported during stimulated filling Pdet never exceeded 55 cm H2O and an average bladder capacity increase of 53% was achieved in suprasacral SCI patients.

d) Guidelines for further research:

Most of the papers relating to epidemiology and pathology of urinary incontinence in spinal cord lesion patients were case series; and few papers were clinical trials or RCTs relating to pharmacological treatments. As UTI is a common complication among SCI individuals, further RCT to prove whether a weekly oral cyclic antibiotic for UTI prophylaxis as well as optimal
dosage, effectiveness and safety of bladder relaxants including drugs for blocking nerves innervating bladder is beneficial in SCI with NBD should be done. Regarding types of catheter, RCT should be conducted to prove whether to reuse catheters is safe. In addition, to make an automatic, event driven electrical stimulation for the treatment of NDO suitable in a clinical setting further investigations are needed.

CONCLUSIONS

- Bladder contraction in neuropathic patients can be mediated by M2 muscarinic receptor subtype density. (LOE 3)
- The strongest bladder contraction was usually caused by stimulation on S3 ventral root.
- Skin sympathetic responses and motor evoked potentials seem to be a tolerated diagnostic tool to assess autonomic and somatomotor pathways of the lower urinary tract. (LOE 3)
- Over time changing of bladder-emptying method is common and usually depends on renal function. (LOE 3)
- Long-term urethral indwelling catheterization leads to bladder and urethral complications including continuously incontinent. (LOE 3)
- Encrustation of a catheter is predictive of bladder stones whereas abdominal x-ray is not adequate to detect bladder stones. (LOE 3)
- Hydrophilic-coated catheters seem beneficial regarding UTI. (LOE 3)
- A reusable silicone catheter may be a suitable and safe choice in developing countries if it is properly cleaned and applied to reduce infection. (LOE 3)
- Volume-dependent intermittent catheterization has economic and probably also clinical advantages over time-dependent intermittent catheterization. (LOE 3)
- Combined clean intermittent catheterization during the day time with indwelling contemporary balloon catheter used only at night time showed less urinary infection than clean intermittent catheterization with incontinence and permanent urethral indwelling catheterization. (LOE 3)
- Clean intermittent catheterization was a risk factor for epididymo-orchitis. (LOE 3)
- Increased dosage of Tolterodine or Trospium gave a better effect to control neurogenic detrusor overactivity with incontinence. (LOE 2)
- Oral administration of nitric oxide may reduce bladder outlet obstruction due to DSD as shown in one study. (LOE 3)
- Serum creatinine is reliable and superior to creatinine clearance. (LOE 3)
- Posterior position of ureteral orifices seems associated with vesicoureteral reflux. (LOE 3)
- Urethral flora was a significant source for the development of urinary infection. (LOE 3)
- Low bacterial concentrations in the urine \((10^5 \text{cfu/L})\) of patients who were on intermittent catheterization might be due to contamination. (LOE 3)
- Cranberry extract, methenamine hippurate or phosphorus supplements were not found to be effective in acidifying urine or preventing urinary tract infection. (LOE 2)
- Botulinum-A toxin injection seemed to provide better clinical and urodynamic benefits than intravesical resiniferatoxin. (LOE 2)
- A weekly oral cyclic antibiotic seemed efficacious in preventing UTI. (LOE 3)
- bacteriuria in persons with neurogenic bladder and using indwelling catheterization.

RECOMMENDATIONS

- Regular/annual urological monitoring to early detect complications and to adjust bladder management in patients with neurogenic bladder dysfunction. (A/B)
- Recommend urine culture only there is high risk of urinary tract infection. (C)
- Routinely observe catheter encrustation to early detect bladder stone. (C)
- Cystoscopy is necessary if bladder stones are suspected. (C)
- Change urinary treatment according to urological results and complications. (B)
- Combine EMG and VCUG to identify DSD. (C)
- Correct instructions about catheterization to prevent complications. (B)
- Increase bladder relaxant dosage to control neurogenic detrusor overactivity and incontinence; if side-effect cannot be tolerated, try botulinum toxin injection into the bladder. (B)
2. FAECAL INCONTINENCE

a) Epidemiology and prevalence

According to Dvorak et al, 2006[1], in patients with central cord syndrome, bowel and bladder continence was reported by 81% in those with American Spinal Injury Association (ASIA) motor score improvement from a mean of 58.7 at injury to a mean of 92.3 at follow-up. However, neurogenic bowel dysfunction (NBoD) is common among spinal cord injury (SCI) patients. From 2004 to 2007, there were 6 studies reporting epidemiology of NBoD in chronic spinal cord injured (SCI), from various countries [2-6] (more details see section D1 in this chapter). Apart from SCI [2-6], there were other spinal cord lesions (SCL) that causes NBoD such tumors (e.g. a conus medullaris ependymoma and filum terminale lipoma [7]; a clear cell meningioma along the thoracic and lumbar levels [8], neuroblastoma [9]); venous congestive myelopathy, mostly at thoracolumbar and/or conus medullaris levels [10]; transverse myelitis [11]; and iatrogenic [12,13]. Tanaka et al (2006) [11] 77% of 22 transverse myelitis (average age at onset 8.8 years, mean follow-up 7.1 years) had NBoD (Table 22).

b) Pathology and disease specific lower gastrointestinal (LGIT) problems

According to electromyography (EMG) of external anal sphincter (EAS), 18 and 22 of 64 patients with cauda equina or conus medullaris lesions had bilateral and unilateral EMG abnormalities [14]. In addition, it was found that those with no such reflexes had significantly more severe FI than those with spinal sacral reflexes (p < 0.005) [5] (see more details in section D2 – III Clinical assessment); FI was found to associate with higher severity of injury[4] whereas constipation was associated with a higher level of injury (cervical OR= 5.6 vs. lumbar) [3] which was due to incapacity to increase the intra-abdominal pressure, and the absence of anal relaxation during the defecation maneuver [5].

According to the anorectal manometry, the maximum anal resting pressure of a 26-lumbosacral SCI patients group with mixed symptoms of constipation and/or FI was slightly lower than that of a 13-normal volunteers control group (Li and Xiao, 2006)[15]. During defecation , 88.5% of the patients but 7.7% of the control group significantly showed pelvic floor dysfunction (PFD). Rectoanal inhibitory reflex (RAIR)

Table 22. Shows prevalence of neurogenic bowel dysfunctions reported in spinal cord injury patients
was identified in both groups. The rectal volume for sustained relaxation of the anal sphincter tone in lumbosacral SCI patients group was significantly higher than the control group. The mean rectal volume to generate the first sensation was significantly higher in SCI patients than in the control group. Regarding constipation, its association with level of injury was supported by many studies [3-5] i.e., upper motor neuron vs lower motor neuron NBoD (p =0.0013)[4]; cervical injury had more than 5 times more frequent constipation than lumbar injury (OR =5.6, p =0.02)[3]; lesion above T7 had more constipation than lesion below T7 (p <0.05)[5]; it was also associated with severity of injury [4] and taking bladder relaxants [4]. In addition, decreased colonic pressure activity was found during sleep in SCI individuals and may contribute to delayed colon transit time after SCI [16].

Furlan and Fehlings (2006) [17] examined the characteristics of the top 100 most frequently cited articles (so-called “citation classics”) on traumatic SCI that were published between 1986 and 2003, and compared this selected professional literature with the consumers’ perspective on the key issues in SCI research. From a SCI consumers’ perspective, the areas of greatest interest included motor function, bowel and bladder control, sexual function, and pain. Motor function was the leading topic in the matching list between professional literature and consumers’ perspective. According to Anderson’s quality of life (QOL) survey of the SCI population (2004)[18], regaining arm and hand function was most important to quadriplegics, whereas regaining sexual function was the highest priority for paraplegics; and improving bladder and bowel function was of shared importance to both injury groups. Later, according to a web-based survey of 286 SCI population aged 18 years or older completed the survey, results showed that bladder and bowel concerns during sexual activity were not strong enough to deter the majority of the population from engaging in sexual activity (Anderson et al, 2007a)[19]; however, bladder and/or bowel incontinence during sexual activity was a highly significant concern in women with SCI; in addition, the occurrence of autonomic dysreflexia (AD) during typical bladder or bowel care was a significant variable predicting the occurrence and distress of AD during sexual activity. (Anderson et al, 2007b)[20].

Regarding chronic SCI individuals, FI had 10 times more impact on QOL than those with no FI and NBoD had significant impact on their QOL [21]. They had significantly lower Gastrointestinal QOL score as compared with the normal persons [22]. About one-third needed more help with activities of daily living (ADLs) [2]. There were no statistically significant differences in satisfaction or QOL between those with colostomies and those with traditional bowel care programs; however, 55.7% of those with colostomies and 41.7% of those without colostomies were very unsatisfied with their bowel care program [23].

c) Conservative bowel management

According to the “Neurogenic Bowel Management in Adults with Spinal Cord Injury” Clinical Practice Guideline published by the Consortium for Spinal Cord Medicine [24], rectal stimulations help assist elimination of the stool: mechanical stimulations — digital rectal stimulation (DRS) and manual evacuation; and chemical stimulations — suppository and mini-enema (liquid suppository). Korsten et al (2007)[25] used a manometric catheter to assess colonic motility at baseline, during DRS, and after DRS and evacuation of barium oatmeal paste in six subjects with SCI; and results showed that manometric changes in response to DRS were accompanied by expulsion of barium oatmeal paste in every subject by the fifth DRS. In patients with cervical SCI, a significant increase in systolic blood pressure (BP) was induced by insertion of rectal medications and persisted during additional DRS, and the manual removal of stool induced AD were reported; however, systolic BP recovered to pre-program values within 5 min after defecation[26].

Recently, Uchikawa et al. (2007) [27] reported a successful bowel movement in 75% of 20 SCI patients by using a modified washing toilet seat equipped with a camera monitor and an electronic bidet to facilitate precise hitting of the anal area with water streams to stimulate bowel movement for a maximum of 30 minutes. Regarding transanal irrigation, it showed improvement in constipation, FI and symptom-related QOL in SCI individuals [28].

According to the CPG, push up, abdominal massage and a forward-leaning position may aid evacuation by increasing abdominal pressure [24]. Aya? et al., 2006 [29] studied in patients with SCI and showed that abdominal message gave positive effects — increase in frequency of defecation per week, decrease in total colonic transit time and lesser FI. As contraction of the abdominal wall musculature plays a role in normal defecation, Korsten et al (2004)[16] assessed whether an abdominal belt with implanted electrodes would improve difficulty with evacuation in SCI individuals and demonstrated that neuromuscular stimulation of the abdominal wall improved defecation function, including time to first stool and total bowel care time.

Regarding medications to enhance bowel movement, Cisapride, oral does not seem to have clinically useful effects in people with SCI (Coggrave et al., 2006) [30]. Korsten et al (2005) [31] did a randomized, blinded design, to test the efficacy of neostigmine in SCI persons with defecation difficulty by infusing one of three intravenous infusates (normal saline, 2 mg neostigmine, or 2 mg neostigmine + 0.4 mg glycopyrrolate — to prevent neostigmine’s muscarinic effects) on separate days and determining on bowel evacuation of the barium paste, heart rate and airway resistance; and results indicated that both neostigmine and neostigmine + glycopyrrolate resulted in prompt bowel evacuation. Studies have shown that neo-
stigmine + glycopyrrolate intravenous administration is safe and well tolerated in persons with chronic SCI [31,32] and studies have been under way to assess the efficacy of neostigmine by other routes [32].

d) Guidelines for further research

Most of the studies reported were case series and used different definitions of faecal incontinence and constipation. Therefore further researches should base on internationally acceptable definitions so that they can be compared. In addition, RCTs on rectal or anal stimulations both mechanical and chemical as well as medications promoting bowel movement are needed.

CONCLUSIONS

- Constipation is more common than faecal incontinence among established SCI persons. (LOE 3)
- Constipation is more common in those with preserved sacral reflexes whereas faecal incontinence is more common in those without sacral reflexes. (LOE 3)
- Faecal incontinence has impact on QOL of SCI individual and is highly concerned by SCI women during sexual activity. (LOE 3)
- Digital rectal stimulations aid bowel evacuation in individuals with SCI in part by increasing left-side colonic motility. (LOE 3)
- Transanal irrigation with water improves constipation and quality of life in individuals with SCI. (LOE 2)
- Abdominal massage seems effective in enhancing bowel movement and defecation. (LOE 3)
- Anal stimulation by water stream seems effective in stimulating bowel movement and shortening bowel care time. (LOE)

RECOMMENDATIONS

- Encourage adherence to the clinical practice guidelines on neurogenic bowel management in adults with spinal cord injury. (A)
- Apply mechanical stimulation e.g. digital rectal stimulation to aid bowel evacuation especially in those with preserved sacral reflexes. (B)
- Use chemical stimulations when mechanical stimulations fail. (C)
- Beware of autonomic dysreflexia during bowel care especially in those with high lesion. (C)
- Consider transanal irrigation with water for those with severe chronic constipation and faecal impaction. (B)

VII. SPINAL CANAL STENOSIS

1. EPIDEMIOLOGY AND PREVALENCE

According to our previous extensive review of spinal canal stenosis (SCS) and incontinence published in the 3rd ICI (2005)[1], about half of the patients with intractable leg pain also had bladder symptoms – urinary difficulty with high post-void residual (PVR) and reduced flow rate and/or incontinence indicating cauda equina syndrome. Such symptoms including urinary incontinence (UI) may usually improve after surgical decompression.

Schkrohowsky et al (2007) [2], one third of patients with achondroplasia developed SCS, especially at lumbar level, requiring surgical intervention; and 77% had UI. According to Johnsson and Sass (2004) [3], in the County of South Jutland, Denmark during a 5-year period (1996-2000), the annual incidence of SCS was 272 per million inhabitants; and of 340 cases diagnosed with SCS during that period, only one patient presented with acute cauda equina syndrome: a 74-year-old woman with SCS from L2 to L4 appeared with urinary retention and fecal incontinence (FI) for the previous 24 hours; after an urgent operation and she recovered within 5 days from her anal sphincter paresis and within 5 weeks from her bladder paresis.

2. PATHOLOGY AND DISEASE SPECIFIC PROBLEMS

Goh et al (2004) [4] carried out a comprehensive retrospective review of the clinical features, radiological changes and outcome of 75 patients with radiologically diagnosed lumbar SCS; imaging of the lumbar spine showed that moderate to severe central spinal stenosis correlated with complaints of weakness and abnormal motor power on clinical examination; and the commonest symptom was numbness or tingling of the legs. According to the study of Inui et al (2004)[5], 58.8% of the 34 patients were diagnosed with positive neuropathic bladder; however there was no difference in the cross-sectional area of dural sac between those with and without neurogenic bladder dysfunctions (NBD) in patients with lumbar SCS; but the anteroposterior diameter of the dural was shorter in those with NBD; and a critical size for the dural sac of patients with NBD was revealed as 8 mm in this study.

Usually signs and symptoms of compressive neuropathy of multiple lumbar and sacral roots, so called ‘cauda equina syndrome’ is an indication for surgical intervention but relatively unknown as a postoperative complication following surgery [6]. Four years after diagnosis, 65% had undergone surgical decompression; a third of patients felt that their symptoms had improved while a quarter felt that they had worsened [4]. Imran and Halim (2005)[7] reported a 63-year-old man who developed acute cauda equina
syndrome due to fat graft compression after decompressive laminectomy, posterior instrumented fusion with pedicle screw fixation for spinal stenosis of L5 and S1 vertebral levels and free fat grafting to cover the exposed dura; three days postoperatively, gradual neurological deficit started with sensory loss and weakness of the affected dermatomes and myotomes, followed by FI on the 12th postoperative day; and immediate removal of the fat graft resulted in recovery from cauda equina syndrome.

Another case was reported by Tubbs et al (2005) [8]; a Caucasian girl who had idiopathic growth hormone deficiency and Klippel-Feil and Duane’s syndromes with symptomatic stenosis of the first cervical vertebra presented with episodes of loss of tone with subsequent falling, facial cyanosis, UI, hand weakness, and difficulties with swallowing; following suboccipital craniectomy and the removal of the posterior arch of the atlas, her symptoms were resolved and UI improved.

3. DISEASE SPECIFIC DIAGNOSIS AND TREATMENTS

To demonstrate narrowing of the lumbar canal with compression of the cauda equina, computer tomography (CT) or magnetic resonance imaging (MRI) is often recommended to reveal either bony or soft tissue compression [9].

Miyata et al (1998) [10] studied the relationship between bladder function and roentgenographic changes in the spinal canals of ossification of posterior longitudinal ligament (OPLL) patients. CO2-filling cystometry, uroflowmetry and PVR were measured and the vertical extent of OPLL and the degree of SCS was estimated by x-ray films and CT. The occurrence of abnormal detrusor activity had no relationship to the degree of canal stenosis, while the occurrence of an areflexic or underactive detrusor correlated with the vertical extent of OPLL [10].

Yamanishi et al (1998) [11] found detrusor overactivity in 14 lumbar canal stenosis patients (29%) and most of them had voiding symptoms and had storage symptoms which seemed to be caused by the irritation of sacral roots. Of 10 patients followed up after surgical decompression, detrusor overactivity disappeared in 5 patients, improved in 1 patient and remained unchanged in 4 patients [11].

Lee et al (1997) [12] did an expansive cervical laminoplasty in patients with nontraumatic cervical spondylosis with myelopathy and found that age greater than 60 years at the time of presentation, duration of symptoms more than 18 months prior to surgery, preoperative bowel or bladder dysfunction, and lower-extremity dysfunction were found to be associated with poorer surgical outcome.

CONCLUSIONS

- Patients with spinal stenosis, especially at lumbar level, may present with bladder and bowel involvements—which urinogenital and faecal incontinence (LOE 3/4)
- Lumbar canal stenosis may cause either detrusor underactivity/acontractility or overactivity. (LOE 3)
- Imaging helps diagnose spinal stenosis where as urodynamic study help diagnose neurogenic bladder dysfunction. (LOE 3/4)
- Acute symptom of incontinence or urinary retention may recover after decompression of spinal stenosis. (LOE 3/4)

RECOMMENDATIONS

- Surgical decompression is recommended in patients with spinal stenosis having acute symptoms of urinary retention/incontinence and faecal incontinence. (A)

VIII. GUILLAIN-BARRE SYNDROME

1. URINARY INCONTINENCE

a) Epidemiology and prevalence

Guillain-Barré syndrome (GBS) is the most common cause of acute, flaccid paralytic disease [1]. The term GBS defines a clinical entity that is characterized by rapidly progressing limb weakness and the loss of tendon reflexes. The disorder affects children and adults of all ages and both sexes. The following stages are observed: progression or acute phase, plateau phase and recovery phase. Despite intensive immunomodulating therapies such as intravenous immunoglobulin or plasma exchange, 4% to 15% of patients with GBS die from this syndrome and nearly 20% have a persistent disability [2]. Therefore, supportive care remains the mainstay of treatment. A recent consensus guideline in supportive care for patients with GBS covers airway problems and tracheostomy, pain, deep vein thrombosis, fatigue, cardiac problems, and bladder and bowel dysfunction [2]. Whereas cardiovascular autonomic dysfunction (mainly reflecting sympathetic adrenergic function) is recognized in up to 60% of GBS patients [3], lower urinary tract (LUT) function has only been studied infrequently in the acute phase of GBS. This is partly because most patients are catheterized as part of their general nursing care to maintain bodily hygiene or to monitor water balance [2].
Sakakibara et al [4] (LOE3/4) studied LUT symptoms in 28 patients with GBS (24 acute inflammatory demyelinating polyradiculoneuropathy, AIDP, 4 acute motor axonal neuropathy, AMAN) during the acute phase. They found that 25% of the patients showed micturitional disturbance. Voiding difficulties were presented by 86%, urinary retention by 43%, nocturnal urinary frequency by 43%, and urge incontinence by 28% of patients suffering from micturition problems. This figure is almost in accordance with the 25% found in the original reports of Guillain and colleagues.[5,6]. Urinary dysfunction in patients with GBS appeared after the occurrence of motor weakness in all cases [4]; whereas in two patients with axonal GBS, it is reported that voiding difficulty and motor weakness appeared almost simultaneously [7,8] (LOE3/4).

Sakakibara et al [4] (LOE3/4) indicated that urinary dysfunction increases with higher Hughes motor grade, although it did not reach statistical significance. Lichtenfeld [9] (LOE3/4) has also reported urinary retention in one-third of patients requiring ventilatory assistance. Even though up to 11% of GBS patients may develop urinary retention at the peak of motor weakness, it will mostly ameliorate along with other neurological signs after supportive patient management, with/without immuno-modulating therapies. In contrast, it is reported that urinary retention failed to recover for 10 months even after one patient (with axonal GBS) regained the ability to walk [8] (LOE3/4).

With regard to subtypes of GBS, it was found that heart rate and plasma noradrenaline concentrations were elevated in AIDP in 7 patients but not in 8 patients with AMAN [3]. This contrasts with the observation of bladder dysfunction in 21% of patients with classic GBS (AIDP) (n=24) but in 50% of those with axonal GBS (AMAN) (n=4)[4]. These findings may reflect the vulnerability of autonomic fiber among these variants, although it is too early to determine urinary function of axonal GBS since the number of such patients was too small.

b) Pathology and disease specific lutproblems

There is a lack of good systemic studies on micturition disorders in GBS during both acute and chronic phases. In a few reports,[10,11,12] detrusor areflexia and disturbed bladder sensation are common, and nonrelaxing urethral sphincter with neurogenic change in the sphincter motor unit potentials is another factor (LOE3/4). Among these, Grimvac et al [12] (LOE3/4) studied uodynamically 4 patients in the acute stage of GBS. All of them had complete urinary retention. They described both detrusor areflexia and detrusor overactivity, as well as detrusor-sphincter dyssynergia. One patient was followed during the chronic stage of the disease showing detrusor overactivity. The most extensive study was performed by Sakakibara et al [4] (LOE3/4) during the acute phase. They performed a urodynamic study on 4 symptomatic patients, and 2 of whom underwent repeated study. Disturbed bladder sensation was noted in one patient, detrusor areflexia in one and absence of the bulbocavernosus reflex in one. In contrast, cystometry also showed decreased bladder volume in 2 and bladder overactivity in 2, one of whom had urgency urinary incontinence and the other urinary retention. GBS primarily affects the large myelinated fibers, but pathology studies have revealed moderate to severe loss of small myelinated fibers and inflammatory cell infiltration in the lumbosacral spinal roots, sympathetic chain, and spinal cord [1,13]. Therefore, one mechanism is postulated for the urinary dysfunction in GBS: peripheral nerve damage and irritation in the sacral autonomic fibers, from either bystander inflammation or immune attack of the autonomic fibers [1,13]. Contrast enhancement in magnetic resonance imaging (MRI) of the cauda equina in GBS has also been reported [14].

Previously Wheeler and colleagues [11] (LOE3/4) found detrusor overactivity in 3 of 7 patients with GBS. However, they used carbon dioxide as a cystometry medium, which is not now recommended since it is an irritant to bladder mucosa. In addition, 2 of his patients with detrusor overactivity had extensor plantar responses, which raise questions regarding the diagnosis of GBS. However, water cystometry findings in the following studies showed detrusor overactivity with clinico-neurophysiologically definite GBS [4]. Whereas GBS patients do not have extensor plantar responses, some axonal GBS patients exhibited increased tendon reflexes [15]. Therefore, another mechanism is postulated for the urinary dysfunction in GBS: immune attack of the inhibitory spinal cord interneurons [15].

c) Disease specific diagnosis and treatment

Urinary dysfunction occurs in up to 25% of GBS patients including urinary retention in 11%, particularly in those with higher Hughes motor grade or those under mechanical ventilation. Therefore, in such patients, we should check post-void residual volume repeatedly by ultrasound echography. We then determine which supportive care is better; including the indwelling urinary catheter. Recovery of LUT function usually occurs along with the recovery of motor weakness in GBS. However, in rare cases it might take months. During the recovery period, not only voiding difficulty but also urinary urgency and frequency could occur. At this stage, urodynamic study is easily performed in order to optimize the therapy for the symptomatic patients. Clean, intermittent catheterization (CIC) is the treatment of choice to prevent over-distention bladder injury.

d) Guidelines for further research

There is only one study about the prevalence of LUT problems in GBS, which is however concentrated on the acute phase of the disease. Therefore a long-
term follow-up of these patients is needed. We still don’t know what are the long-term consequences of this disease for the LUT including urinary incontinence.

CONCLUSIONS

- In the acute phase of GBS, about 25% of patients demonstrate LUT functional problems (LOE3/4).
- Both storage and voiding dysfunctions are observed in GBS (LOE3/4).
- Recovery of LUT functions occurs along with the recovery of motor weakness. However, in rare cases it might take months (LOE3/4).

RECOMMENDATIONS

- Recovery of the LUT functions is expected in GBS; while supportive care including indwelling catheter and the following CIC is the treatment of choice in order to prevent over-distention bladder injury (C).
- During and after the recovery of paralysis a detailed functional evaluation of the LUT in symptomatic patients is needed in order to optimize the therapy (C).

2. FAECAL INCONTINENCE

a) Epidemiology and prevalence

Among various autonomic dysfunctions, whereas cardiovascular dysfunction occurs in up to 60% of Guillain-Barré syndrome (GBS) patients, [3,16] bowel dysfunction is less common, occurring in up to 15% [17,18]. In Burns’ study (LOE3/4) [17] in which adynamic ileus was noted in 17 out of 114 GBS patients, cardiovascular symptoms coincided with ileus in only 5 patients, suggesting a different pathomechanism may underlie in these two autonomic dysfunctions. Indeed, in 4 patients, mechanical ventilation and immobilization could be implicated. In 8 patients, preexisting conditions such as prior abdominal surgery or incremental doses of opioids could also be linked to ileus. However, three case reports by Gazulla Abio et al (LOE3/4) [19], Sawai et al (LOE3/4) [20] and Noew et al (LOE3/4) [21] have also shown that paralytic ileus can be the initial presenting symptom in GBS.

b) Pathology and disease specific lutproblems

There is a lack of good systemic studies on bowel disorders in GBS during both acute and chronic phases. However, there are some reports suggesting an involvement of bowel autonomic fibers in GBS. Sawai et al (LOE3/4) [21] performed a detailed bowel function test in a 47-old man with acute motor axonal neuropathy (AMAN) type of GBS who presented with ileus (also called intestinal pseudo-obstruction) by an abdominal X-ray. Sitzmarks showed prolonged total colonic transit time (86.4 hours; normal 16.0-48.0), suggesting slow transit constipation. As indicated in the bladder part, pathology studies of GBS have revealed moderate to severe loss of small myelinated fibers and inflammatory cell infiltration in the lumbosacral spinal roots, sympathetic chain, and spinal cord. Therefore, involvement of bowel autonomic fibers might also occur in GBS [21], as shown in an autopsy case of autoimmune gastroparesis [18].

c) Disease specific diagnosis and treatment

Adynamic ileus or intestinal pseudo-obstruction occurs in up to 15% of patients during a course of GBS, particularly in those with severe motor dysfunction or those under mechanical ventilation [17]. Supportive care remains the mainstay in the treatment of bowel dysfunction in GBS, including laxatives or enemas [22,23]. Recovery of bowel function usually occurs along with the recovery of motor weakness in GBS, after an intensive immune therapy including intravenous immunoglobulins.

d) Guidelines for further research

There is still a lack of a detailed functional evaluation of the bowel in GBS patients. Such studies are needed in order to optimize the therapy in the future.

CONCLUSIONS

- About 15% of patients demonstrate bowel functional problems particularly in the acute phase, but they can also be presenting symptoms (LOE3/4).
- Constipation and intestinal pseudo-obstruction are observed in GBS (LOE3/4).
- Recovery of bowel functions usually occurs along with the recovery of motor weakness.

RECOMMENDATIONS

- Recovery of the bowel functions is expected in GBS; while supportive case including laxatives or enemas is the treatment of choice (C).

IX. LUMBAR DISC PROLAPSE

Medline through Pubmed between 1966-2007

- Data base was searched for keywords:

Disc prolapse (or disc hernia), bladder dysfunction, neurogenic bladder, sphincter dysfunction, bowel dysfunction, fecal incontinence, and constipation

1. PATHOPHYSIOLOGY, EPIDEMIOLOGY AND PREVALENCE

Central lumbar disc prolapse compresses sacral nerve
fibers to and from the bladder, the large bowel, the anal and urethral sphincters, and pelvic floor resulting in so-called cauda equina syndrome. Cauda equina syndrome due to central lumbar disc prolapse has been reported to be relatively rare, the incidence being from 1 to 5% of all prolapsed lumbar disc [1-8]. Clinical features of the cauda equina syndrome include low-back pain, bilateral sciatica, saddle anesthesia, and urinary retention, loss of urethral sensation as well as constipation and erectile dysfunction [4,7,9,10]. Those patients with cauda equina syndrome usually have some sensory disturbance in the sacral dermatomes [4,10]. A Retrospective cohort study with prospective clinical follow-up showed that bowel dysfunction at presentation was associated with sexual problems at follow-up [11].

2. DISEASE SPECIFIC DIAGNOSIS AND LUT DYSFUNCTION PATTERNS

The most common urinary symptom associated with lumbar disc prolapse is acute urinary retention [12,13]. At the onset, acontractile detrusor with impaired bladder sensation is a typical urodynamic finding [4,10,12,13,14]. Severe denervation of pelvic floor [12] and external urethral sphincter [10] is also frequently demonstrated. Detrusor overactivity may occur through the irritation of the sacral nerve root [14,15,16]. Urinary disorders usually follow or accompany more obvious neurologic symptoms, such as lumbar pain and perineal sensory disturbances, that lead a proper diagnosis. However, sometimes voiding disturbances may be the only or the first symptom of this condition, which makes it more difficult to diagnose this disease [4,10]. Nevertheless, urgent MRI assessment is recommended in all patients who present with new onset urinary symptoms concomitantly with lumbar back pain or sciatica because it is impossible in a significant proportion of patients to exclude the diagnosis of prolapsed intervertebral disc in the context of referral with suspected cauda equina [17].

3. DISEASE SPECIFIC THERAPY

Emergency surgical decompression has been reported to be important to increase the chance of satisfactory neurological recovery in patients with cauda equina syndrome due to central lumbar disc prolapse [4,18,19]. In a meta-analysis of surgical outcomes, Ahn et al (2000) [7] reported that a significant improvement in sensory and motor deficits as well as urinary and rectal function occurred in patients who underwent the surgery within 48 hours compared with those who had the surgery more than 48 hours after the onset of the cauda equina syndrome. Although there is still a controversy [11], most of other reports support the concept that decompression performed within 48 hours of onset of this syndrome resulted in improved functional outcomes [3,8,20]. However, acontractile detrusor is usually irreversible even after immediate decompression [10,21,22], although many patients can empty their bladder postoperatively, but only by straining or changing their voiding postures [10,22]. In contrast to bladder dysfunction, urethral function shows a better recovery after surgery [10,13].

Please refer to the chapter on children. We have looked in the scarce literature on adult patients.

1. URINARY INCONTINENCE

a) Epidemiology and prevalence

Myelomeningocele (spina bifida) is one of the most common birth defects of the spine and brain. It occurs in 1-2 births per 1000, involving all levels of the spinal column (lumbar 26%, lumbosacral 47%, sacral 20%, thoracic 5% and cervical spine 2%). Associated Arnold-Chiari malformation is seen in 85% of children, often requiring ventriculo-peritoneal shunting of cerebrospinal fluid. Ingestion of folic acid prior to conception and during the first trimester of pregnancy has significantly reduced the incidence of this problem and other associated neural tube defects. The neurologic defect produced is quite variable and cannot be totally predicted by the vertebral level of the lesion. Additionally the fibrosis associated with myelomeningocele closure, may tether the cord. Subsequent growth of the infant or child will produce further neurologic problems, manifesting as changes in bladder, bowel and lower extremity function.

The incidence of urethrovaginal dysfunction in myelomeningocele is not absolutely known, but most studies suggest it is very high (>90%). Similarly, anorectal dysfunction is very common, but its exact incidence has not been reported. Congenital neurologic bladder dysfunction with spina bifida and sacral dysgenesis that manifested itself only at middle age in a 48-year-old male is reported by Kaneoya et al (LOE4)[1]. Yamamura et al reviewed the literature of tethered cord of adult onset and found 56 cases published.(LOE 3) [2].

b) Pathology and disease specific LUT problems

The two major consequences of the vesicourethral dysfunction are urinary incontinence and hydronephrosis which can occur early or later in life.

There are many studies documenting the urodynamic characteristics of the vesicourethral unit in myelomeningocele patients but almost all in children. Almodhen and colleagues examined myelomenigocele patients in postpubertal age and correlated these findings with upper urinary tract changes [3] (LOE 3). Of the 26 patients with urinary incontinence before puberty 12 achieved continence following puberty. Hydronephrosis remained stable in 4 patients, improved in 3 and was new onset in 3, whilst vesi-
c) Disease specific diagnosis and treatment

Urodynamics is the cornerstone in the diagnosis and management of vesicourethral dysfunction in myelomeningocele. As previously stated, urodynamic findings may predict the patients at risk of upper tract deterioration. Controversy continues as when to initiate these studies, either as soon as possible after back closure, at the first sign of upper tract changes or before considering management of incontinence. Studies supporting each position have been reported, although the preponderance of evidence suggests earlier diagnosis of hostile factors is advisable. Taskinen et al [4] examined 30 patients with anorectal anomalies mainly because of fecal or urinary incontinence. All patients underwent spinal magnetic resonance imaging and urodynamic investigation. Major lumbosacral abnormalities were detected in 57% of patients, including 13, 4 and 3 with a tethered cord, syringomyelia and caudal regression, respectively. Significant dysfunction of the LUT in 57% of the cases involved an overactive detrusor in 11, detrusor-sphincter dyssynergia in 4, distended bladder in 4 and lazy bladder in 1. When the spinal cord was normal, 54% of the patients had abnormal urodynamic findings but when the spinal cord was abnormal, 59% had abnormal urodynamics. When the bony spine was normal, 33% of the patients had an abnormal spinal cord but when the bony spine was abnormal, 69% had an abnormal spinal cord. (LOE3).

As hydronephrosis and vesico-ureteric reflux are a consequence of detrusor dysfunction, synchronous fluoroscopic evaluation of the urinary tract is advisable at the time of urodynamics. Similarly, renal ultrasound has become an invaluable routine serial evaluation in these patients, assessing renal growth, development of scarring and, most importantly, hydrouretonephrosis. Studies suggest a role for repeat urodynamics and ultrasound in this patient population, however, the timing and frequency of these studies still needs to be elucidated.

Although, renal scans are routinely used, especially in the myelomeningocele patient with hydronephrosis, the exact role of this study in these patients is not clear.

Urologic treatment depends on the age of the patient and the nature of the vesico urethral dysfunction as characterized by urodynamics. In a retrospective study urinary sepsis accounted for the majority of admissions (62%), while 38 of 62 patients required 60 surgical procedures[5]. Targeting the primary urological abnormality (the dysfunctional and usually poorly compliant bladder) allowed implementation of effective treatments, including regular intermittent bladder catheterisation (52%) in order to preserve upper renal tract function. Associated postural abnormalities complicated both conservative and interventional therapies.

The mainstay of treatment is clean intermittent catheterization and antimuscarinic medication. As continence is not at issue in the neonate and infant, treatment may be postponed, unless upper tract changes are present. Some evidence exists pointing to the fact that early initiation of treatment may prevent subsequent deleterious bladder changes. Recently botulinum toxin was suggested as a possibility to avoid invasive surgery in these patients [6].

Bruschini et al evaluated 104 patients who were not managed and followed-up adequately during their childhood [7] (LOE 3). Reflux and urinary tract damage were found in 30 patients, 6 patients presented signs of upper tract damage without reflux. The cystometry showed detrusor overactivity in 48% of patients, poor compliance in 49% of patients, increased bladder capacity in 2% and normal cystometry in 1%. Detrusor leak point pressure over 40 cm H(2)O was associated with upper urinary tract damage. Patients with a decrease of functional bladder capacity over 33% had more renal scars than their counterparts. Overall, 26 % of urological untreated myelomeningocele patients have kidney damage.

On the other hand there is a work by Olsson and colleagues, evaluating 175 Swedish myelomeningocele patients in adult age [8] (LOE 3). Clean intermittent catheterisation for bladder emptying was used by 85%, and 59% used enemas on a regular basis because of the neurogenic bowel dysfunction. Renal dysfunction was than seen only in 1.7% of the adolescents.

Management of incontinence and/or upper tract deterioration mirrors the treatment of neurologic bladder. Variations in this algorithm include the use of vesicostomy in the younger child who has failed conservative measures and has evidence of deteriorating upper tracts. External sphincterotomy
has no place in the management of these patients and the use of the appendico vesicostomy in continent LUT reconstruction (Mitrofanoff) has become very popular. Most studies on surgical management of the myelomeningocele bladder are descriptive (LOE 4) at best. Data from adult and paediatric surveys show renal damage to be the single most prevalent cause of morbidity and mortality; even in children, 30-40% exhibit evidence of renal damage. Additional factors such as chronic infection and stone formation will then render the kidney more vulnerable to progressive loss of renal mass and subsequent chronic renal failure. Renal transplantation is now considered the optimal treatment for end-stage renal disease in all age groups. Although more prone to complications, recent data on patients with meningomyelocele or severely abnormal LUTs demonstrate excellent patient and graft outcomes. [9] (LOE 3)

d) Guidelines for further research
Further clarification of the role of fetal surgery to repair the neural tube defect is required. Similarly the role of early intervention, conservative or surgical is required. The timing of surgical intervention needs further study as well as better quality of life assessments and risk/benefit analyses of LUT reconstructive procedures. The development of a tissue-engineered substitute for cystoplasty is being studied. Finally, the fate of the adult myelomeningocele patient, especially those who have undergone reconstruction needs to be documented.

CONCLUSIONS

- Myelomeningocele is one of the commonest birth defects (LOE 1)
- Incidence decreased by folate ingestion (LOE 2)
- Most have bladder dysfunction which can lead to incontinence and / or upper tract deterioration (LOE 3)
- Majority will derive significant benefit from conservative measures (LOE 3)

RECOMMENDATIONS

- Regular surveillance, from infancy, with urodynamics and renal ultrasound is mandatory. However the exact timing is not defined. One must observe the general rules for neurogenic bladder(B)
- Early initiation of conservative measures (clean intermittent catheterization, anti-muscarinic medication) generally provides protection of the upper urinary tract (B)
- Surgery is reserved for failed conservative treatment ( B)

2. FAECAL INCONTINENCE AND BOWEL PROBLEMS

• Methods
Using MEDLINE we identified English-language journal articles and reviews published from 2000 to April 2008, looking for the keywords myelomeningocele, fecal incontinence, management.

a) Pathophysiology
Voluntary control of defecation requires rectal sensation, peristalsis and adequate anorectal sphincter function. Neurological defects in patients with spinal lesions may affect one or more of these components resulting in different types of defecation disorders: fecal incontinence, chronic constipation or both. Incontinence is one of the major stigmas affecting patients born with myelomeningocele [1].

b) Prevalence
Bowel dysfunction occurs in most children with spinal cord impairment from disease or injury.

c) Management (LOE 3)
Although many different regimens have been used to manage this problem none has had universal success. Behavioural modification and laxatives failed to achieve an acceptable result because of the persistence of soiling. A small dose of laxatives alone accomplished nothing while administering a large dose to an incontinent patient only resulted in profound embarrassment [2]. Bearing in mind that none of these patients can resist the push of peristalsis, the most effective therapy is the emptying of the colon, which takes at least 24–48 h to refill again.

The main goal, to empty the colon as much as possible to achieve continence during the next 24–48 h, can be achieved nowadays by two ways, (A) by a retrograde colonic enema (RCE) using a special ballon catheter or (B) an operative procedure which allows an antegrade continence enema (ACE).

1. CONSERVATIVE
• The retrograde colonic enema (RCE)
In neurological fecal incontinence the standard enemas are difficult if not impossible to administer because there is inability to retain the enema which flows out involuntarily through the weak anus during its instillation.

Therefore a catheter system, which allows to perform the retrograde colonic enema, has been developed by industry, the application of which can easily be applied either by the parents or even by children over the age of 7–8 years. Not all children tolerate this procedure, in some of them colonic peristalsis creates pains. However the reported results are good according to Eire et al. [3], in 1998.
Shandling et al. [4] reported 100% success in using the enema continence catheter in the management of his patients with spina bifida.

These authors regard the RCE as one of the best conservative methods of treatment for relieving fecal incontinence originating from myelomeningocele and other neurological problems within intestinal dysfunction.

With intravesical electrical stimulation (IVES) also concomitant improvement in fecal incontinence was observed in children with myelomeningocele and IVES is regarded by some as another viable option for controlling fecal incontinence in these children [5].

Biofeedback was introduced for use in children with intact rectal sensation [6], but recent trials have reported less encouraging results [7]. “Digital disimpeachment” is unpleasant to perform and only succeeds in emptying the distal rectal ampulla.

2. Operative

• The antegrade colonic enema (ACE)

The impact of antegrade colonic enema (ACE) [8] in the management of patients with myelomeningocele was analysed recently by Lemelle et al [1]. 47 patients were treated with ACE, of whom 41 used the method at a mean time of 4.1± 1.9 years after the ACE operation: only six abandoned ACE for conventional management. With ACE, faecal incontinence was significantly improved compared with conventional management and neither retrograde rectal enema nor digital extraction were required.

In most cases, ACE was performed using the appendix or the caecum. Among the 47 patients operated with the ACE procedure, six patients (12.8%) stopped performing antegrade enema for various reasons, from conduit problems due to stomal stenosis or catheterization difficulties, lack of motivation or “too long time to empty the enema” in one case. Antegrade colonic enema was applied before, concomitantly or after urinary incontinence surgery in 5, 27 and 10 cases respectively. Antegrade enema was performed at most three times a week. Tap water was used in the majority of patients. Mean enema volume for ACE was 1.2 L (range 0.25–3.0 L). Mean enema time for colonic washout with ACE was 50 ± 19 min (range 15–90 min), however mean washout duration for ACE tended to be shorter with implantation of the conduit on the left-segment of the colon.

Casale et al. [9] were unable to find any differences in the continence rate or stomal complications between total reconstruction (ACE and continent urine stoma) or staged reconstruction. However, because of shared pathology the authors believe, that most patients benefit from intervention in the gastrointestinal and the genitourinary tract. Therefore, a major advantage of total continence reconstruction is avoidance of the morbidity of a second major surgical procedure (LOE 3).

Nevertheless, conventional treatment should be tested first, and the efficacy of retrograde enemas may be a predictor of the efficacy of ACE on bowel management. Moreover, percutaneous endoscopic insertion is fully reversible and does not present drawbacks and encountered with the catheterizable conduit [2]. Nevertheless, experience with the Malone procedure has proved that a suitable continent and catheterizable conduit can be obtained with an appropriate technique. In selected and motivated patients, and with the help of a specialist nurse providing close support in the postoperative period, surgical ACE procedure might be preferred according to the surgeon’s experience.

• Sacral neuromodulation has been recently described also in the therapy of these patients, but the persistence of continence control and tolerance of the patient need to be evaluated for a prolonged period of time(). Sacral neuromodulation may only be successful in a small selected number of patients, in whom preserved anatomy of the sacral nerves permits placement of the electrodes on the sacral nerves [10].

d) Quality of life – QoL (LOE 3)

As no absolute indication has been defined for ACE, other criteria should be used to evaluate clinical outcome of bowel management, including health – related quality of life (HRQoL). This assessment should be performed prospectively when ACE produce is planned and performed during pre and post-operative periods.

According to Eire et al. (1998) ACE procedure and RCE can be the best options for achieving the best social integration. For wheelchair users and other selected patients the ACE (being faster and easier) is better than the retrograde continence enema which needs some help in its use [3,6].

CONCLUSIONS (LOE 3)

• Neurologic bowel dysfunction and bowel problems incl. fecal incontinence and constipation are prevalent among myelomeningocele patients.

• Fecal incontinence and methods of bowel care affect the QoL and social activities of myelomeningocele patients.

• The main goal, to empty the colon as much as possible to achieve continence during the next 24–48 h, can be achieved nowadays either by retrograde colonic enema (RCE) using a special balloon catheter or by an operative procedure which allows an antegrade continence enema (ACE).
RECOMMENDATIONS B/C

- Colorectal problems deserve more attention in the treatment of myelomeningocele patients
- Appropriate bowel programme/management should be properly designed to each person after adequate counselling.

FURTHER RESEARCH

The development of a disease-specific HRQoL measure for use with myelomeningocele has been proposed by Parkin et al. [11]. In addition specific questionnaires should be designed to assess fecal incontinence.

XI. DIABETES MELLITUS

1. URINARY INCONTINENCE

a) Epidemiology and prevalence

Diabetes is one of the commonest causes of polyneuropathy. Amongst different types of polyneuropathies in diabetic patients “diabetic cystopathy” occurs in 43% to 87% of insulin-dependent diabetics, with no sex or age differences. It is also described in about 25% of diabetic patients on oral hypoglycemic treatment. A Scandinavian study showed that in patients who have had diabetes for 10 years, the prevalence of diabetic cystopathy in those who were insulin-dependent was 2 to 4 per 1000 and in those on oral hypoglycemic agents was 1 to 3 per 1000. The correlation between diabetic cystopathy and peripheral neuropathy ranged from 75% to 100%. Nephropathy was seen in 30% to 40% of cases [1] (LOE 3).

Diabetes duration, treatment type, peripheral neuropathy, and retinopathy were significantly associated with severe incontinence in multiple regression models adjusted for age, education, and history of UTI [2] (LOE 3). Lewis et al in a cross-sectional studies of 50-90 years old women found that insulin dependent diabetes was strongly associated with urinary incontinence, while non insulin dependent diabetes was not [3] (LOE 2).

b) Pathology and disease specific LUT problems

Van Poppel et al had neuropathological examination of bladder biopsies done on 14 patients with severe insulin-dependent adult-onset diabetes and compared with the acetylcholinesterase and S100 staining of 38 control specimens. A decrease in acetylcholinesterase activity, due to axonal degeneration was found in all cases. An increase in S100 positivity was found in the majority and is due to Schwann cell proliferation as a regeneration attempt after demyelination or axonal degeneration. When acetylcholinesterase activity decreases and an S100 density increase is found in a patient with diabetes, this combination is highly suggestive of diabetic cystopathy amenable to early symptomatic treatment [4] (LOE 2).

Since the peripheral nerves are involved, the clinical manifestations of diabetic cystopathy might be very different. Usually there is reduced sensation of bladder fullness, and decreased frequency of voiding. This is followed by slowing of the urinary stream and difficulty in voiding due to impaired detrusor contraction. Post-voiding dribbling may also occur. The impaired bladder emptying and urinary retention predispose to urinary tract infections. No prospective studies referring specifically to the problem of functional disturbances of the LUT in diabetic patients were performed.

Yamaguchi et al. recently studied 84 diabetic cystopathy [5]. In addition to large post-void residual and decreased sensation, urinary urgency, detrusor overactivity (DO), and increased bladder sensation were seen in 55%, 42%, and 14%, respectively. The frequency of DO in patients with increased bladder sensation was 58%. DO increased with age, but not with the duration of diabetes. A brain MRI was performed in 32 cases. The frequency of multiple cerebral infarction in patients with DO was 76.5%. They concluded that urinary urgency (overactive bladder symptom) is not uncommon in diabetic cystopathy. Both central and peripheral mechanisms are involved, e.g., MCI due to diabetic cerebral vasculopathy for the DO, and, to a lesser extent, peripheral nerve irritation for the DO and increased bladder sensation [5] (LOE 3).

c) Disease specific diagnosis and treatment

Since diabetic polyneuropathy occurs in most patients after prolonged insulin-treatment and in about a quarter of patients treated with oral hypoglycemic drugs, it would be interesting to know the patients who are at risk of developing diabetic cystopathy without performing extensive functional tests of the LUT.

Ishigooka et al [6] (LOE 3) described the results of the ice-water test in diabetic patients with and without cystopathy. 12.5% patients without cystopathy and 25% of patients with cystopathy did not feel the ice water sensation. Ueda et al [7], (LOE 2) performed studies evaluating sympathetic skin response in correlation with cystometry.

They found that patients without sympathetic skin responses had increased residual urine and decreased detrusor contraction pressure, while patients with a lower amplitude of sympathetic skin response and more prolonged latency than controls had a significant decrease in detrusor contraction pressure. The changes within the bladder functions were observed as early as within one year from the diagnosis of diabetes.
Beylot et al [8], (LOE 2) found that the presence of residual urine in diabetic patients, after exclusion of co morbidities, was strongly associated with peripheral neuropathy.

No specific treatment has been described in regards to the population of patients with diabetic cystopathy. Therefore general rules as for the other bladder conditions with impaired (absent) detrusor contractions should be followed.

d) Guidelines for further research

No good epidemiological studies of the true incidence of diabetes related functional disorders of micturition were performed. The same is true for the treatment of diabetic “neurologic bladder”. There are no studies referring to the theoretically effective prompted voiding, and intravesical electrostimulation

CONCLUSIONS

- Diabetic cystopathy occurs in up to 80% of insulin dependent diabetes mellitus (LOE3)
- Urinary incontinence is strongly associated with insulin dependent, but not with insulin independent diabetes (LOE 2)
- Patients with diabetic cystopathy generally have impaired detrusor contractions and increased post-void residual (LOE ?)
- Overactive bladder is not uncommon in diabetes, presumably reflecting both central and peripheral mechanisms (LOE 3)
- Recurrent urinary tract infections might be a long term problem (LOE ?)

RECOMMENDATIONS

- Post void residual and urine dipstick (optional culture) in all patients with insulin dependent diabetes mellitus should be performed yearly ( C)
- In case of increased post-void residual prompted voiding, intravesical electrostimulation might be useful ( C/D)
- Treatment of choice for acontractile bladder in this group remains intermittent catheterization ( B/C)

2. FAECAL INCONTINENCE

Caruana et al [1] (LOE 3) found that diabetes patients with faecal incontinence showed increased thresholds of phasic external sphincter contraction compared with controls (P<0.05) and had reduced resting and maximal voluntary anal sphincter pressures compared with controls (P< 0.05). Increased thresholds of conscious rectal sensation in some incontinent patients with diabetes may contribute to faecal incontinence by impairing the recognition of impending defecation. Nakayama et al [2] (LOE 3) found that age and diabetes have an independent negative influence on faecal incontinence after stroke. It could be due to an abnormal internal-anal-sphincter function in diabetes patients with faecal incontinence [3] (LOE 3).

Talley [4] (LOE 3) studied gastro-intestinal symptoms, frequent abdominal pain, bowel-related abdominal pain, reflux, dyspepsia, constipation, diarrhea, and fecal incontinence in diabetes patients. There was a clinically significant decrease in QoL scores in diabetics compared with population norms across all subscales. The impact on QoL in diabetes was predominantly observed in type 2 diabetics. For all the Short Form-36 subscales, GI symptom groups were significantly (all p < 0.0001) associated with poorer QoL in diabetes, independent of age, gender, smoking, alcohol use, and type of diabetes.

Russo found that acute hyperglycaemia inhibits external anal sphincter function and decreases rectal compliance, which could explain the ethiopathogenesis of faecal incontinence [5] (LOE 3)

CONCLUSIONS

- Faecal incontinence in diabetes patients may be due to impaired anorectal sensation and/or decreased anal closing pressure after hyperglycemic episodes (LOE 3)
- Gastro-intestinal symptoms impact negatively on health-related QoL in diabetes mellitus (LOE 3)

RECOMMENDATIONS

- Patients with diabetes and fecal incontinence should have anorectal manometry performed before introducing the therapy for fecal incontinence (C/D)
- More studies on neurologic bowel dysfunction and management in diabetes are needed before giving further recommendation (B).

XII. PERIPHERAL NEUROPATHY DUE TO IATROGENIC LESION (FOCAL NEUROPATHY)

1. EPIDEMIOLOGY AND PREVALENCE

LUT dysfunctions can occur from damage to the nerves innervating the pelvic organs, anywhere in the course of these nerves through the cauda equina, the spinal nerve roots, the sacral plexus, or to the various individual nerves that arise from the plexus
Most injuries to these nerves are iatrogenic. Extensive pelvic surgery as abdomino-perineal resection for rectal cancer, radical hysterectomy, and aortoiliac surgery are all likely to damage the pelvic parasympathetic nerves to the bladder and genitalia. Of course this listing is not complete and practically any surgery performed within the pelvis could damage some nerves e.g. adenomectomy, radical prostatectomy, prolapse surgery. Complications of these procedures are described elsewhere in this in the relevant chapters.

Additionally pelvic irradiation, apart from causing damage to the irradiated tissue could cause damage to the adjacent nerve fibers, resulting in altered functions.

A variety of types of voiding, erectile and fecal dysfunctions can result.

**a) Hysterectomy (simple and radical)**

It is difficult to attribute certain dysfunctions to neuronal damage alone, taking into account the altered, after hysterectomy, static and dynamic functions of the pelvic structures.

Parys et al [1] (LOE 3) studied 126 women after simple hysterectomy. The results show that 47.0% had detrusor overactivity, 36.7% had urethral obstruction, and 24.8% stress incontinence. Sekido et al [2] (LOE 3) described 9 women treated with radical hysterectomy more than 10 years before the study. Obstructive voiding symptoms and/or urinary incontinence were observed in 7 patients. Cystometry revealed impaired bladder sensation, detrusor acontractility, straining on voiding, and impaired relaxation of the sphincter in all assessable patients. In addition, decreased bladder compliance was observed in 5 patients. Axelsen [3] (LOE 2) studied 100 women after radical hysterectomy and found that these women who reported incontinence had lower urethral pressure. In a prospective study of over 1000 women Jackson et al found hysterectomy to be an independent risk factor of incontinence [4] (LOE 2). There is however significant lack of long term observations of patients after radical hysterectomy in terms of lower urinary tract neurogenic dysfunctions.

**b) Abdominoperineal resection**

Retrospective analysis of 52 patients after abdominoperineal resection was performed by Eickenberg et al [5] (LOE 3). Neurologic bladder dysfunction of various degrees was found in 50 per cent of all patients but represented a long-term problem in only 10 per cent.

Baumgarner et al [6], (LOE 3) studied 86 consecutive cases of abdominoperineal resection and described 11 cases of various functional problems of micturition. All these studies however lack specific tests of the LUT functions and are not prospective.

However curative total mesorectal excision can be done with high rates of preservation of such function: Pocard et al. [7] (LOE 3) investigated 20 patients, 13 men and 7 women following curative total mesorectal excision with autonomic nerve preservation for rectal cancer. There was no difference in preoperative and postoperative LUT function, International Prostatic Symptom Score or urodynamic results, nor in the results of the quality of urinary function questionnaire. Also sexual activity and potency were unchanged in these men. Therefore the authors conclude that autonomic nerve preservation is possible and does not impair urinary and sexual function. Also Kim et al [8] (LOE 3) showed relative safety in preserving sexual and voiding dysfunction with total mesorectal excision with pelvic autonomic nerve preservation. Evaluation was based on uroflowmetry, voided volumes and residual volume, symptoms were evaluated with the IPPS: There were significant differences in max. urinary flow rate and voided volume before and after surgery, however no differences in residual volume before and after surgery were apparent. The IPPS however increased after surgery from 6.2 +/- 5.8 to 9.8 +/- 5.9 (= < 0.05).

Similar results are reported by Turaldo et al. [9] (LOE 3) evaluating incidence and pathogenesis of LUT dysfunction after surgical treatment of rectal cancer in a series of 219 patients with normal urinary function preoperatively: in the immediate follow-up only 17 patients with dysfunction were observed, 14 stage II, 2 at stage III and 1 at stage IV according to Astler-Koller classification; six months later only 8 patients had claimed urinary dysfunction and 1 required catheterisation. However no urodynamic studies were performed. There was no correlation of those with LUT dysfunction with staging, radiotherapy, size of tumour, surgical technique, however worst functional results were observed in patients who underwent abdomino-perineal resection. Lim et al have found that not only surgery but also preoperative irradiation could cause lower urinary tract and anorectal dysfunctions. The maximum resting anal pressures were unchanged after chemoradiation, but the maximum squeeze anal pressures were reduced after chemoradiation. They concluded therefore that preoperative chemoradiation for rectal cancer carries a significant risk of pudendal neuropathy, which might contribute to the incidence of fecal incontinence after restorative proctectomy for rectal cancer [10] (LOE 3).

**2. PATHOLOGY AND DISEASE SPECIFIC LUT PROBLEMS**

Focal injury to peripheral innervation of the bladder and/or sphincter results in decentralization or denervation of the above mentioned organs. Therefore detrusor hypocontractility (acontractility) and/or sphincteric deficiency will be the result of such a damage. This in turn will result in impaired bladder...
emptying and/or stress incontinence. No prospective studies referring specifically to the problem of functional disturbances of the LUT in focal iatrogenic neuronal injury in patients after hysterectomy or colorectal surgery have been performed.

3. INFLUENCE ON FECAL INCONTINENCE

Iatrogenic faecal incontinence can be caused by sphincter damage caused by childbirth, anorectal surgery, trauma, fistulae and abscesses. Vaginal delivery can cause not only sphincteric, but also neuronal damage to the innervation of the anal sphincter [11] (LOE 3).

There is a significant paucity of the epidemiological data regarding fecal incontinence after pelvic surgery.

Studing of anorectal reflexes and performing anorectal manometry could predict function restoration.[12,13] (LOE 3)

4. DISEASE SPECIFIC DIAGNOSIS AND TREATMENT

The only test in this specific patient population was described by Nordling et al [14] (LOE 3). In patients after radical hysterectomy, those who had a completely denervated bladder had a greater rise in maximum urethral pressure during noradrenaline infusion (exceeding 20 cm H2O) than normal subjects (1 to 15 cm H2O). Therefore authors concluded that urethral supersensitivity to noradrenaline may be a promising test in diagnosing damage of the sympathetic nervous innervation of the LUT.

Since the major cause of focal neuropathy is surgical intervention, the best method is to avoid peripheral neuronal injury during surgery. The detailed knowledge of pelvis neuroanatomy and meticulous preparations of the structures adjacent to the possibly affected nerves was shown to be the best technique [15-19] (LOE 3). An interesting method of incontinence surgery is the feasibility of the use of the artificial urinary sphincter [11] (LOE 3). Preservation of parasympathetic nerves seems also to play a role in rectal cancer surgery. Kneist and Junginger studied 62 patients undergoing mesorectal excision. Pelvic autonomic nerve preservation (PANP) was assessed macroscopically and with the aid of intraoperative electrical stimulation of pelvic autonomic nerves.

In 46 patients preservation of parasympathetic nerves was confirmed and these patients remained unchanged in early and long-term urinary function opposite to the remaining patients without confirmed preservation of the nerves [23] (LOE 3).

Zanolla et al [24] (LOE 2) suggested that early implementation of rehabilitative treatment (prompted voiding) allows satisfactory functional recovery of the bladder activity in 91% of the symptomatic patients after radical hysterectomy. Another interesting issue is the feasibility of the use of the artificial urinary sphincter in patients after colorectal surgery, hysterectomy and or radiotherapy for the treatment of stress incontinence. Only one study on this subject was identified [25] (LOE 3), describing a series of patients after radical prostatectomy and amongst them a patient after abdominoperineal resection with adjuvant radiation [16].

Authors concluded that this method of incontinence therapy should be the method of choice, however there is a significantly greater risk of revision (38% versus 22% in the literature for low risk groups). Fecal incontinence after colorectal surgery, if not resulting from sphincter damage could be successfully treated by sacral neuromodulation [26] (LOE 3).

5. GUIDELINES FOR FURTHER RESEARCH

No good epidemiological, prospective studies of the true incidence of peripheral injury related functional disorders of micturition were performed. Neither the descriptive studies of the disorders were performed. No specific, injury related therapy was described. There is a strong need for registry database of urinary and fecal incontinence after different types of pelvic surgery in order to establish the true prevalence and prepare guidelines on treatment/prophylaxis.

CONCLUSIONS

- Injury to the bladder/sphincter innervation occurs in 30-50% of patients after extensive pelvic surgery (LOE 3)
- Pelvic irradiation could cause nerve damage attributing to the altered bladder/bowel functions (LOE 2).
- Fecal incontinence due to iatrogenic innervation damage could occur after complicated labor, anorectal surgery and pelvic irradiation (LOE 3)
RECOMMENDATIONS

- Focal injury results in impaired detrusor contractions and external urethral sphincter deficiency or detrusor/sphincter dyssynergy (LOE 3-4)
- The key issue in avoiding these complications are nerve sparing techniques and intraoperative nerve identification (LOE 3)

**c) Disease specific diagnosis**

Sakakibara et al. (LOE 4) [1] published the findings of 6 women and 2 men, mean age 23 years, suffering from SLE for 2-25 years under immunosuppressant therapy. All 8 patients had urodynamic abnormalities, 5/8 showed decreased urinary flow, 3/8 increased post-void residual urine, 2/8 increased max. urethral closure pressure, 5/8 showed detrusor overactivity, and 5/8 impaired detrusor contractility; furthermore detrusor-sphincter dyssynergia was found in 4/8, and neurologic motor unit potentials of the external sphincter in two of four patient studied. They found detrusor overactivity more common in patients with brisk deep tendon reflex (80 %) than in those without (33 %). Repeated studies during a follow-up period between 2 months and 8 years showed deterioration in 3/8 including loss of bladder sensation, development of a low compliance bladder and decreased bladder capacity (LOE 4).

Yu et al. studied 152 women with SLE and found a significant relationship between central nervous system involvement and the adapted AUA index score. The most common urodynamic finding was a small cystometric bladder capacity (<150 ml; n = 7 patients), followed by a a weak urinary flow rate (<12 ml/second; n = 6 patients). In 3 of 7 patients with small cystometric bladder capacities, imaging studies documented a contracted bladder with marked hydroureteronephrosis [2] (LOE 3)

CONCLUSIONS

- Half of the patients with systemic lupus erythematosi show nervous system involvement. In 30 % of them subacute and chronic encephalomyelopathy may cause LUT dysfunction with variable patterns including reduced bladder capacity, detrusor overactivity, impaired detrusor contractility, pathologic voiding pattern and increased post-void residual urine (LOE 4).

XI. SYSTEMIC LUPUS ERTHREATOSIS

As the literature contains only a case report of faecal incontinence, this will not be described here

1. URINARY INCONTINENCE

a) Epidemiology and prevalence

Nervous system involvement occurs in about half of patients with systemic lupus erythematosi (SLE). Seizures and psychiatric disorders are most common manifestations; spinal cord lesions are uncommon. Symptoms of LUT dysfunction can occur, however data on prevalence are not available.

b) Pathophysiology

Neurological manifestations of systemic lupus erythematosis are subacute encephalomyelopathy, subacute myelopathy (rarely) and chronic encephalomyelopathy.

XIII. SYSTEMIC LUPUS ERTHREATOSIS

- Patients after extensive pelvic surgery demonstrating functional disorders of micturition should be properly evaluated due to a variety of possible disorders (C)
- Early rehabilitation of the LUT and of the anal sphincter might improve voiding in a majority of patients (C)
- In case of increased post-void residual after prompt voiding, intravesical electrostimulation might be useful (C/D)
- Treatment of choice for acontractile bladder in this group remains intermittent catheterization (B/C)
- Surgeons should aim for autonomic nerve preservation when performing surgery for rectal cancer. Post-operative post-void residual urine measurements as well as a targeted history on micturition before and after are mandatory in order to avoid secondary myogenic damage of the detrusor by chronic urinary retention. (C)

RECOMMENDATIONS

- The dysfunction pattern may change over time, therefore urological follow-up is recommended. (C)
- Urodynamics are necessary to define the underlying pathophysiology of the urinary symptoms (C).
- Patients with SLE and voiding dysfunctions should be managed expectantly, accordingly to the urodynamic results (C).
XIV. HERPES ZOSTER

As the literature contains only a case report on faecal incontinence this will not be described here.

1. URINARY INCONTINENCE

a) Epidemiology and prevalence

Incidence of LUT dysfunction is as high as 28% if only lumbosacral dermatome-involved patients are considered. The overall incidence is 4% [1]. Despite such high prevalence only case reports are available.

b) Pathophysiology

Herpes zoster in the lumbosacral dermatomes may manifest according to Chen et al., based on 17 patients, as cystitis-associated (12/17), neuritis-associated (4/12) and myelitis-associated (1/17).

c) Disease specific diagnosis

Two case reports describe urodynamics findings in herpes-zoster patients. Usually patients develop complete urinary retention, with or without overflow incontinence due to detrusor acontractility and lack of bladder sensation. Repeated urodynamic studies at week 10 after the onset of the disease demonstrated a return of the detrusor contraction, which returned to normal after 14 weeks [2,3] (LOE 4).

Herpes zoster associated voiding dysfunction is a transient phenomenon and is not uncommon in patients with lumbosacral dermatome involvement. As long as voiding is unbalanced the treatment with intermittent catheterisation or indwelling catheter placement is recommended in order to avoid secondary damage to the LUT due to infection or chronic urinary retention. The disease usually is of a benign clinical course and almost every patient will either regain normal voiding or, at least balanced bladder function.

CONCLUSIONS

- P28% of patients with Herpes zoster in the lumbosacral dermatomes show LUT dysfunction with impaired voiding as the most common symptom (LOE 4)
- The most common symptom is overflow incontinence due to detrusor acontractility and lack of bladder sensation (LOE 4)
- Voiding dysfunction has a transient course and almost every patient will either regain normal voiding within 3-4 months or at least balanced bladder function (LOE 3).

RECOMMENDATIONS

- Till functional recovery takes place treatment with intermittent catheterisation or indwelling catheter are recommended (C).

XV. HIV

1. EPIDEMIOLOGY AND PREVALENCE

HIV virus belongs to the family of retroviruses. This family of viruses is known for latency, persistent viremia, infection of the nervous system, and weak host immune responses. HIV has high affinity for CD4 T lymphocytes and monocytes. HIV binds to CD4 cells and becomes internalized. The virus replicates itself by generating a DNA copy by reverse transcriptase. Viral DNA becomes incorporated into the host DNA, enabling further replication. HIV enters the nervous system early, at the time of initial infection, and may immediately cause symptoms, or may cause symptoms any time during the person’s lifetime.

All parts of the nervous system may be involved. Neurological disorders could be HIV-related, due to secondary infections, malignancies, metabolic or nutritional problems and to therapy.

It is estimated that without anti-retroviral treatment, up to 80% of patients are symptomatic in terms of nervous system and for 30%, neurological symptoms are the initial clinical problem.

Neurological syndromes may be the sole clinical problem or cause of death. The following brain symptoms were described: meningitis, dementia, stroke, seizures, degenerative disorders. For spinal cord both transverse myelitis and progressive myelopathy were observed.

Taking all these information together it is evident that nervous system involvement in HIV infection should be reflected to a various degree in the LUT [1].

Shin et al (LOE3) described a higher prevalence of incontinence in HIV-positive patients in nursing homes as compared to HIV-negative [2]. Whether this represents a true trend or is an observation related to the terminal stage of the disease and associated comorbidities remains to be elucidated.

Gyrtrup et al (LOE 3) found voiding problems in 12% of HIV-infected patients, mostly in advanced stage of the disease [3].
2. PATHOLOGY AND DISEASE SPECIFIC LUT PROBLEMS

As already described virtually all parts of the body could by involved in AIDS patients, either as the primary location of HIV infection or secondary to HIV-related complications.

Among these different manifestations particular attention should be paid to the primary locations as they develop early in the stage of the disease.

HTLV-I associated myelopathy (HAM) affects up to 3% of HIV positive patients and is manifested by slowly progressive spastic paraparesis, including deterioration of bladder problems [4](LOE 2). Another interesting primary demonstration of HIV infection is lumbosacral polyradiculopathy, described by Matsumoto et al (LOE 3)[5]. In this case report voiding difficulties and lower limb paresis were the primary manifestation of HIV infection.

Also Mahieux et al (LOE 3) described a case of acute myeloradiculitis due to cytomegalovirus as the initial manifestation of terminal stage [6].

Begara et al (LOE 3) performed urodynamic studies in 10 patients with AIDS and voiding disorders and found that the most common symptom was urge incontinence and the most common urodynamic finding was detrusor-external sphincter dyssynergia [7]. In 3 patients they found demonstrable functional disorders of the LUT (2 patients had detrusor overactivity: one of them had a history of encephalopathy from HIV and the other patient had polynéuritis; the third patient had myelitis and a urodynamically diagnosed sympathetic decentralization. Detrusor areflexia was described in 2 HIV-positive patients by Menendez et al [8](LOE 3). One of them had an ascending myelitis of probable herpetic origin, the other had a cerebral abscess caused by Toxoplasma gondii.

3. DISEASE SPECIFIC DIAGNOSIS AND TREATMENT

Since during the course of the disease all parts of the nervous system can be involved, either as the primary location or secondary to AIDS-related complications, no disease specific diagnosis or treatment can be proposed. It is important to observe that sometimes functional disorders of the LUT can be the first manifestation of the HIV infection.

When managing the patient with HIV infection one must bear in mind that both storage and voiding problems can occur and that both should be treated according to the results of urodynamic studies.

4. GUIDELINES FOR FURTHER RESEARCH

All rapports about HIV and voiding problems are rather anecdotal and no good prospective studies exist. The need for such studies is particularly important, when realizing that it takes up to 20-30 years from HIV infection to AIDS full manifestation and that new antiviral treatment modalities could prolong the life of a patient with HIV significantly.

Particular attention should be paid to primary nervous system involvement by HIV and to related voiding dysfunction as well as to the voiding dysfunctions that could be the side effects of HIV drug therapy.

5. FAECAL INCONTINENCE

As diarrhoea is common in HIV infected patients, the faecal incontinence can also occur, mostly due to anal sphincter weakness. Again the true incidence of HIV neuropathy related faecal incontinence is not known and further studies are needed [9], (LOE 4)

CONCLUSIONS

- HIV can influence the nervous system and the LUT functions in two ways: as primary infection site or secondary to AIDS related complications (LOE2/3)
- Nervous system manifestation of HIV infection can be the only sign and it is therefore important to take the possibility of HIV infection into consideration when facing unusual signs and symptoms from the LUT without any other obvious cause (LOE 3)
- HIV/AIDS is a progressive disease and dynamic changes to the LUT functions can occur during the evolution of the disease (LOE 2)
- Faecal incontinence in HIV/AIDS patients is usually associated with diarrhoea, however the true incidence is not known (LOE 4)

RECOMMENDATIONS

- Patients with HIV and nervous system pathological signs and symptoms should be evaluated towards functional LUT problems (B)
- Due to the variety of LUT functional damage in HIV patients urodynamic study is essential for tailoring the optimal therapy (C)
- No HIV specific therapy of LUT problems and faecal incontinence exist. Due to variety of functional damage therapy should be individually tailored, accordingly to the results of functional/imaging studies (C)

Older persons have the highest known prevalence of urinary incontinence (UI) of any group, other than persons with specific neurological disorders (e.g., spinal cord injury). The absolute numbers of older persons with UI is increasing exponentially worldwide with the global phenomenon of population aging [1]. In developed countries, the population of centenarians has doubled every decade since 1960, mostly as a result of increases in survival after age 80 [1]. As the baby boomers age, the number of persons aged 85 or older will rise steadily from just under 2 percent of the population now to nearly 5 percent by 2050. Thus, the absolute numbers of older persons will increase dramatically [2]. Even if the observed improvements in physical functioning among older persons continue, and research is able to demonstrate improved health and lower costs, the impact on future health care and long-term care costs will be profound [1].

Throughout the world, no matter how one defines “older” or “elderly,” this population is characterized by its variety, ranging from active, community-dwelling, working, healthy nonagenarians to bed-bound, chronically ill, functionally- and cognitively-impaired persons in their late 60’s. The former healthier group is closer in phenotype and physiology to middle aged persons than to frailer older persons. For these reasons, beginning with the Third Consultation, information about persons older than 65 years of age is organized by health status. Data regarding healthier older persons is integrated in the chapters covering anatomy, physiology, evaluation, and treatment, and this chapter focuses on frailer older persons, emphasizing not only the different aetiologies and treatment of UI, but the additional issues of disease burden, disability, altered responses to drug therapy, the role of caregivers, and goals and organization of care. This chapter is aimed at all types of providers who work with populations of frail elderly, and is also intended to be relevant to specialists who find standard approaches ineffective in this population. Faecal incontinence in frail elderly is now covered in the report of Committee ?.

UI in the frail elderly is uniquely different from UI in healthy older persons. The pathophysiology of UI in the frail requires a broader conception of “disease,” which centers on patient-level factors rather than just the lower urinary tract (LUT) and its neurological control. UI in the frail elderly constitutes a syndromic model of multiple interacting risk factors, including age-related physiologic changes, comorbidity, and potentially common pathways between them. Unlike UI in healthy older persons, the impact of UI in the frail elderly includes functional impairment, and extends beyond affected individuals to their caregivers, leading to outcomes of caregiver stress and institutionalization.

Therefore, the assessment of UI in frail persons requires a much broader medical and functional scope. Failure to address the multifactoral nature of UI limits not only clinical care and research regarding aetiology and treatment, but also important opportunities to improve function and quality of life [3]. Treatment must always be multicomponent, and must address the multiple associated factors and shared underlying impairments with other geriatric syndromes (for example, by combining lower extremity exercise with prompted voiding) [4]. Drug therapy must be placed in context of altered pharmacology, polypharmacy, and susceptibility to adverse effects. Effective management requires system-level approaches, with different models of care (e.g., for institutionalized persons).

A final challenge in providing a review of UI and FI in frail older people is the relative dearth of Level 1 evidence for interventions. This is not to say that existing studies are not robust, as the frail present multiple challenges for research (not the least of which is substantial trial drop-out due to intervening illness and death). What it does indicate is the continuing paucity of new clinical trials, despite the clear epidemiological imperative that the oldest-old are the fastest growing group of affected individuals. Reasons for this are myriad, including a lack of funding for multi-component interventions and “riskier” trials involving drug therapy. At the same time, one cannot assume that treatment outcomes from conventional therapy will be worse in the frail elderly than the healthy elderly without special data to so prove.
Intervention studies and outcomes need to be more broadly based, incorporating caregivers, a range of care settings, alternative models of care, and goals of care unique to this population [5].

II. SEARCH STRATEGY

Given the broad range of this report, we used multiple searches using the following MESH terms (in caps) and phrases, alone and in combination, using the PubMed and Ovid search engines: AGED, AGED OVER 80, ACTIVITIES OF DAILY LIVING, DEPRESSION, elderly, FALLS, frail, FRAIL ELDERLY, FRAILTY, function, geriatrics, LONG TERM CARE, MEDICATIONS, NURSING HOME, older, QUALITY OF LIFE, RANDOMIZED CONTROLLED TRIAL, and BLADDER, GYNAECOLOGICAL SURGICAL PROCEDURES, PELVIC FLOOR, PROSTATE, STRESS INCONTINENCE, SURGERY, URETHRA, URINARY INCONTINENCE, URINATION DISORDERS, UROGYNECOLOGY, UROLOGY, VAGINA, VOIDING DYSFUNCTION; Ovid Expert Search Filter; Publication years 2004-08. We included, where possible, information from non-English language articles where an English language abstract with sufficient information was available. References in retrieved articles were reviewed for additional relevant articles. We also searched the Cochrane Database and National Guideline Clearinghouse for relevant systematic reviews, meta-analyses, and evidence-based recommendations.

III. DEFINING THE FRAIL ELDER POPULATION

1. FRAILTY

Who, then, are the frail elderly? Consistent with increasing consensus in the geriatric literature, we define “frail older persons” as those over the age of 65 with a clinical presentation or phenotype combining impaired physical activity, mobility, balance, muscle strength, motor processing, cognition, nutrition, and endurance (including feelings of fatigue and exhaustion) [6-8]. Frailty is not, however, identical to disability and comorbidity. Among persons meeting strict phenotypic criteria for frailty, only 22% also had both comorbidity and disability, 46% had comorbidity without disability, 6% disability without comorbidity, and 27% had neither comorbidity nor disability [7]. Frail persons usually have multiple chronic medical conditions, take multiple medications, require care by other persons and assistance to perform some or all of the activities of daily living (ADLs) (e.g., bathing, dressing, toileting, and ambulation), are often homebound or in care institutions, and have a high risk of intercurrent disease, increased disability, hospitalisation, and death [1-6]. For example, in Japan, 10% of all persons over 65 require help or supervision with at least one ADL, [9] and the total prevalence of frail elders has been estimated at 6.1% [10].

Several studies suggest that the relationship between UI and frailty is not unidirectional. Incident UI in persons over age 65 has been associated with a two-fold increased risk of impairment in ADLs, instrumental activities of daily living (IADLs – e.g., transportation, finances, shopping, laundry, housekeeping), and poor performance on three physical measures, suggesting that incident UI may be an early marker of the onset of frailty [10]. In a population-based study of older Mexican Americans, incident but not prevalent UI was independently associated with functional decline in ADLs, IADLs, and physical performance [11]. Another population-based study found an association between UI and IADL decline, but not ADL decline, nursing home admission, or death, after adjustment for age and comorbidity [10A]. The authors suggest that the relationship between UI and adverse outcomes may be mediated by baseline illness severity and functional impairment [10A].

2. IMPACT OF UI ON MORBIDITY AND INSTITUTIONALIZATION

UI in frail persons can have much more severe consequences than in healthy older persons. Although one early study suggested that older persons with UI had a higher mortality risk, [12] subsequent studies that more fully adjusted for comorbidity and functional status have not found any association [10A, 10, 13, 14]. Several multivariate studies suggest that patients with new onset UI at the time of stroke have higher rates of death or disability at 2 years (OR 4.43; 95% CI 1.76 to 11.2) [15] and 6 months (OR 3.21 [95% CI 1.04 to 9.91]), [16] especially if UI persists (OR 7.47 [95% CI 2.29 to 24.42]) [16].

Given its association with frailty, it is not surprising that UI remains a risk factor for nursing home admission, despite global variation in services and temporal changes in elder care. Studies showing a significant association between UI and institutionalization have been done in: Finland (men [not women] with urgency UI); [17] Germany; [18] New Zealand (persons ≥ age 65); [19] US (men more than women), [20] after hip fracture, [21] among Hispanic elderly, [11] and patients attending a dementia clinic [22]); and Japan (men only) [23]. Two studies failed to find a significant association after controlling for comorbidity, using US [10A] and Canadian databases [24]. It is estimated that the fraction of US NH admissions attributable to UI in men is 0.10 (95% CI 0.08–0.13) and in women 0.06 (95% CI 0.05–0.09) [25]. The prevalence of UI at NH admission in the U.S. shows small area variation of almost 50% and differs by race, [26] suggesting that patient and caregiver factors and local resources affect the role UI plays in institutionalization. An important methodological issue for such studies is
the erroneously low prevalence of UI in administrative long-term care databases when UI is defined by physician diagnosis in the medical record [27,28]. Another issue, particularly in studies of institutionalization in persons with dementia, is the failure to include UI as a risk factor [29] or defining it only by a composite function score [30].

IV. AETIOLOGY

1. BACKGROUND

As noted above, the aetiology of UI in frail older adults is grounded in the concept of a classic geriatric syndrome, involving multiple interacting risk factors, including age-related changes, comorbidity, and potentially common pathways between them. This section addresses all of these components.

2. QUALITY OF THE DATA

The data on the aetiology of UI in the frail elderly population is limited, and the Consultation does not grade the level of observational studies, which constitute much of this literature. Moreover, longitudinal studies of large numbers of frail individuals are difficult to carry out. Despite the lack of such studies, many relatively large, careful descriptive studies and case series, as well as expert consensus processes, have made important contributions to our understanding of the aetiology of UI in this population.

3. UI AS A GERIATRIC SYNDROME

In older adults, especially those who are frail, UI is considered to be a geriatric syndrome, because many of its risk factors are not directly related to the genitourinary tract [31, 32]. Geriatric syndromes have been defined as “multifactorial health conditions that occur when the accumulated effects of impairments in multiple systems render an older person vulnerable to situational challenges [31]. Thus, large numbers of different baseline as well as precipitating risk factors may interact with each other in influencing the ability of an older individual to remain continent in the face of common daily challenges (Figure 1). This multifactorial complexity, combined with the fact that most individual risk factors typically account for only a small proportion of the overall risk, have greatly complicated the development of a pathophysiological framework for the study of common geriatric syndromes [31].

Nevertheless, because common risk factors (e.g. lower and upper extremity weakness, sensory and affective impairment) may be shared by different geriatric syndromes (such as UI, falls, and functional dependence), [33] they may represent particularly attractive sites for intervention development [31]. For example, as proposed by Kuo and Lipsitz, [34] the presence of brain white matter hyperdensities within critical periventricular and subcortical regions could represent key risk factors for the development of different geriatric syndromes such as falls, impairment in executive cognitive function, depressive symptoms, and UI. In fact, recent functional magnetic resonance imaging (fMRI) studies have begun to identify central nervous system areas that are particularly relevant to an individual’s ability to suppress urgency [35-37]. Therefore, failure of activation within orbitofrontal regions may contribute to individuals’ decreased ability to suppress urgency [37]. Connectivity pathways within the right insula and anterior cingulate gyrus may also play a role maintaining continence, [36, 37] supporting the concept that declines in connectivity [38] and coordination [39] between different brain regions represent early critical events in aging. These findings suggest the possibility that interventions to prevent the development of white matter hyperdensities, such as control of vascular risk factors, could also prevent UI.

4. AGE-RELATED CHANGES RELEVANT TO UI IN THE FRAIL ELDERLY

Age-related changes in the LUT can function as risk factors for the development, continuation, and worsening of UI in frail elderly persons (Table 1). At the same time, they rarely are alone sufficient to cause UI, and in some persons have no effect on lower urinary tract symptoms (LUTS) or UI. Furthermore, the literature on “normal” LUT ageing has many potentially confounding methodological limitations. Normal ageing changes are difficult to study, because longitudinal data including large numbers of individuals spanning many years are necessary to definitively separate “normal LUT ageing” from confounding factors and comorbidity. Cross sectional studies are subject to confounding by comorbidity and time-dependent cohort effects, such as change in labour and delivery practices. Thus, to date many studies actually describe “age-related” associations, as opposed to normal ageing. Other limitations include: derivation of much of the cellular and neurochemical data from animal studies; morphologic studies based on cadavers with unknown parity, comorbidity, and LUT symptoms; “age-effects” derived from studies of symptomatic persons; and use of surgical patients at tertiary centres as “normal” controls. Even the definition of “normal” can be difficult: is it continence, absence of LUTS, lack of comorbid disease, or normal physiologic testing? [40] The following sections focus on findings from more robust and, where possible, confirmatory studies.

a) Bladder

Understanding age-related changes in the bladder is complicated by a paucity of longitudinal data, variable definitions of “normal,” and use of potentially biased (and symptomatic) referral populations. It is difficult to isolate such factors as the role of decreased blood flow, poor voiding habits, comorbidity, central and peripheral

Figure 1: Mechanistic Model of Geriatric Syndromes. Traditional pathophysiological models are based on a linear relationship proceeding from risk factors to early disease and then advanced disease (A), with prevention and treatment (red) directed at the causative risk factor. These models, while effective for many conditions, do not address the multifactoral nature of geriatric syndromes. Cancer researchers have used an alternative “concentric” model (B), in which a set number of risk factors (e.g., oncogenic pathways) lead to the clinical phenotype, and can become targets for therapy. This model also is insufficient for geriatric syndromes. Targeting individual RFs is unlikely to be effective because each RF accounts for only a small portion of the overall risk of disease. Geriatric syndromes are best described by an interactive concentric model (C), in which multiple risk factors likely interact with one another and (either common or separate) modulating factors. Interventions may be best targeted at those points that alter “downstream” risk factors [adapted from reference 31].
nervous system innervation, and reflex patterns as determinants of bladder function in older persons [41]. The research focus has been urodynamic function, neurohumoral responsiveness of detrusor smooth muscle, and ultrastructure. While the key role of the urothelium and afferent systems on micturition are increasingly appreciated (See Committee 2, Cell Biology; Committee 3, Neural Control; and Committee 4, Pathophysiology), there are only limited human data on urothelial changes with age.

Urodynamic changes associated with age typically include smaller voided volume, increased residual volume, smaller bladder capacity, and increased involuntary detrusor contractions (detrusor overactivity [DO]). Correlations with age are often small, suggesting that other factors are at least as important [42]. Urodynamic findings may not relate to symptoms: in a urodynamic study of community-based healthy persons over age 55, [40] DO was found in 42% of continent women, one-third of whom were totally free of LUTS. Within this older healthy cohort the prevalence of DO did not increase with age. Notably, completely normal urodynamic studies were found in only 18%. Nevertheless, in a cross-sectional study involving ambulatory, cognitively intact, community-dwelling older female volunteers, maximum urethral closure pressure, detrusor contraction strength, and urine flow rate all declined significantly with age, regardless of whether DO was present or not [43].

Detrusor contractility also declines in healthy older men who have no evidence of bladder outlet obstruction (BOO) or significant confounding disease [40]. A variety of different risk factors associated both with ageing and common comorbid conditions may contribute to age-related declines in detrusor contractility, which may ultimately lead to detrusor underactivity [44]. Decreased contractility during voiding in older persons is associated with lower urine flow rates and a small increase in postvoiding residual volume (PVR) (generally < 50 ml) [45]. Even in men with BOO, an elevated PVR may reflect decreased bladder contractility rather than obstructed voiding [46]. While some studies suggest a myogenic origin of impaired contractility, others suggest that impaired blood supply, with concomitant ischemic-reperfusion injury causing patchy denervation, leads to decreased contractility (see Committee 3, Neural Control). Incomplete bladder emptying from all causes can reduce functional bladder capacity, and thereby contribute to the urinary frequency and nocturia common in frail older persons [44].

The observation that bladder volume at the initial desire to void declines with age [48] may have been confounded by comorbid conditions and concurrent medications. Furthermore, unlike the positive association between detrusor contraction strength and DO found in younger subjects, older adults fail to demonstrate this DO-associated increase in detrusor contractility [49]. Moreover, many frail older persons with UI present with a combination of DO on filling and poor contractility during voiding, a condition termed detrusor hyperactivity with impaired contractility (DHIC) [44, 50]. In such cases, the bladder contraction does not empty the bladder fully, leaving a large PVR otherwise not explained by BOO. Because DHIC symptoms can include urgency UI, stress and mixed UI, dribbling, frequency, and nocturia, they may be mistaken for other conditions. At the same time, DHIC may be mistaken for DO with normal contractility because significant detrusor underactivity may be present in the absence of any relevant symptoms.

Ultrastructural studies demonstrate cellular changes associated with age-related changes in detrusor function. One series of such studies involved symptomatic and asymptomatic persons aged 65 to 96, using urodynamic testing and electron microscopy of bladder biopsy specimens, which were read in a blinded fashion using explicit protocols [45, 51-57]. A consistent, one-to-one correlation between specific urodynamic findings and bladder ultrastructure was observed. Patients with urodynamic DO had a “dysjunction pattern” with “protrusion junctions” and “ultra-close abutments.” The latter were postulated to be the anatomic explanation for the propagation of involuntary detrusor contractions in older patients. Patients with impaired bladder contractility had fibrosis with widespread degeneration of detrusor muscle and axons. A subgroup of patients had both types of pathology and urodynamic DHIC [50]. In the small number of asymptomatic patients with no DO, normal contractility, and no obstruction, detrusor muscle fascicles were largely intact, with two distinctive ultrastructural findings that may be related to ageing alone: muscle cell membranes characterized by numerous “dense bands” and markedly depleted caveolae, and slightly widened spaces between muscle cells with limited content of collagen and elastin. Depletion of caveolae may be related to de-differentiation of muscle cells, which could eventually result in the reversion of actively contractile cells to inactive, synthetically immature cells. A similar phenomenon has been reported in atherosclerotic blood vessels and postmenopausal myometrium, and may be related to reports of increased collagen in bladders from older women [45, 58]. Moreover, lack of oestrogen contributes to, and oestrogen replacement reverses, both caveolar depletion [59] and detrusor fibrosis [60]. Thus, both ageing and postmenopausal decline in oestrogen levels may contribute to bladder muscle cell differentiation and contractility [44].

The natural history of these ultrastructural changes remains largely unknown. From the ultrastructural studies described above, a subset of 23 patients was followed longitudinally [54]. The previously observed
one-to-one correlation between ultrastructure and function was maintained, but it was unclear whether urodynamic or ultrastructural changes occurred first in subjects who developed or had a change in LUTS. The pattern of dense-bands and nondisruptive muscle cell degeneration varied over time: the DO with dysjunction pattern developed in some subjects, and impaired detrusor contractility and the corresponding degeneration pattern was observed to progress in severity or develop. Other investigators have found similar results but without the one-to-one correlation (e.g., see Brierly et al [61]).

b) Urethra

Due to their common embryological origin, the urethra undergoes age-related mucosal and stromal changes similar to the vagina, and urethral changes in older women can be partially inferred from examination of vaginal tissue. Because of the difficulty of obtaining non-cadaveric urethral tissue, data on urethral smooth and striated muscle changes with age are complicated by confounding factors and definitions of controls.

Urethral closure pressure decreases with age [62, 63]. Based on a sample of 82 women aged 20-70, urethral closure pressure was found to decrease by 15 cmH2O per decade [64]. A number of anatomical and physiologic changes may account for this decline. Mucosal thinning and lack of proteoglycans reduce urethral wall apposition; this also may contribute to retrograde movement of perineal bacteria into the bladder causing urinary tract infections [65]. These mucosal changes may extend up to the bladder trigone, causing irritation of sensory afferent nerves, and possibly triggering DO [66]. The submucosal venous plexus in the proximal urethra loses its corkscrew shape, the number and volume of arterial vessels decrease, and vascular pulsations lessen [67]. Several studies, using different measurement techniques, have shown that urethral vascular density and blood flow decrease with age, but not vascular flow velocity [68-70]. However, age explained only 9% of the variability in vascular density in one study, [68] and none of the studies controlled for vascular risk factors such as hypertension and diabetes. The relative importance of decreased vascular volume versus hypoxia on urethral functional integrity is unclear. Other alterations in the urethral stroma are increased volume of connective tissue, decreased ratio of proteoglycans to collagen, and decrease in nerve density [71, 72].

Cadaver studies suggest that the number and density of urethral striated muscle fibres decrease with age, especially in the ventral wall of the proximal urethra [73, 74]. These authors estimated that striated fibers decrease by 1% per year. Large inter-individual variations were observed, with age and parity accounting for only a small part of the variability, suggesting that other yet to be defined factors are important. These studies also found that cross-sectional striated muscle fibre area decreased while fibre diameter was preserved. Another cadaver study by the same group found that circular smooth muscle width was 25%-50% higher in younger women (aged 20-39 years) than older (aged 70-89), and that younger women had higher fibre counts [75]. Smooth muscle loss in the older women correlated with loss of striated muscle in the anterior urethra.

Urethral sensation, measured as current perception thresholds, was significantly impaired in older women in two studies (by the same authors), one comparing 48 asymptomatic women and 13 with urgency UI, [66] and another in asymptomatic women [76]. The authors concluded that age-related LUT sensory neuropathy could contribute to the higher prevalence of overactive bladder (OAB) symptoms with age; however, urethral sensation thresholds were higher in women with urgency UI when controlled for age and parity, [66] and the “asymptomatic” older women may have had urodynamic DO [76].

With age, the urethral meatus generally moves toward the vaginal introitus, and may be difficult to see if there is considerable introital stenosis. Caruncles—benign violaceous soft swellings—often appear at the meatus, and are not problematic unless they cause discomfort or obstruction. Urethral diverticula can be a diagnostic challenge, especially in older women, because the symptoms (dysuria, pain, UI, frequency, urgency, dyspareunia) may be attributed to postmenopausal changes, age, OAB, or urgency UI [77]. Diverticula should be considered in women who have repeatedly failed “conventional” UI treatment. Diagnosis requires imaging by either voiding cystourethrography, ultrasound, or magnetic resonance scans.

Urethral obstruction is relatively uncommon in older women, and is nearly always secondary to other LUT dysfunction (e.g., pelvic organ prolapse) or is iatrogenic (from LUT/pelvic surgery or radiation).

In men, age-related decrease in striated sphincter muscle cell density occurs as well, [78, 79] and has been associated with increased muscle cell apoptosis [78]. While some investigations describe an increase in resting prostatic urethral pressure with age, [80] others note the increase occurs only to the sixth decade then subsequently decreases, along with a shortening of sphincteric urethral length [81]. These discrepancies may reflect differences in prostate volume and morphology.

c) Pelvic floor

Pelvic floor changes in normal older men have not been well studied. In women, the effect of age on pelvic floor structure and function is difficult to differentiate from the effects of hormonal status and parity. A number of studies are cross-sectional rather
than longitudinal, and focus on symptomatic women. For example, a questionnaire study of over 4,000 community women aged 25-84 found no association between age and stress UI (SUI), OAB, or anal UI, after adjustment for obesity, birth history, menopause, and hormone use [82]. Similarly, in a random sample of 343 Austrian women aged 18-79 years, impaired pelvic muscle contraction (graded by the Modified Oxford Scale) was weakly associated with parity and body mass index but not age [83]. Evidence of denervation and changes in pelvic striated muscle fibre number, type, and diameter have been found in asymptomatic and nulliparous women (see Committee 2, Cell Biology). For example, in a sample of 82 nulliparous women, neither levator function (measured by resting vaginal closure force and augmentation of vaginal closure force) nor pelvic organ support (on pelvic exam) showed an association with age [64]. A histomorphometric study, using levator ani muscle from 94 female cadavers (aged 15-58), 10 male cadavers (aged 23-35), and 24 women undergoing pelvic surgery, found that myogenic cell damage was associated with both parity and age (</> age 35), but there was no difference between nulliparous women, men, and women with pelvic organ prolapse and/or UI [84]. Total collagen content in pelvic muscle and fascia declines with age, with increased cross-linking and decreased elasticity, [85] but this association does not imply a direct causative effect of “ageing.” Constipation may independently contribute to pelvic floor dysfunction in older women [86, 87].

d) Vagina

The prevalence of age-related changes in the vagina varies with hormonal status, coexistent vascular disease, and the continuation or lack of sexual activity [88]. The postmenopausal decrease in oestrogen plays a part in many age-associated vaginal changes. Oestrogen is trophic for much of the LUT track in women, with oestrogen receptors found in the vagina, vestibule, distal urethra, bladder trigone, pelvic muscles, and ligamentum rotundum [89]. Yet, as the Women’s Health Initiative trial has shown, [90 91] one cannot assume that the association between low oestrogen levels and physiological changes implies that hormone replacement will reverse these changes, restore function, or reduce symptoms. Moreover, the data are equivocal whether and how LUT oestrogen receptors change in number, density, or function with age [67].

Following menopause, the vaginal epithelium loses the majority of its superficial and intermediate layers. Mucosal thinning may be associated with inflammation, evident as erythema, telangiectasia, petechiae, friability, and erosions. This may be responsible for urgency and frequency in some frail elderly women. In addition, there is loss of epithelial glycogen and lubrication, and mucosal pH increases from 4.5-5.5 to 7.0-7.4 [67]. These changes can lead to loss of normal adherent flora (lactobacillus), colonization with pathogenic organisms such as E. coli and enterococci, and the observed increase in bacteriuria and recurrent symptomatic urinary tract infections (UTIs) in older women [92].

Vaginal blood flow, which is important for mucosal integrity and submucosal fullness, decreases with age [67]. Whether this is oestrogen-related, and/or due to concomitant vascular disease is not known. Collagen and lipofuscin deposition in the stroma increases, and may be accompanied by invasion by lymphocytes and plasma cells [67]. The combined epithelial and stromal changes are associated with vaginal wall thinning and flattening of rugae [89]. The vaginal vault may shorten and narrow, and the introital opening decrease (and in severe cases become stenotic), which may make vaginal examination, intercourse, and use of pessaries difficult. However, it is not clear that vaginal shortening is clinically relevant: in one case series of over 3,000 women attending a general clinic, total vaginal length decreased by only 0.08 cm every 10 years [93]. Vaginal shape also may be altered by POP.

Because of the multiple potential confounding factors discussed above, a causal relationship between urogenital atrophy and urogenital symptoms/LUTS should not be automatically assumed. Very few randomized trials of oestrogen (oral or topical) for urogenital symptoms include women over age 75, use patient-defined outcomes in addition to physiological measures, or evaluate quality of life outcomes [94]. There are insufficient data to provide an evidence-based approach to symptomatic urogenital atrophy in older women. Oral oestrogen should not be used, but expert opinion supports topical oestrogen treatment (cream, intravaginal tablets, or oestrogen-impregnated pessary-like ring).

e) Prostate

Histological benign prostate hyperplasia (BPH) is strongly age-related, [95] and may lead to prostate enlargement (BPE) and outlet obstruction (BOO). While many LUT changes in women are associated with lower oestrogen levels, BPH results from the development of an oestrogen-predominant hormonal milieu in the prostate. The trophic prostatic androgen, dihydrotestosterone, is formed by the 5 - reduction of testosterone. Dihydrotestosterone levels decrease with age, while estradiol concentrations increase in the prostate stroma and remain constant in epithelial tissues, leading to an increase in the estradiol/dihydrotestosterone ratio [96, 97] and promoting stromal proliferation. Epithelial hyperplasia in turn is mediated by an array of stromal factors [98].

Histological BPH occurs in nearly 80% of men by age eighty [95]. Mean prostate volume increases with age but is very variable; its strongest predictor is prostate
specific antigen level of >1.4-2 ng/mL [99]. LUTS in men increase linearly over time, with the fastest increase during the seventh decade, such that by age 80 approximately one-third of men have received treatment for moderate to severe LUTS [100]. Natural history studies and randomized intervention trials, however, consistently demonstrate that symptomatic progression of benign prostate disease is not inevitable. LUTS remits in about one-third of symptomatic men without treatment [101]. Approximately one-third to one-half of affected men develop DO [102]. Thus, even in the presence of demonstrable BPE and/or BOO, the aetiology of LUTS is multifactorial, making prostate-related LUTS in older men a diagnosis of exclusion.

Although most patients are asymptomatic at the time of prostate cancer diagnosis, this is another possible cause of LUTS, including urgency UI, in older men. However, evaluation for prostate cancer in frail elderly men is rarely if ever indicated, given the high likelihood of limited remaining life expectancy.

The evidence is contradictory as to whether prostatic inflammation, either acute or chronic, contributes to urinary retention and LUTS in frail older men. In a single institution case series of 374 men undergoing TURP for acute urinary retention (AUR) or LUTS, pathological evidence of acute inflammation was significantly more common men presenting with AUR than LUTS (70% vs. 45%) [103]. However, in a much smaller case series of 70 men presenting with AUR, there was no association between inflammation from prostate infarction and AUR [104].

f) Other changes

The role of various neurotransmitters in the central and peripheral nervous system in UI is under active investigation (see Committee 2, Cell Biology). Nevertheless, age-related changes in the actions of these neurotransmitters, their receptors, or the cellular events they stimulate may contribute to the development of UI in frail older persons.

The prevalence of both asymptomatic bacteriuria and UTIs increase with age, [92] and the two are often found together in the frail elderly. Age-related changes in immune function, vaginal epithelium, faecal incontinence, and insufficient hygiene related to disability, cognitive impairment, and/or lack of caretakers may predispose the frail elderly to bacteriuria and recurrent UTIs. However, the role of otherwise asymptomatic bacteriuria (often found in association with pyuria), [105] in the aetiology of UI in frail elderly people remains unclear [106]. Treating otherwise asymptomatic bacteriuria in frail elderly patients with chronic, stable UI does not, in general, reduce UI severity [107]. UTI symptoms may be subtle and non-specific in this population, and include worsening of UI, altered mental status in patients with dementia, decreased oral intake, or a minor but important decline in functional ability [106]. At the same time, current consensus criteria for UTI are poorly sensitive and only fairly specific for UTI in frail elderly. In a prospective cohort of 340 nursing home residents, in which UTI was defined as pyuria (>10 white cells) with >100,000 colony forming units on culture, the McGeer, Loeb, and revised Loeb UTI criteria had sensitivities of only 19-30% and specificities of 79-89% [92].

5. FACTORS OUTSIDE THE LOWER URINARY TRACT CAUSING OR CONTRIBUTING TO UI

A hallmark of UI in the frail elderly population is the wide variety of factors and conditions outside the lower urinary tract that can cause or contribute to leakage (Table 2).

a) Comorbid medical illness

Numerous comorbid conditions are common in frail elderly with UI, and many patients have multiple such conditions. For example, in a large population-based observation study, [108] UI (defined as use of pads) was independently associated with one or more other geriatric conditions (cognitive impairment, injurious falls, dizziness, vision impairment, hearing impairment) in 60%, two or more conditions in 29%, and three or more in 13%. Comorbid conditions can affect continence through multiple mechanisms: e.g., diabetes mellitus, present in approximately 15-20% of frail elderly, may cause UI by diabetes-associated LUT dysfunction (DO, cystopathy), poor diabetic control (causing osmotic diuresis and polyuria), medications (see below), and/or diabetes-associated comorbidity (e.g., constipation) and impairment (amputation, vascular dementia).

b) Neurological and psychiatric disorders

Neurological and psychiatric disorders are highly prevalent in the frail elderly population. Stroke, dementia syndromes (most commonly Alzheimer’s disease, multi-infarct dementia, or a combination of the two [109]), and Parkinson’s disease can each contribute to UI through multiple mechanisms. First, these disorders may affect the brain’s pontine micturition centre and frontal lobes, and interfere with the normal ability to inhibit voiding. Second, each of these disorders can impair cognition. And third, each can impair mobility, and interfere with the ability to toilet independently. Frail older persons with these neurological conditions usually have multiple impairments and are at high risk for worsening disability. For example, in a UK cross-sectional survey of over 15,051 subjects, persons with cognitive impairment (MiniMental State Exam score ≤ 23, prevalence 18%), were significantly more likely to have UI (odd ratio [OR] 1.3), impaired hearing (OR 1.7), poor vision (OR 1.7), have had at least two falls in the previous six months (OR 1.4), and report poorer

</table>
health (OR 1.9) [110]. Older persons with cognitive impairment have a nearly 6-fold increased risk of developing UI when they are hospitalized [111]. However, not all patients with neurological conditions causing cognitive impairment develop UI: in a six year longitudinal study, cognitive decline had only borderline association with UI, and only with UI that interfered with activities [112].

With the introduction of magnetic resonance brain imaging into routine clinical practice, radiology reports in older patients have increasingly emphasized the presence of structural abnormalities involving the white matter [113]. Terminology has also undergone a great change, moving away from subcortical atherosclerotic encephalopathy (a specific and relatively rare form of dementia), towards leukoaraiosis and, most recently, to the concept of white matter signal abnormalities (WMSA) [113, 114]. As noted above in Aetiology, recent fMRI studies [35, 37] demonstrate failure of activation within orbitofrontal regions in older persons with urgency UI, possibly contributing to a decreased ability to suppress urgency [37]. To date, there are no published studies of quantitative regional assessments of WMSA within these critical regions. While a dichotomous diagnosis of “cerebral white matter lesions” provided by a radiologist demonstrated no relationship to the presence or absence of UI, [115] a semi-quantitative measure of global WMSA appears to be associated with increased urgency UI and nocturnal frequency [116].

Normal pressure hydrocephalus should be a diagnostic consideration in any frail elderly patient who presents with new onset of UI in association with gait disturbance and cognitive impairment. A subset of these patients benefits from surgical implantation of a cerebrospinal fluid shunt [117].

LUTS, UI, and urodynamic DO are common in older persons with Parkinson’s disease, yet they may be related more to age and comorbidity than Parkinson’s-specific CNS pathophysiology [118-120]. The presence of UI in persons with Parkinson’s may in turn increase their risk for disability: in one series of patients with Parkinson’s, UI increased the risk of falling by nearly six-fold [121].

c) Depression

As in younger persons, frail elderly with UI have a higher risk of depression, a finding that has been replicated across cultures. Depression in older persons with UI may be under-diagnosed and under-treated: in one study of homebound adults with UI and severe depression, only 35% carried a previous diagnosis of depression and only 34% had been prescribed an antidepressant [122]. UI may add to the burden of depression by decreasing life satisfaction [123, 124] and self-rated health, [125] and by its association in frail elders with comorbidity [126].

Studies of the association of depression and UI in older persons are consistent across several depression measures. The validated Center for Epidemiologic Studies-Depression was used in two U.S. studies: a cross-sectional analysis of nearly 10,000 community-based persons (adjusted risk ratio for depression with UI 1.39 [95% CI 1.24, 1.55]), [127] and a large community-based study of older Mexican Americans (adjusted OR for depression 1.94 [95% CI 1.46-2.59]) [128]. Other multivariate studies finding significant associations between depression and UI in older patients used the Beck Depression index, [129] the

UI = urinary incontinence
emotional disturbances and social isolation subcales of the Nottingham Health Profile Questionnaire, [130] and have included studies in Asia [131]. Although no association between UI and depression was found in a Korean study, it used a higher cut-off on the Geriatric Depression Scale and, unlike many other studies, found no association between UI and mobility [132]. Self-report of sadness has [133] and has not been associated with UI [134]. Psychological distress, assessed by the General Health Questionnaire, was associated with UI in African Americans (adjusted OR 5.60 [95% CI 1.88–16.67]), but not in whites, in a cross-sectional study of community based older persons with mean age 67 [135]. However, a longitudinal analysis of the same population over 13 years found that persons with UI and psychological distress were more likely to report UI-specific functional impairment (e.g., avoidance of social activities, shopping, and physical activities) (adjusted OR 6.55 [95% CI 1.94–22.12]). Additionally, persons with UI and condition-specific functional loss were more likely to develop psychological distress (OR 3.66 [95% CI 1.61–8.33]).

The direction of the causal relationship between UI and depression in frail persons is unclear, as nearly all of these studies were cross-sectional. The results of the one longitudinal study suggested that it is not UI itself but UI-specific functional loss (e.g., avoidance of social activities, attending church, etc.) that is most closely associated with psychological distress, even after controlling for important covariates [122].

d) Medications

Older persons consume the majority of prescription medications and are therefore at greater risk of experiencing adverse events associated with their use. The risk of difficulty in controlling urination in community dwelling older women taking medications with LUT effects was about 30% higher compared to those who did not take such medications (OR 1.31 [95% CI 1.05–1.21]) [136]. UI was independently associated with antianxiety/hypnotic medications in one large sample of US nursing home residents [109]. Many classes of medications commonly prescribed for the frail elderly can cause or contribute to the development of UI (Table 3). The possibility that UI could be caused by a medication should be taken into account before prescribing drug treatment for UI in older persons.

e) Functional impairment

Impaired functional ability is a common pathway by which several medical and neuropsychiatric disorders cause or contribute to UI in frail elderly (see above). Impaired mobility can preclude a frail older person with urinary urgency from reaching the toilet in adequate time to prevent UI. The apraxia associated with moderate to severe dementia can interfere with independence in toileting and hygiene. Visual impairment is common in frail elderly, and may affect the ability to toilet independently.

Numerous studies support a close association between functional impairment and UI in frail elderly [33, 109, 137-141]. For example, UI was significantly associated with perceived limitations in usual role activities among community-based older persons [142]. In a longitudinal population-based study of older Mexican-Americans, prevalent UI was associated with an almost 60% increased risk of difficulty walking 8 feet (nearly 3 metres), and incident UI was associated with a two-fold increased risk for difficulty with ADLs and IADLs, as well as poor performance on three physical performance tasks [11]. Older women who experience a significant decline in physical performance over six years were more likely to report weekly UI (OR 1.31-1.40, depending on the physical measure) [112]. In the Health and Retirement Study, a population-based observational study of Americans aged ≥ 65 living in the community and nursing homes (n =11,093), UI sufficient to require pads was independently associated with multiple impairments, including toileting (OR 2.9 [95% CI 2.3–3.4]), transferring (OR 2.8 [2.4–3.2]), dressing (OR 2.3 [2.0–2.6]), eating (OR 2.1 [1.8–2.4]), bathing (OR 2.0 [1.8–2.2]), and dependency in one or more ADLs (OR 1.9 [1.7–2.0]) [108]. Among NH residents in one US state, both baseline UI and FI were associated with ADL loss over one year (for UI, adjusted OR 3.1; for FI, adjusted OR 2.9; combined UI-FI (adjusted OR 3.4) [143].

UI may have particular prognostic implications after stroke. Among Italian stroke patients admitted to home care program after post-acute rehabilitation, those with UI were more likely have a significant decline in physical function at one year (OR 1.64 [95% CI, 1.01-3.29]) [144]. Similarly, stroke patients admitted to a Spanish multidisciplinary geriatric rehabilitation unit who had UI on admission made less functional gains in mobility and self-care [16].

International studies demonstrate a bi-directional association between UI and falls, including those resulting in fractures. In a study of elderly women using day-care services in Japan, mixed UI (but not urgency or stress alone) was associated with falls over one year (RR 3.05 [95% CI 1.01-10.2]) [145]. Baseline UI was an independent risk for falls in longitudinal studies of frail elders in residential care in Australia, [146] long-term care in Germany, [147] and in the community in the Netherlands [148]. There is a significant association between UI and fractures as well. Supporting studies include: a secondary analysis of an observational study of community-dwelling women in the US (adjusted relative hazard ratio for non-spine nontraumatic fracture 1.34 [95% CI, 1.06-1.69]); [149] a cross-sectional analysis of the Canadian National Population Health Survey; [150] a cross-sectional analysis of older women attending a

UI = urinary incontinence
We could find no evidence-based guidelines for the optimal assessment and management. Professionals, and caretakers is usually necessary geriatricians, surgical specialists, nurses, other health collaboration among primary care physicians, identifying all potential contributing factors. A comprehensive assessment with the goal of the frail elderly is multifactorial, it is essential to conduct elderly persons with UI are summarized in the prevention of UI. Clothing also may be altered to make toileting easier (e.g., Velcro fasteners and pants with elastic waist bands rather than buttons and zippers).

Recommendations for the basic assessment of the frail elderly persons with UI are summarized in the Algorithm (see Summary Document). Because UI in the frail elderly is multifactorial, it is essential to conduct a comprehensive assessment with the goal of identifying all potential contributing factors. Collaboration among primary care physicians, geriatricians, surgical specialists, nurses, other health professionals, and caretakers is usually necessary for optimal assessment and management.

We could find no evidence-based guidelines for the assessment of UI in frail elderly. The United Kingdom (UK) NICE guidelines for UI in women do not address the assessment of frailer elderly women [155]. The US Agency for Health Care Policy and Research Clinical Practice Guideline on UI is significantly out of date (last revision 1996). The US government sets minimum quality standards for UI assessment and management in long term care, but these standards, along with basic fundamental principles of UI, are poorly understood by long term staff [156]. Two groups, the US Assessing Care of Vulnerable Elders (ACOVE) project and the UK Clinical Effectiveness and Evaluation Unit, have developed quality performance measures for UI care in frailler older persons, using structured literature review and expert panel review [157-160]. These measures are not guidelines per se, and in some instances lack sufficient detail. Unfortunately, both groups have demonstrated using their measures the poor quality of UI assessment and care by community practitioners in the US and the UK, including inadequate integration of continence services. Thus, there is an urgent need to re-establish the fundamentals of UI assessment and management for all personnel who care for frail older persons with UI.

1. COMPONENTS

a) Identification of frail older persons

Health care providers can screen older patients with UI for frailty using the Vulnerable Elders Survey, which can be administered in person or by phone (Table 4) [161]. Persons with a score of 3 or greater have four-fold increase in the risk of death and functional decline compared with persons with lower scores.

b) Primary care assessment

Geriatricians’ and primary care physicians’ (PCPs) UI assessments were compared in a randomized multicentre study involving 364 subjects, 42% of whom self-reported UI to the investigators. Geriatricians were significantly more likely to detect UI (59% of cases vs. 16%), regardless of the severity of UI, and were more likely to refer to Continence Programs (25%); all referrals by PCPs were to urologists [162]. An assessment strategy based on clinical evaluation, simple cystometry, and several criteria for referral was compared with urodynamic diagnosis. Approximately 25% of patients met criteria for referral, half of patients accepted urodynamic evaluation, yet urodynamics changed the treatment plan in only 12% of the patients who did not met the a priori criteria for referral [163].

Practice patterns and adherence to US UI guidelines were evaluated by retrospective chart review of 300 consecutive patients aged ≥ 65, seen by either an internist or geriatrician for UI at a tertiary care centre. Geriatricians ordered more testing, such as urodynamics, before referring patients to a surgical specialist [164]. Overall, primary care practitioners rarely follow the US Agency for Healthcare Research and Quality UI guidelines, [165] and nursing home practitioners rarely follow the Federal guidance for UI care regarding recommended physical examination, PVR testing, uranalysis, and identification of potentially reversible causes [166].

Systematic review of articles identified only 5 studies meeting eligibility criteria, and all were in women. None of studies found sufficient diagnostic evidence (defined as positive > 5 and negative likelihood ratios < 0.02) for different types of UI. The best was a general population study reporting the utility of history and exam for the diagnosis of SUI (positive and negative likelihood ratios 3.23 and 0.40, respectively) [167].
Table 4. Vulnerable Elders Survey (VES-13): see text for scoring

1. Age_____ (1 point for age 75-84, 3 points for age 85 or greater)

2. In general, compared to other persons your age, would you say that your health is:
   A. Poor (1 Point)
   B. Fair (1 Point)
   C. Good
   D. Very Good, or
   E. Excellent

3. How much difficulty, on average, do you have with the following physical activities: (SCORE 1 POINT FOR EACH BOLD RESPONSE, MAXIMUM OF 2 POINTS)

4. Because of your health or a physical condition, do you have any difficulty: (SCORE 4 POINTS FOR ONE OR MORE YES RESPONSES IN THIS SECTION)

   A. Shopping for personal items (like toilet items or medicine)?
      o YES>> Do you get help with shopping? YES NO
      o NO
      o DON'T DO: Is that because of your health YES NO

   B. Managing money (like keeping track of expenses or paying bills)?
      o YES>> Do you get help with managing money? YES NO
      o NO
      o DON'T DO: Is it because of your health? YES NO

   C. Walking across the room? (USE OF CANE OR WALKER ALLOWED)
      o YES>> Do you get help with walking YES NO
      o NO
      o DON'T DO: Is that because of your health? YES NO

   D. Doing light housework (like washing dishes, straightening up, or light cleaning)?
      o YES>> Do you get help with light housework? YES NO
      o NO
      o DON'T DO: Is that because of your health? YES NO

   E. Bathing or showering?
      o YES>> Do you get help with bathing or showering? YES NO
      o NO
      o DON'T DO: Is that because of your health? YES NO
c) **Cough stress test**

Utility of the cough stress test was studied in 97 incontinent female long-term care residents using blinded comparison with single channel cystometry. Of the 77% in whom single channel cystometry diagnosis was congruent with the stress test (i.e., urodynamic DO with negative cough test, no DO and positive cough test), all were correctly classified; no woman with SUI was missed nor were any with DO misclassified [168]. An analysis 200 older women with UI found that provocative full-bladder cough test was as effective as radiographic or urodynamic pressure measurement in detecting SUI. Clinical diagnosis incorporating the cough test with leakage symptoms was 78% accurate, with only 6% false negatives for SUI, but was only 44% accurate with 45% false negatives for urgency UI [169].

d) **Postvoiding residual measurement**

We identified no studies evaluating the impact of PVR measurement on clinical diagnosis and treatment outcomes. Frail elderly may have a higher prevalence of elevated PVR, especially in association with DHIC. One study of 100 patients consecutively admitted to a geriatric ward found that 34% had PVR > 50 mL; these patients tended to have more UI (57% vs. 38%, p >.05), greater functional dependency, and a higher mortality rate (36% vs. 9%) [170].

However, the prevalence of elevated PVR in community dwelling frail elderly, especially those without associated disability or comorbidity, is not known.

e) **Urodynamic testing**

Urodynamic testing is feasible and safe, even in frail nursing home residents [171]. There is no evidence, however, that urodynamic diagnosis changes the outcome of treatment. Expert guidelines have recommended urodynamic testing before surgical or minimally invasive UI treatment in frail elders [172].

6. Urodynamic testing is feasible in frail elderly (Level 1) but it is unlikely change management or outcomes except in frail persons considered for surgical treatment of UI (Level 4)

### 3. RECOMMENDATIONS FOR EVALUATION (SEE ALGORITHM)

The essential first step is to screen all frail elders for UI, as the condition may be underreported across settings. The second is to identify treatable, potentially reversible conditions and other factors (medications, environment) that can cause or contribute to UI. Although UI associated with such factors has been commonly called “transient UI,” most frail elderly with UI have it as a chronic and often progressive condition. It is important to evaluate for such contributing factors because their amelioration may improve UI directly, make UI more amenable to other interventions, and overall improve the patient’s (and carer’s) quality of life [173].

Tables 2 and 3 list the common, treatable, potentially reversible conditions that can contribute to UI in frail older people. A mnemonic, “DIAPPERS” (delirium, infection [urinary tract], atrophic vaginitis, pharmaceuticals, psychological, excess fluid (in/out), restricted mobility, and stool impaction [and constipation]), has been commonly used to teach and remember these conditions [174]. However, treatment of two of these elements, atrophic vaginitis and UTI, may not improve UI (see Treatment section) and over-treatment of what is actually asymptomatic bacteriuria as UTI can lead to serious adverse outcomes (resistant organisms, secondary infections such as *Clostridium difficile*).

### VI. FACTORS IN MANAGEMENT

#### 1. BACKGROUND

This section, introduced in the 3rd ICI, highlights the issues that distinguish management of UI in frail elderly persons from that of healthier older adults. These include preferences for care, goals of care, determination of costs and benefits, special issues in drug treatment and issues unique to frail elderly men. They incorporate knowledge of physiological, psychological, sociological, and economic changes associated with frailty and advanced age, and reflect the importance of patient-centred goals and the role of caregivers in this population. These factors provide the context of continence care and should be incorporated into the management of all incontinent frail persons, *regardless* of the choice of specific treatment.
2. ROLE OF COMORBIDITY IN MANAGEMENT DECISIONS

Many frail elderly have concomitant disability and comorbidity, both of which can influence the clinical presentation and assessment of UI, as well as responsiveness to interventions. Frail older persons are not only at higher risk for unintended adverse effects from treatment (e.g., fulminate *Clostridium difficile* colitis from antibiotics used to treat otherwise asymptomatic bacteriuria in the setting of UI), but also may realize additional benefits in domains other than UI [173] from UI treatment that is aimed at underlying comorbidity and impairment (e.g., topical oestrogen for irritating atrophic vaginitis reduces recurrent UTIs; a nursing home exercise programme done in the course of toileting improves both physical function and UI [4]).

3. DEFINING OUTCOMES FOR TREATMENT

Outcome measures for frail older persons with UI must be fundamentally different from those used in healthy older persons, because of the heterogeneity of this frail population regarding comorbidity, remaining life expectancy (RLE), patient perceptions, personal values, and the involvement of caretakers and proxy decision makers. Unfortunately, intervention studies in the frail elderly remain focused on UI frequency and not these factors, and comorbidity is frequently used as an exclusion criteria in therapeutic trials. Also, there are no data on patients’ or carers’ expectations for the outcome of UI therapy.

Although quality of life (QoL) is a key concern for UI in all persons (see Committee 5, Initial Assessment Including Quality of Life), and has special relevance in the frail elderly with limited RLE, there are few validated QoL outcome measures applicable to this population. Only one validated UI-related QoL measure is derived specifically from patient-based data among persons older than 65, and these subjects were community-dwelling and relatively healthy [175]. None of the ICI-endorsed UI-related QoL measures have been validated in oldest-old or cognitively and/or functionally impaired persons. Traditional UI QoL domains—e.g., impact on IADLs, travel, sexual relations—are often not relevant to frail elderly, and there could be significant “floor effects” for social and role function domains. One alternative QoL domain for frail elderly is social interaction, especially for nursing home residents; [176] an analysis of cross sectional and longitudinal data from over 100,000 US nursing home residents found that prevalent and especially incident UI had negative impact on social interactions, particularly among persons with moderate ADL impairment [176].

The profound question when considering UI outcomes in frail older persons is, Is cure possible? The short answer is: it depends on patient factors, specific treatment(s), and the target outcome. While no geriatrician endorses “ageism” and therapeutic nihilism, research evidence suggests that complete dryness is unlikely for certain frail patients, particularly frail institutionalized persons with severe cognitive and functional impairment. Even “intractable” UI is amenable to interventions that may improve the patient’s urinary and bowel function and quality of life [3]. The Frail Elderly Committee of the Third ICI introduced an alternative continence paradigm for frail elderly (Figure 2), which subsequently was generalized for all persons with UI [177]. In this paradigm, persons with “dependent continence” are dry as a result of ongoing assistance, behavioural treatment, and/or medications. UI would return if the interventions ceased, a situation analogous to chronic disease models [178] such as “controlled hypertension” or “controlled diabetes.” Persons with “independent continence” are cured with or without need for ongoing treatment (e.g., dry after successful anti-incontinence surgery). For patients who are unable to achieve independent or dependent continence, “contained incontinence” should be possible by use of appropriate products such as pads, catheters, and appliances (See Committee 20, Management Using Continence Products), thus providing “social continence” or “accepted incontinence” [179, 180]. The balance between the types of continence achieved may vary as UI severity changes, and in conjunction with patient and caregiver preferences. All of the continence outcomes encompass a common need: to be both realistic and hopeful about UI in frail elders while avoiding nihilism and neglect, and maintaining comfort and dignity, and preventing avoidable complications of UI.

Although the ICS standardization document on outcomes in older patients is now 10 years old, little progress has been made and many of the identified needs still pertain (see Recommendations for Research) [5].
4. ROLE OF REMAINING LIFE EXPECTANCY IN TREATMENT DECISIONS

Remaining life expectancy (RLE) is a key yet often misunderstood concept in treatment decisions for frail older persons. RLE is not uniformly short in this population; moreover, there is a demographic trend of increasing RLE, with a smaller proportion of persons spending their remaining years living with disability [181]. Incorporation of RLE into treatment decisions in urology and gynaecology has been studied only in relation to cancer treatment. Only two studies, both in prostate cancer, examined specialists’ ability to estimate RLE. Canadian urologists were more accurate in estimating longer RLE: using scenarios based on actual patient data, 31% were accurate within 1 year, 67% within 3 years, and 82% in estimating greater than or less than 10 years in 82% of responses [182].

Walter and Covinsky [183] developed a graphical tool for estimating quintiles of RLE by age (Figure 3). Medical conditions most closely associated with shorter RLE are class III/IV congestive heart failure, end-stage renal disease, and oxygen-dependent chronic obstructive pulmonary disease. Estimates of RLE are significantly affected by frailty and cognitive and functional impairment [184]. Alzheimer’s dementia decreases RLE profoundly (by nearly 75%) among older persons who otherwise would be in the top quintile of RLE [185]. Compared to older persons with at most one IADL deficit, persons with more deficits have significantly higher 5-year mortality (with two deficit, adjusted RR 1.46 [95% CI 1.20 – 1.78] ; with three or more deficits, adjusted RR 1.64 [1.26 – 2.14]) [184].

5. PREFERENCES FOR CARE

Because there are multiple treatment options available for frail older adults with UI, and individualised care is emphasised, obtaining patients’ and carers’ opinions regarding preference is essential for quality care planning. It should not be assumed that persons with cognitive impairment are unable to make their care preferences known or participate in treatment decisions.

Three studies have directly addressed patient and caregiver preferences for UI care. Preferences for toileting and changing were studied in 111 nursing home residents with UI; residents preferred an average of 2 pad changes, 1.5 toilet assists, and 2 walking assists more than they actually received, yet even these levels were lower than guidelines recommend, suggesting that residents may have reduced expectations based on their experience [186]. In the second, residents of board-and-care facilities and two nursing homes, their family members, and facility nursing staff were given definitions of and information about five UI treatment options (indwelling catheter, prompted voiding, adult diapers [sic], electrical stimulation, and medications) [187].

Respondents were asked their preferences between pairs of treatment options (e.g., “diapers” versus prompted voiding). Most of the board-and-care respondents were continent, although some were undergoing UI treatment at an outpatient clinic. Patients and family members were evenly divided between “definitely” and “probably” preferring prompted voiding versus diapers. Almost 80% of nursing staff, however, preferred prompted voiding to diapers. Families perceived staff members as unwilling to perform prompted voiding, and some thought prompted voiding was degrading to the resident and that it was bothersome to be asked to go to the toilet frequently. Using a similar method, a German study with 117 geriatric hospital patients (mean age 85; 43% with UI), 72 staff members, and 71 family members, found that most patients preferred diapers (79%), medications (78%) and scheduled toileting (79%) over urinary catheters and 64% preferred scheduled toileting [188].

When choosing between diapers and medication, equal proportions preferred each option. Patients with greater functional dependence were more likely to
prefer catheters, and those with experience with diapers were more likely to prefer medications and toileting. Notably, spouses showed moderate to almost perfect agreement with patient preferences, but those of other family proxies had only slight to fair agreement.

6. COSTS AND BENEFITS OF UI TREATMENT IN FRAIL ELDERLY

An overall discussion regarding UI-related costs is covered by Committee 22, Economics of Incontinence. The following discusses UI cost issues specific to the frail elderly.

a) Estimating Costs

Successful ageing is a hallmark of modern society. For many populations, the greatest increase in population is occurring in the oldest old, those ≥ age 85. This group has the highest prevalence of UI, and accordingly their increased prevalence number will result in higher UI care costs. Such an increase has already been observed between 1992 and 1998 amongst US women aged ≥ 65 [189]. The costs of care for older persons has been estimated at double that for people under 65, but care for those older persons living in institutions was less than for community dwelling individuals [190]. Likewise, the cost of OAB in five European countries is estimated to rise by one billion Euros between 2000 and 2020, [191] and in the US it has been estimated that by 2030 the greatest increase in demand for UI care (81%) will be in older women aged 60-89 with OAB symptoms [192]. In one US study using of a community managed care population, the presence of OAB and comorbidity doubled the associated costs of UI care [193].

Costs can be expressed as direct costs, indirect costs, and intangible costs [194]. Previous estimates have focused on diagnostic costs, treatment (including routine care and pads), and consequence costs (skin irritation, urinary tract infection, falls, fractures, additional nursing home and hospital admissions, longer hospital length of stay). Direct healthcare costs are most often estimated but there is a lack of meaningful research into indirect costs and those related to comorbidity often present in the frail elderly. Intangible costs have not been considered in these estimates because of their subjective nature and the methodological difficulty of collection and estimation. Much of the evidence for the cost of UI in older persons has been gathered from either epidemiological surveys or analyses of claims from insurance databases, and have often involved many assumptions or complicated formulae to calculate final costs. There is a consistent theme that the cost of caring for older adults with UI will increase, but the estimated magnitude of this increase is variable.

For the frail elderly, especially those in long term care, cost calculation is especially complex. The greatest costs for UI care in nursing homes are by far nursing labour costs [195]. Extrapolated costs for nursing home admission due to UI was $6 billion (2000 US dollars), [25] with institutional costs of UI management and consequences of $5 billion (2000 U.S. dollars) [196]. In one small 6-month study, the mean daily cost of UI care, including direct nursing care, indirect nursing overhead, and supplies, was $9.09 (± $ 10.52 ) per resident (2003 U.S. dollars) [197]. The costs for UI pads alone in Dutch long-term care has been estimated at 160 million Euros [198]. In an Australian sub-acute care setting, the costs of daily UI care was $49 AU, with most spent on staff wages [199]. In Canada, researchers found that 1% increase in UI prevalence was associated with an 11-12% increase in costs [200]. The extra nursing time needed to maintain toileting programmes contributes to high costs [201]. Routine garment and laundry costs may be lower than estimated because in practice residents are not changed as often as needed. In addition, for prompted voiding to remain effective, such things as regular refresher education programmes for staff or wet sensors may be necessary, and thus are rarely considered in cost estimates.

Moreover, the time period over which the costs and benefit are calculated needs to be explicit because both benefit and costs will change, and patient morbidity and mortality need to be considered. The costs of correcting functional and medical causes of UI are rarely considered. Also, the potential differential in costs across the span of cognitive and functional impairment has seldom been assessed, [202] despite evidence that UI care costs are closely related to the degree of functional impairment [203]. Costs related to caregivers of frail persons with UI living in the community include lost wages, decreased productivity (both within and outside of the home), the additional number of caretaking hours when a frail person develops UI, [204] and the cumulative effect of increased strain and burden, along with any resulting illness. Overall, there are still limited data on costs of UI treatment in other residential (such as assisted living or rest homes) and acute care settings [205 204]. Costs may vary by access to care; because so many frail elderly are homebound or live in institutions, they often do not have the same access to the UI therapies as other populations. Their health care providers may be limited to primary care physicians, community nurses, and care assistants or aides with little to no expertise in UI management. Specialist consultation may be minimally available in home or long term care settings, leading to a focus solely on behavioural management and/or containment products.

Cost relates strongly to reimbursement, which varies considerably from country to country, depending not only on structure of the health system but special programmes for the aged and persons with UI (see Models of Care below). Within particular countries, there may be further variation based on insurance, co-
insurance, drug versus procedure coverage and incentives, access to care, programmes for vulnerable populations and urban/rural differences.

b) Benefit and effectiveness of treatment

The ability to define the benefit of UI treatment in frail older people is highly dependent on the individual, their caregivers, and the health care system. Outcomes research indicates that patients value quality of life, which encompasses many domains besides reduction in UI (See Committee 6, Symptom and Quality of Life Assessment). Even in cognitively impaired persons, one can still elicit treatment preferences, [188, 206] evaluate domains of quality of life (e.g., social interaction), [176] and assess treatment satisfaction directly or behaviourally. At the same time, we found no data on the value or utilities the frail elderly or their caregivers assign to varying degrees of UI (with or without treatment intervention) versus “dryness.” Standard outcomes such as quality adjusted life years (QALYs) may overestimate effectiveness in older people, [207] not just because of potentially different utilities but the altered importance of “years of life saved” in a population with variable and sometimes limited remaining life expectancy.

The above issues underline the need for novel and specific outcomes for use in both trials of UI interventions and clinical care of the incontinent frail elderly. Outcomes measured by single item tools of perceived benefit or satisfaction with treatment are unlikely to be generalizable across the heterogeneous frail elderly population. It should not be assumed that perceived benefit of treatment can be measured with the same tools across cultures and health systems, unless such tools are sensitive to differences in such things as reimbursement for continence services and supplies. Associations between expectations, preferences, and outcomes need to be prospectively studied. New approaches and tools to assess UI-specific quality of life in the cognitively-impaired frail elderly are needed, as well as better understanding of the interaction between functional impairment and the impact of UI [176]. When QALYs are included as an outcome in UI treatment trials in older persons, they should be specifically analyzed by age and also possibly health status.

7. ISSUES IN DRUG TREATMENT

a) Age-related changes in pharmacology

Specific age-related changes in pharmacokinetics, alteration in drug absorption, distribution, metabolism and clearance, and their potential effect on UI drugs, are shown in Table 5. Age-related pharmacokinetic changes are rarely if ever considered in planning the

<table>

</tbody>
</table>

Vd = volume of distribution, T 1/2 = half life
duration of time off previous UI medications, placebo-
run in periods, and wash-out periods in UI drug trials
in older persons. The numerous factors potentially
affecting drug clearance in such patients, as well as
previous and/or cross-over compounds, may confound
observed drug effects. Age-related changes in
pharmacodynamics have been described for
benzodiazepines, beta-adrenergic agents, and opiates
[208, 209] but there are little available data concerning
changes in the frail elderly.

b) Availability of low dose agents

One effect of the under-representation (if not exclusion)
of frail older persons in UI drug studies is a lack of
knowledge regarding minimal effective drug doses
for this population. The age-related changes in
pharmacology noted above suggest that some UI
drugs may be effective at lower than standard doses
in frail elderly with concomitant decreased adverse
effects [210]. This issue is especially relevant for
extended-release preparations, which cannot be
divided into smaller doses. There are some data
supporting the effective use of low dose oxybutynin
in older persons, but such studies are exceptional
[211, 212].

c) Inappropriate polypharmacy

Approximately 60% of persons over age 65 take at
least one prescribed medication, and about one-third
take more than five prescribed drugs. In addition,
many take over-the-counter and naturopathic or herbal
agents, with the rate of use varying across countries
and cultures. The likelihood of adverse drug reactions
(ADRs) and drug interactions rises exponentially
as the number of medications increases. This has led to
the recommendation in geriatric prescribing to “subtract
before adding,” to consider whether target symptoms
might be due to medications before adding another
drug targeting those symptoms. This approach is
relevant in geriatric UI, as UI may have been
precipitated and/or worsened by medications (see
Table 3). Changes to existing drug regimens should
be considered in the management of UI in all frail
older people.

d) Adverse drug effects

ADRs are extremely common in older persons, [213]
with rates up to 35% among community-dwelling
persons aged ≥ 65 in the US, [214] to two-thirds of
long term care residents. [215]. In a recent UK study,
59% of ADRs requiring hospital admission involved
patients aged ≥ 60 [216]. Factors associated with
higher ADRs in the elderly are higher drug doses,
age-related pharmacological changes, polypharmacy,
comorbid conditions, and the interactions between
them. Older people are at higher risk of ADRs from
antimuscarinics because of age- and comorbidity-
related changes in muscarinic receptor number and
distribution, blood-brain barrier transport, and drug
metabolism [217]. Whereas antimuscarinic ADRs in
younger persons are bothersome, in the frail elderly
they can result in serious morbidity such as increased
heart rate, sedation, heat intolerance, delirium, and
falls with fractures [3].

A major antimuscarinic ADE of concern in frail adults
is cognitive decline, yet there are little data about its
actual incidence or prevalence. Cognitive effects may
be under-detected because they are clinically subtle,
neither asked about nor reported by the patient, or
mistaken for age-related diseases and ageing [218].
Persons with pre-existing cognitive impairment
(especially from conditions known to affect central
cholinergic pathways) may be at greater risk for this
ADE. Actual incidence rates of cognitive impairment
with antimuscarinic agents for UI are difficult to estimate
because of probable under-reporting, the different
measures used across studies, failure to specify the
measure in published trials, the use of proxy measures
(such as quantitative EEG), and differences in
psychometrics and clinical relevance of self-report,
physiologic and performance measures of cognition.

Antimuscarinic agents for UI also cause dry mouth
(xerostomia), which is already present in approximately
30% of persons over age 65. Most older persons take
at least one drug that causes xerostomia [219]. The
morbidty from xerostomia-dental caries, problems
chewing, poorly fitting dentures, dysphagia, and
sleeping difficulty should be included when assessing
the risks and benefit of antimuscarinics in frail older
persons. Another antimuscarinic ADE to which the
frail elderly may be predisposed is decreased visual
accommodation, yet this has been specifically
evaluated only in young healthy volunteers, [220] and
drug trials typically report only “blurred vision,” without
further characterization.

The incidence of increased PVR as an ADE is
seldom reported in clinical trials of antimuscarinics
for UI or OAB. When it has been reported, the
magnitude of increase is seldom of clinical significance.
The incidence of acute urinary retention with
antimuscarinics in general is low, but it has not been
systematically evaluated in frail elderly. There is no
consensus as to what constitutes a sufficiently high
PVR to preclude antimuscarinic treatment or to require
dose adjustment of an already prescribed agent. If
urinary frequency or UI worsens after an antimuscarinic
is started or increased, then PVR should be checked
because an increased PVR will lower functional
bladder capacity and worsen UI. PVR should be
monitored in frail older men treated with
antimuscarinics who may not reliably report change
in LUTS or voiding difficulty.

e) Drug interactions

Because frail older persons take higher numbers of
drugs and usually have several comorbid conditions,
Drug interactions are more common [221]. All antimuscarinic agents for UI will have additive side effects when combined with other anticholinergic agents. Antimuscarinics could potentially alter absorption of other drugs by slowing gastrointestinal motility.

**Drug-drug interactions** for oxybutynin, solifenacin, darifenacin, and tolterodine include potent CYP3A4 inhibitors (azole antifungals, macrolide antibiotics, cyclosporin, vinblastine). Fesoterodine, a produg that is converted to tolterodine by non specific esterases, is also dependent upon CY3A4 for its excretion. There is one case report of interaction between tolterodine and warfarin in 2 older patients, [222] which has not been seen in healthy volunteers. Naturopathic/ herbal preparations should also be considered for potential interactions, especially in areas where these agents are used frequently.

There is still uncertainty regarding interactions between antimuscarinic agents for UI and cholinesterase inhibitors (CEIs) used for dementia. There is evidence CEIs can cause or worsen UI from a case report [223] and also a case series of 216 consecutive patients with probable Alzheimer’s disease attending a memory treatment center [224]. In the latter, CEI treatment was overall associated with 7% risk of new UI; the highest risk was observed in patients with more behaviour problems, and lower risk in patients who demonstrated positive cognitive and/or behavioural response to CEI. Evidence for an interaction between antimuscarinics and CEIs comes from a database study of nursing home residents in one US state [225]. Residents with dementia newly treated with cholinesterase inhibitors were subsequently more likely to be prescribed a bladder antimuscarinic than dementia patients not given CEIs, suggesting a classic geriatric “prescribing cascade” [226]. Concomitant use of antimuscarinic and CEIs in nursing home residents was associated with a decline in ADL function but not worsening cognition, possibly because the cognitive measure (MDS-COG) was inadequately sensitive [227].

Drugs also may interact with comorbid conditions (drug-disease interactions), such as diseases that affect hepatic or renal metabolism and clearance, slow gastric motility (e.g., advanced diabetes), predispose to delirium, or are associated with impaired central cholinergic transmission (Alzheimer’s and Parkinson’s diseases).

**f) Potentially inappropriate drugs for older persons**

Efforts at quality improvement for older populations have led to the development in several countries of expert consensus guidelines regarding inappropriate drugs for older persons, [228, 229] although the continuing relevance of these guidelines has been questioned and alternative systems suggested [230, 231]. These guidelines focus on drugs with lower risk-benefit ratios and higher potential for drug-drug and drug-disease interactions, and are used for nursing home regulation and quality performance measurement. Several UI drugs are included in the US guidelines (the “Beers criteria”): immediate-release oxybutynin (because of “high risk of anticholinergic adverse effects, sedation, and weakness”); oxybutynin (immediate- and extended-release), tolterodine, and flavoxate in the patients with BOO (because of “high risk of decrease[d] urinary flow, leading to urinary retention”); all anticholinergic drugs in patients with cognitive impairment (because of “high risk of CNS-altering effects”) or constipation (because of “risk of exacerbat[ing] constipation”); and tricyclic antidepressants in patients with stress UI (because of “high risk of produc[ing] polyuria and worsening of incontinence”). Whether or not one agrees with these recommendations, there is value in the concerns they raise, especially their emphasis on the level of thought needed for “best practice” prescribing for frail older persons.

**8. SPECIAL ISSUES UNIQUE TO FRAIL OLDER MEN**

Although their ranks thin into the ninth decade, men still comprise a significant portion of frail older persons. The prevalence of UI increases in men after age 80, going from about one-third of the rate in women to the same. Over the past ten years, the prevalence of UI in US male nursing home residents aged 65-74 has increased to a greater extent than in female residents (from 39% to 60%, compared with 45% to 59%) [232]. At the same time, frail men are under-represented in UI treatment trials, whether behavioural, pharmacological, or surgical (see also Committee 15: Surgery for Urinary Incontinence in Men).

This under representation is unfortunate, because results from treatment trials in frail women cannot be directly extrapolated to men for several reasons:

- Differences in comorbidity: frail older women have higher rates of functional impairment, [233] which may mean that frail men may be more likely to respond to behavioural interventions.
- Differences in caregivers: more older men have living spouses who can provide care, with a potential impact on the risk and type of caregiver burden associated with UI management.
- Differences in the relationship between UI and cognition: one systematic urodynamic study of nursing home residents with UI found a significant association between DO and more severe cognitive impairment in women, but not in men (although power was likely low, as the number of men was only 17) [171].
- Benign prostate disease: the prevalence of histological BPH, BPE, and BOO increase with age, and is associated with LUTS, UI, and DO. In the urodynamic study cited above, 29% of men had
BOO and 59% had DO as the predominant cause of UI, [171] versus 4% BOO and 61% DO in women.

- Prostate cancer: nearly all men in their ninth decade have histological evidence of prostate cancer. However, it is not clear that frail elderly men have an increased risk of prostate cancer-specific mortality, especially given that their RLE is primarily affected by comorbid conditions. The need to screen for and treat prostate cancer diminishes with functional status, comorbidity, and RLE [234]. At the same time, more men are living with the sequelae of prostate cancer treatment, particularly stress UI after radical surgery.

- Risk of urinary retention: because of age-related decrease in detrusor contractility and increased likelihood of BPE and BOO, it is often assumed that frail elderly men have a higher prevalence and risk of urinary retention. However, this has never been demonstrated. Among NH residents with UI, the prevalence of underactive detrusor was similar in women and men (38% and 41%, respectively), despite the higher prevalence of BOO in men [171].

Despite the issues noted above, evaluation and management of UI in most frail older men follows the same roadmap as for frail women (see Algorithm).

9. SUMMARY OF THE EVIDENCE

1. Patients and caregivers have clear preferences for the type of UI management, and they are often discordant between the two groups (Level 2)
2. Age-related changes in pharmacokinetics affect antimuscarinic drugs for UI and should be incorporated into treatment planning. (Levels 1-2)
3. Drugs may be effective at lower doses in frailer compared with healthier older persons (Level 3)
4. Polypharmacy increases the chance of adverse reactions to drug therapy. (Level 1)
5. Adverse drug events are more common in the frail elderly. (Level 2)
6. Drug-drug and drug-disease interactions are common in frail older persons (Level 1-3).
7. The economic burden of UI in frail elderly, as well as the cost-benefit, cost-effectiveness, and cost-utility of its treatment, has been incompletely characterized (Level 4)

VII. TREATMENT

1. LIFESTYLE INTERVENTIONS

As potentially treatable correlates of and risk factors for UI are determined, interventions that ameliorate their effects have been devised. Several lifestyle interventions have been evaluated in healthier older and younger women, including weight loss regimens, diet, fluid selection and management, smoking cessation, and constipation management (See Committee 12, Adult Conservative Management). Although many health care professionals advocate lifestyle interventions to treat UI, [196, 235, 236] we did not locate any studies of these interventions for the frail elderly. Several of these interventions may be inappropriate in frail elders (e.g., weight loss), yet advanced age alone should not preclude their use if assessment warrants. Inadequate fluid intake and dehydration are common in incontinent frail elderly in long-term care, in part because nursing assistants offer them less fluids in the belief that this will reduce UI [237]. Dehydration may actually increase the risk of UI in frail elders, because of the former’s significant association with constipation [238] and impaired cognition, [239] both known risk factors for UI.

a) Quality of data and results

We located articles addressing lifestyle interventions for UI in older women, but the number of oldest-old subjects was very small, few to none appeared to be frail, and no studies stratified results by age. Two very small older trials point to the possibility that increased hydration for incontinent frail elderly may actually decrease UI [240, 241].

b) Summary of the evidence (see Table 6)

No recommendations are possible regarding lifestyle interventions for UI in the frail elderly (Level 4)

2. BEHAVIOURAL INTERVENTIONS

Behavioural interventions have been especially designed for frail older people with cognitive and physical impairments that may affect their ability to learn new behaviours or to actively participate in self-care activities. These interventions evolved from classical behavioural change theory, using antecedent and/or consequent conditioning to shape the desired behaviour. Because behavioural interventions have no side effects, they have been the mainstay of UI treatment in the frail elderly [242]. Behavioural therapies used predominantly in frail adults, all of which require active caregiver participation, include:

- Quality of data and results
- Summary of the evidence (see Table 6)

- Behavioural interventions have been especially designed for frail older people with cognitive and physical impairments that may affect their ability to learn new behaviours or to actively participate in self-care activities. These interventions evolved from classical behavioural change theory, using antecedent and/or consequent conditioning to shape the desired behaviour. Because behavioural interventions have no side effects, they have been the mainstay of UI treatment in the frail elderly [242]. Behavioural therapies used predominantly in frail adults, all of which require active caregiver participation, include:
Prompted voiding, involving prompts to toilet with contingent social approval, is designed to increase patient requests for toileting and self-initiated toileting, and decrease the number of UI episodes. It was first used in the 1980s for incontinent nursing home residents [243].

Habit training, which requires the identification of the individual's voiding pattern, involves pre-empting UI episodes. Habit training involves the identification of the individual's voiding pattern, and the use of a toileting schedule to prevent UI episodes [244, 245]. There is no attempt to alter an individual's voiding pattern.

Timed voiding involves toileting an individual at fixed intervals, such as every 3 hours. This is considered a passive toileting programme; no attempts are made at patient education or reinforcement of behaviours, or to re-establish voiding patterns [246]. Other terms used to describe timed voiding are scheduled toileting, routine toileting, and fixed toileting [247].

Combined toileting and exercise therapy involves strengthening exercises into toileting routines by nursing home aides [248]. Another combination intervention, administered by occupational or physical therapist, involves toileting and mobility skills [249].

Cognitive and functional impairments common in frail elderly and/or lack of caregivers may preclude the use of some of these interventions. Studies repeatedly show that, once a trial ends, indigenous long-term care staff rarely maintain the intervention at the same level, if at all (see, e.g., [4]). Outcome evaluation or even conduct the interventions. Studies repeatedly show that, once a trial ends, indigenous long-term care staff rarely maintain the intervention at the same level, if at all (see, e.g., [4]).

We identified a systematic review of prompted voiding (9 trials, 674 patients) [252] and a Cochrane review of habit training in nursing home and home care patients updated since the last ICI (4 trials, 378 patients) [253]. The majority of trials did not determine the type of UI, or sufficiently describe whether comorbidity possibly contributing to UI was evaluated or treated. Randomized trials in long-term care have overwhelmingly demonstrated that long-term care staff do not maintain interventions that are feasible in some frail older women.

Although pelvic floor muscle rehabilitation has not been studied extensively in frail elderly, age and frailty alone should not preclude their use in appropriate patients. Similarly, a combined cognitive and functional training programme involving pelvic floor muscle exercises, bladder training, and mobility skills [250].

* Fluid management: Self-monitoring was individualized and women were counselled on fluid consumption, quick pelvic floor muscle contraction, management of constipation and voiding frequency.
* Caffeine reduction: Treatment group received education regarding caffeine reduction; control received no information.
* Combined toileting and exercise therapy: Functional intervention training incorporates strengthening exercises into toileting routines by nursing home aides [248]. Another combination intervention, administered by occupational or physical therapist, involves toileting and mobility skills [249].
* Combined toileting and exercise therapy: Functional intervention training incorporates strengthening exercises into toileting routines by nursing home aides [248]. Another combination intervention, administered by occupational or physical therapist, involves toileting and mobility skills [249].
luation is usually limited to “wet checks” (percentage of times the patient is found to be wet on a set schedule of checks) and not UI, and no studies report cure or patient-based outcomes such as satisfaction with treatment and quality of life. Little intervention research has been conducted with incontinent hospitalised and homebound frail elders.

Limitations in many studies include: small samples with low power to detect significant differences; variable terminology and operational definitions, making comparisons across studies difficult; little ethnic or cultural diversity; data limited to women, especially in nursing home trials; little focus on night-time UI; little consideration to the psychological impact of toileting programmes on patients and caregivers; [254] and no long-term follow up. Many studies excluded frail older adults with terminal illness, [255] inability to respond to an one-step command, [255, 256] or poor language ability [256-258]. Ethical concerns for human subjects prohibits withholding treatment, thus true “control” groups were nearly impossible to create. Two studies used delayed treatment as controls [257, 258]. The frequency of the intervention varied across studies as well, with toileting conducted every two hours over 12-hour, 14-hour, and 24-hour schedules [243].

b) Efficacy (Table 7).

Prompted voiding is more effective than no intervention for improving daytime dryness in nursing home residents and some home care clients (Level 1) [252]. Prompted voiding is not effective and should not be used for persons with end-stage dementia (unable to state name or point to one of two named objects), who are bedbound or require 2-person assist to transfers, or who have more than four UI episodes during a 12 hr daytime period; such persons should be managed by “check and change,” with the goal of dependent continence. Eligible persons should have a three-day trial of prompted voiding, and the intervention should be continued after only in those that achieve appropriate toileting rates (the number of times the resident voided into the toilet divided by the total number of voids) of ≥ 66% or a wet check rate (number of times the resident was wet when physically checked) of ≤20% [259]. All others should be managed by check and change. This approach allows prompted voiding to be targeted to only the approximately one-third of residents who are eligible for and respond to prompted voiding, and could help decrease the considerable time and labour costs now used for inappropriate, unsuccessful toileting [195]. The 2005 revised US guidelines for continence care in nursing homes approved this approach as quality care [260].

No data are available about the long-term effects of prompted voiding. Self-initiated toileting increased, as anticipated, in some trials but concern was raised about increased dependence on the caregiver for toileting assistance.

There is insufficient evidence to determine if timed voiding improves continence (Level 4) [246]. No additional intervention studies on timed voiding since the previous Consultation were located. Several of the studies included in a systematic review had only female subjects with cognitive impairment, and included use of additional interventions such as antimuscarinic drugs (propantheline or flavoxate), staff education, bedside commodes, and absorbent products.

There is insufficient evidence to determine if habit training improves continence (Level 4) [253, 254].

Functional Incidental Training (FIT) incorporates endurance and strengthening exercises (e.g., sit-to-stand, bicep curls) while an aide conducts prompted voiding with a resident [248]. FIT significantly improves physical endurance and UI (measured by wet check). Across several different long-term populations, FIT led to a 38% reduction in daily urine loss [4, 249] However, all FIT efficacy trials relied on trained research nursing stuff, FIT costs more than usual care, [4] and it may be difficult to implement in nursing homes without changes in existing staffing levels, [261] limiting its generalizability [262].

Operant behavioural strategies have shown some effectiveness in improving UI in long-term care residents (Level B) [243, 263]. The underlying principle is that behaviour is modified by its consequences, [264] even in frail adults. A balance must be struck, however, between encouraging self-care activities and patient functional status.

c) Summary of evidence

1. Prompted voiding is effective in the short-term treatment of daytime UI in nursing home residents and home-care clients, if caregivers comply with the protocol (Level 1).

2. Prompted voiding is ineffective and should not be used in persons who are unable to state their name or need the assistance of more than one person to transfer, and these persons should be managed with “check and change.” (Level 1).

3. Prompted voiding should not be continued in eligible persons who after a three day trial have less than a 20% reduction in wet checks (Level 1) or toilet successfully less than two-thirds of the time; these persons should be managed with “check and change.” (Level 1).

4. Interventions combining toileting and exercise decrease wet checks and improve endurance in nursing home residents, including those with psychiatric disease (Level 1).

5. Efficacy of behavioural interventions decrease when implemented by indigenous nursing home staff (Level 1) and the associated labour costs may be difficult to offset (Level 2).

6. It is uncertain whether habit retraining reduces UI in frail older persons (Level 4).

7. It is uncertain whether timed voiding reduces UI in frail older persons (Level 4).

8. There are no proven interventions to reduce nighttime UI in frail elders (Level 4)

3. INTERVENTIONS WITH LONG TERM CARE STAFF AND CAREGIVERS

Many frail elderly persons must rely on family, caregivers, or residential and/or nursing staff for toileting assistance and personal care. These carers may not be available as frequently as necessary for the frail elder to maintain continence, and even if available they may not be able or willing to provide the needed assistance. Research has shown that the frequency of toileting assistance actually provided in US nursing homes is too low to maintain continence [265].

There is dissonance between nursing home surveyors, nursing staff, and nursing home administrators' knowledge and beliefs about UI and its management, which may be an important barrier to effective UI care [156]. One study suggests that nurses in the acute and long-term care settings continue to provide urine containment interventions rather than promoting continence [266 267]. Nursing staff preferences for UI management (toileting) are in conflict with those of residents and their families patient treatment preferences (medications and garments) [187, 188].

In long term care, a two-prong behavioural intervention to UI care, one geared towards the resident and the other geared towards staff members, appears necessary [268, 270]. Nursing assistants play a key role in the success of behavioural programmes, and organisational schemes need to be devised to create incentives for them to keep residents continent [271]. Direct care providers will be unlikely to implement programmes unless residents and their families advocate for them [272].

This advocacy, however, appears unlikely if, based on their experiences, nursing home residents have reduced expectations and do not anticipate receiving sufficiently frequent and prompt toileting, and therefore express no desire for more frequent toileting [265]. One documented barrier to toileting programmes in long term care is their labour intensity. Bladder training programmes are considered one of the three most time consuming activities for long-term care staff [197].

A specialty practice exemplar model has been proposed to improve continence care in long-term care, with a nursing faculty member with expertise in the assessment and treatment of UI having a clinical practice in a facility. Graduate nursing students, working with this individual, focus on the Minimum Data Set Resident Assessment Protocol for UI. Assessment and treatment skills ultimately are transferred to the facility nursing staff members through several mechanisms, including staff education and improved continence care systems [273]. Quality assurance programmes using incontinence quality indicators have also been proposed [157]. A clinical leadership model in the sub-acute setting in Australia used a staff empowerment and mentorship model to make evidence based changes related to continence care during patient's stay and on discharge [244].

a) Quality of data

Several authors point to the difficulty of conducting research in long-term care settings [268, 269, 274]. Factors such as staffing ratios, changes in administrative and regulatory policies, and fiscal issues are beyond researchers' control. Several investigators report that staff compliance was less than total, and some experienced problems with staff training. For instance, in one study several staff members did not attend group-training sessions and needed one-on-one training, and other staff members did not perform the protocol or document its use, especially when staffing levels were low [269]. Little staff intervention research to improve continence in older persons has been conducted in the acute-care setting.

b) Results

One group of researchers investigated the effect of a scheduled toileting programme on nursing home staff injury using a quasi-experimental design using a 75 bed unit and a similar comparison unit [275]. Fifty residents in the intervention unit were selected to participate based on an assessment indicating their eligibility for a toileting programme. Mechanical lifts were purchased for the intervention unit in anticipation of an increase in toilet transfers. Regular toileting increased from 12% pre-intervention to 67% in the intervention and 26% in the comparison unit. Staff injuries related to toileting did not increase in the intervention group, and the staff also noted less resident agitation. In-service classes on UI did not change staff knowledge and attitudes about UI, or improve resident toileting (only 70% of toileting assists were completed) [268]. The authors noted that staff members believed that toileting was “not worthwhile” for some residents. In a randomized study using advanced practice nurses (with post-graduate training) to work with staff to implement evidence-based protocols, residents in the intervention arm experienced significantly greater improvement in UI compared with those receiving usual care [276].

Several studies detail extensive barriers to UI care [166, 277, 278]. A staff survey revealed that nursing assistants believed prompted voiding was very helpful to residents in reducing the frequency and volume of incontinent voids, but that inadequate staffing, staff work load, turnover, and absenteeism were significant
barriers to prompted voiding. They believed that increased numbers of staff, improved communication, ongoing education, and alternative modes of care delivery were necessary to facilitate prompted voiding. Overall, staff believed toileting programmes improved resident quality of life but the realities of long-term care made them difficult to implement [279]. Nursing assistants believed that UI was a normal part of ageing and that nothing could be done for it, 99% of residents with UI in the study facility wore absorbent products and only 3% had received UI treatment [166].

When staff perceptions regarding completed toileting assistance were compared to research staff observations, staff over-inflated the percent of toilet assists they completed (stating 80-90% when the observed was 70%) [280]. Staff members also believed that residents were happier with a prompted voiding programme, yet only 52% thought the programme improved residents’ continence. In another study, long-term care facility residents reported a mean of 1.8 daily assists to the toilet, regardless of whether they were on a toileting programme or not [272].

Continence care creates additional needs for family caregivers. In a small pilot study, caregivers at home felt that the requirements of a behavioural protocol were more than they could manage [281]. Other family caregivers report embarrassment and social isolation as their most frequent emotional responses to UI, and a need for information about resources [282]. In contrast to long-term care staff, family caregivers were adherent with prompted voiding 89% of the time, and 93% were somewhat or completely satisfied with the decrease in UI [257]. A descriptive study found that caregivers of frail elders with UI report a high level of physical fatigue (70%) [282]. Caregivers dealing with different levels of UI (mild, moderate, catheter managed) have different educational needs and require different levels of support from healthcare professionals. For example, carers of frail persons with mild UI expressed the greatest need for different levels of UI (mild, moderate, catheter managed) have different educational needs and require different levels of support from healthcare professionals. For example, carers of frail persons with mild UI expressed the greatest need for professional care, but those of persons with moderate UI or catheters spent the highest number of daily hours providing care [283].

A computerised quality management programme for prompted voiding was tested in a convenience sample of 85 residents in eight US nursing homes [273]. Each facility was asked to identify staff members for the following roles: main contact person; quality control specialist; two licensed personnel who would conduct UI assessments; and two nursing/health care assistants who would implement the prompted voiding intervention. Information on the computer system included UI assessment and residents wetness rates. Research staff monitored the database and provided the nursing staff feedback by telephone consultation. The programme was effective in improving dryness for six months while research staff monitored the database, but only one facility continued the programme after the research ended [278]. The researchers noted that current incentives for nursing homes to maintain UI management systems are insufficient.

A scheduled toileting programme, designed to explore risk of injury to staff members and resident agitation and aggressive behaviour, required statistically significantly more staff time than “check and change,” with cleaning soiled patients while they were in their bed (slightly longer than 6 minutes to toilet versus slightly longer than 4 minutes to clean) [275].

Acute care patients have preferences for urinary incontinence treatment that is significantly discordant to hospital staff. For example, nurses and physicians preferred scheduled toileting over diapers more than did the patients [188]. The authors suggested that communication about treatment preferences should occur.

c) Summary of evidence

1. Although long term care nursing staff generally believe prompted voiding to be helpful, they fail to implement such programmes. (Level 2)

2. Interventions designed to maintain implementation of patient-focused behavioural interventions by long-term care staff are helpful in promoting continence care. (Level 2)

3. Family caregivers in the community setting can be adherent to behavioural interventions but experience fatigue and social isolation. (Level 2)

4. The use of computerised programmes to manage quality control for UI management does not persist after research studies have ended. (Level 2)

5. Toileting programmes including mechanical lifts may reduce staff injury and decrease resident agitation associated with toileting. (Level 2)

6. There is insufficient data to determine whether long-term care UI quality improvement efforts have an impact on costs related to UI (Level 4)

4. PHARMACOLOGICAL TREATMENT OF UI IN FRAIL ELDERLY PERSONS

a) Background

The pharmacological management of UI in healthy older persons is discussed in Chapter 10, Drug Treatment. This section deals with the management of frail elderly, using the definition at the beginning of the chapter. Specific treatments for bladder outlet obstruction and associated LUTS in frail elderly men are outside the scope of this chapter; special issues in the care of frail older men with UI are discussed above.

Frail persons with UI should be considered for drug treatment only following a comprehensive evaluation
of remediable causative factors, and if they are appropriate for and have had a trial of behavioural and lifestyle interventions. Drug treatment should not generally be used for persons who make no attempt to toilet when aided, become agitated with toileting, or are so functionally and cognitively impaired that there is no prospect of meaningful benefit. Even so, a recent study of US nursing home residents suggested that only a small proportion of incontinent residents potentially suitable for drug therapy ever received it [284]. There is still much to do, with potential benefit for many.

b) Quality of data

We located 17 randomised placebo controlled trials (RCTs) of antimuscarinic medication, predominantly involving subjects over the age of 80. The majority were of modest quality often reflecting their publication date (up to 40 years ago). The available RCTS were predominantly done in the US, with a small number in the UK, Germany, Taiwan and Japan. Approximately half of identified studies were conducted in long-term care facilities, whose residents are overwhelmingly female. All focus on antimuscarinic treatment of presumed urgency UI. UI diagnosis was overwhelmingly symptom-based; only three studies included urodynamic evaluation. The majority of newer studies including older persons but whom overwhelmingly appear to be “fit.” For most studies it was impossible to identify whether subjects were indeed frail, except where the study was performed in an institutional environment, in which it is reasonable to assume a high prevalence of functional and cognitive dependence.

Many older trials used a randomised cross-over design, which lessens power and increases the non-drug effect. The methods of blinding and randomisation in RCTs was seldom specified.

Other than those conducted by the pharmaceutical industry, most studies were generally small and under-powered, and others lost power because of high drop out rates due to illness and death (inevitable in trials with frail elderly persons). Because of these issues, many RCTs provide only Level 2 evidence. Some larger studies in older persons without clear frailty are included here, to recognise that, since the last consultation, there has been an increasing emphasis on including older persons in drug trials.

Precise descriptions of the target population—including the definition of “frail persons” and a comprehensive description of the degree of cognitive and functional impairment—were usually absent. Although some investigators included information on patients’ functional and cognitive status, as well as comorbid conditions, the descriptions were often only qualitative, and none addressed these issues adequately in the analyses. Explicit, concurrent behavioural therapy was used in most nursing home studies, yet may have occurred in many others. Combination therapy and high comorbidity could have attenuated differences between drug and placebo, and make it difficult to compare results directly with studies in healthy older and younger persons. Outcomes were universally assessed by UI frequency (pad-weighing, bladder diaries, and wet-checks), and none reported quality of life outcomes.

Treatment of some reversible causes of UI also may have affected the ability to detect drug effects. In at least six studies, investigators treated subjects with “urinary tract infection” (usually defined as pyuria and bacteriuria in the presence of UI) before initiating antimuscarinic therapy, and one study excluded such subjects. In another, investigators treated urogenital atrophy with oestrogen prior to antimuscarinic therapy, possibly leading to an additional amelioration of symptoms. However, no other reversible causes were addressed prior to entry or randomisation in most studies.

The generally low quality of these trials reflects not just study design, but the larger issue of the difficulty of doing large, prospective intervention trials in frail populations. Moreover, UI in frail elderly is universally a multifactorial problem involving a large number of factors beyond the bladder. Thus, the expectation that drug therapy targeted solely at urodynamic DO or SUI would markedly improve/cure UI in this population is unlikely to be realised.

c) Results

Results from randomised trials are summarised in Table 8; the following sections discuss specific drugs in detail, and include randomised trials as well as non-randomised trials in older persons.

1. **Oxybutynin**

The majority of studies in frail older persons used immediate-release oxybutynin (oxybutynin-IR). There are two studies of extended release oxybutynin (oxybutynin-ER), one examining cognitive effects in nursing home residents with dementia and urgency UI, [285] and the other involving community-dwelling women over age 65 [286]. Published trials of the efficacy of transdermal oxybutynin included subjects up to age 100 and in institutional care settings, but did not stratify results by age or comorbidity [287].

The pharmacokinetics of oxybutynin-IR and its active metabolite, N-desethoxybutynin, in one study tended to show greater plasma levels and bioavailability with increasing frailty and age [288]. Another found peak levels in 21 octogenarians similar to those reported in young normal males (12.5 ng/mL vs. 8.9 ng/mL) [289]. A study of the pharmacokinetics of transdermal oxybutynin showed no significant difference in plasma levels between young and old (up to 77 years) subjects [290].

</table>
• Efficacy

An early, small (n=15) trial of oxybutynin-IR and habit training in long-term care residents showed no effect on UI episodes [291]. However, in a subsequent and larger study in long-term care residents who had failed prompted voiding alone, the addition of titrated oxybutynin-IR resulted in a significant but modest reduction versus placebo [292]. Wet-checks decreased from 27% at baseline to 20% on drug and 24% on placebo, leading the authors to conclude that the improvement was not clinically significant, especially given the continuing requirement for nursing intervention. However, their a priori definition of “clinically significant improvement” (one or fewer episodes of daytime UI) was achieved by 40% on drug but only 18% on placebo (p<0.05). The dose generally associated with improvement was 2.5 mg three times daily. In another controlled study of UI in long-term care residents (n=24), there was little effect of oxybutynin-IR 5 mg twice daily given for 8 days, but all residents were toileted 10 times daily, and the dose may have been too high and given too infrequently [293]. In a randomised two month trial in frail community-dwelling elderly, oxybutynin-IR plus bladder training was subjectively and objectively superior to bladder training alone in improving urinary frequency (95% CI 6-27 fewer voids per 2 weeks) but not UI [294]. Insufficient information was available regarding a Japanese study in 75 “elderly” patients to assess the population and outcomes [295]. A study in 416 community dwelling older persons, including the fitter elderly, found 68% reported a partial or complete symptomatic cure with 2.5 mg three times daily; 30% of subjects experienced ADEs, but only 10% withdrew because of them [211]. Only one of the two identified RCTs examined efficacy of oxybutynin-ER [286]. The other examined the effect on cognition [285] and is discussed below. No published RCTs of transdermal oxybutynin in the frail elderly were found, and post hoc sub-analyses of efficacy in subjects over the age of 65 has been published only in abstract form. In a small Japanese case series (n=13, mean age 75) in persons with urgency UI and cystometric DO, intravesical oxybutynin caused no significant increase in mean bladder capacity one hour after installation of 5 mg oxybutynin at pH 5.85 [296]. In four patients who continued twice daily installation, two had UI “disappear” and one “markedly decrease” (duration until effect not noted). No patient developed an “increased PVR” (not defined).

• Predictors of efficacy

Predictors of efficacy were studied in one study in
persons with urgency UI and urodynamic DO (n=41, mean age 79) treated with 2-4 weeks of oxybutynin-IR (5-15 mg/day) [297]. Factors associated with baseline urine loss (by pad weighing) were impaired cognitive orientation (on the Cambridge Mental Disorders of the Elderly Examination), number of daily voids, and fluid intake. Persistent urine loss after treatment was associated with impaired orientation, reduced sensation of bladder filling during cystometry, and most significantly global cortical under-perfusion on single photon emission computed tomography scan, suggesting that cortical factors are the main determinant of the severity of urgency UI before and after oxybutynin. In a study of 80 older patients (mean age 74), patients with dementia (by Hasegawa dementia scale) were less likely than cognitively intact patients to report subjective improvement in UI with antimuscarinic agents, despite similar objective outcomes [298]. However, these results could reflect treatment-associated cognitive effects.

• Adverse reactions

Cognitive side effects from oxybutynin have been reported in older persons. In one case series, four older men with Parkinson's disease and mild-severe cognitive impairment developed confusion, psychosis, hallucinations, behavioural disturbance, and/or paranoia after receiving oxybutynin-IR (5-15 mg/day), which resolved when oxybutynin was stopped [299]. Of note, each patient was also on L-dopa (co-beneldopa) and selegiline, and the observed effects could reflect drug-drug interactions. However, these results are belied by a large RCT in which oxybutynin-ER 5 mg daily did not cause more delirium than placebo in NH residents with UI and dementia [285].

There are case reports of reversible peripheral neuropathy confirmed by re-exposure in a 70 year old woman taking oxybutynin-IR 5-7.5 mg/day [300] and recurrent heat stroke associated with oxybutynin in one elderly patient [301]. Few studies have addressed cardiac effects. A small study of older persons in the community with UI (n=20, mean age 75) found no change in resting heart rate or electrocardiograph evidence of either prolonged PR interval or QTc, or QTc dispersion after 4 weeks of oxybutynin-IR (mean daily dose 7.6 mg [range 2.5-10 mg]) [302]. Using a large administrative utilization database, no association was found between antimuscarinics (oxybutynin, flavoxate, hyoscyamine) and ventricular arrhythmia and sudden death [303]. Post-marketing adverse events with extended release oxybutynin include tachycardia and hallucinations [304].

2. TOLTERODINE

Studies of tolterodine in “older patients” do not include frail persons. For example, “older” patients in one RCT of tolterodine-ER were all community-dwelling, able to complete a 7-day bladder diary, had a high prevalence of previous antimuscarinic treatment (53-57%), and a low prevalence of arthritis (15-18%), unlike most frail older persons [305]. Although several trials include elderly persons in their ninth and tenth decades, [305-307] mean age (~64 years) was much lower, persons with “[unspecified] disease which the investigator thought made the patient unsuitable” and/or “renal disease” were excluded, and results were not stratified by age. In a secondary analysis of a large, open label German trial of tolterodine-IR 2 mg twice daily, higher age was significantly associated with “less favourable efficacy” [308]. However, the absolute difference in odds was only 0.019, there was no association of tolerability with age, only mean age is described, and UI frequency was based on patient report, not bladder diaries, all of which fail to add up to a clinically meaningful difference. In a non-randomised study, tolterodine was given to 48 nursing home residents who did not respond to toileting alone; 31 of these patients had a 29% increase in dryness (versus 16% in residents on toileting alone) [309].

• Adverse reactions

There are no prospective systematic data on tolerability in frail patients. There have been case reports of hallucinations (73 year old woman with dementia [310]) and worsening memory, [311] including a 65 year old cognitively intact woman [312]. There is a case report of delirium when tolterodine was given with a cholinesterase inhibitor [313]. Analysis of prescription-event monitoring in the UK (mean patient age 63) found a significant association between age (>74 years) and psychiatric events and tachycardia (odds ratios not given) [314]. In a similar database study, the age- and sex-adjusted risk of hallucinations with tolterodine was 4.85 (95% CI 2.72-8.66) compared with 10 other drugs (acarbose, alendronate, famotidine, 3 proton pump inhibitors, finasteride, meloxicam, misoprostol, and nizatidine) chosen for presumed lack of antimuscarinic, cardiovascular, and CNS activity, and available in the database. Important confounders such as other drugs and comorbidity were not evaluated. Similar to oxybutynin-ER, post-marketing information on tachycardia and hallucinations was added to the tolterodine-ER package insert in 2003 [315].

3. FESOTERODINE

There are no published data in the frail elderly. Older, fitter subjects have been included in clinical trials, with persons over age 65 comprising approximately one-third of the total number of subjects studied, [316] yet no published results stratify by age.

4. SOLifenacin

Pharmacokinetics of solifenacin were evaluated in 23 older subjects (mean age 68); tmax was longer and a there was a higher maximum plasma concentration,
but the differences from results in younger patients were small and deemed by the authors to be clinically irrelevant [317]. There are no randomized controlled trials specifically examining its efficacy in frail elderly. A secondary analysis of pooled Phase III data in patients aged 65 and older (all community dwelling and fit, mean age 72) found similar efficacy to that reported for younger and middle aged persons [318]. However, direct comparison with subjects < 65 yrs from the same pooled trials was not done. Adverse effects in older frailer patients have not been specifically reported. However, data from an open-label, 12-week trial in patients treated by community urologists found that overall treatment-emergent adverse events were more likely in patients aged >80 years (OR 3.9 [95% CI 1.3-11.5]) and taking concomitant medications (OR 1.8 [95% CI 1.2-2.6]) [319]. Patients with concurrent medications were more likely to be male and on average about 12-14 years older, have comorbid disease, and be administered higher doses of solifenacin, yet had no observed increase in heart rate or blood pressure with solifenacin.

5. Darifenacin

We located one RCT of darifenacin for OAB in persons aged ≥65 (mean 72), in which there was no statistically significant difference between drug and placebo for the primary end point, UI frequency [320]. There were statistically significant improvements with drug for urinary frequency (-25.3% vs. -18.5% with placebo; p < 0.01) and quality of life, as measured by OAB-q and patient perception of bladder condition. Although subjects were not frail, this is the only prospective study of a more modern antimuscarinic in older persons.

- **Adverse effects**

Cognitive adverse effects of darifenacin have been prospectively studied in a series of trials. The first was a 3-period crossover RCT in 129 older subjects (mean age 71, 54% of those screened), 88% of whom had comorbid medical conditions and 93% were on other medications [321]. Cognition was assessed using a standardized computerized battery. Darifenacin at variable doses did not adversely affect cognition compared to placebo, but results were aggregated so that patients did not serve as their own controls. A subsequent study in cognitively intact older persons (n = 49, mean age 66) using a similar computer cognitive battery compared titrated darifenacin and oxybutynin-ER with placebo over 3 weeks [322]. Oxybutynin-ER but darifenacin or placebo adversely affected the primary endpoint, delayed recall on the Name-Face Association test. However, oxybutynin was titrated one week earlier than darifenacin, and to a final dose (20 mg daily) much higher than is commonly used in clinical practice. Also, there were no differences between the two drugs and placebo for many other domains of the cognitive battery.

6. Trospium Chloride

Although often promoted for use in the elderly because of the reduced likelihood that the drug crosses the blood-brain barrier, we found no studies that evaluated the agent specifically in frail older persons. All studies have included “younger elderly,” but even the most recent have not stratified results by age [323].

7. Propiverine

In 46 patients with dementia (mean age 81), there was a 40% decrease in urgency UI with propiverine 20 mg/day for 2 weeks, [324] similar to two small Japanese trials [325, 326] and a German trial in 98 patients [327]. The agent’s high protein binding, extensive first pass metabolism, 15-hour half life (in normal younger persons), and renal clearance [324] need to be considered if used in frail older persons.

8. Duloxetine

There was a statistically significantly reduced rate of clearance of duloxetine in patients over age 65, based on a study in 12 fit women aged 65-77 [328]. The authors felt the differences were not clinically significant given the “similar safety profile” of the drug in older and younger women. In three large RCTs in women (with SUI, aged 24-83 years, n = 494 [none frail]; [329] with OAB, aged 21-84 years [none frail], n = 306; [330] and with mixed UI, up to age 85 [331]), duloxetine decreased UI and urinary frequency, but none stratified outcomes or adverse effects by age. Duloxetine is not approved by the US FDA and is not recommended by the UK National Institute of Healthcare and Clinical Excellence.

9. Oestrogen

Oral oestriol 3 mg/day was compared to placebo for 12 weeks in 34 women aged 75 [65]. The group was highly self-selected; complete results were available for 11 with SUI, 12 with urgency UI, and 8 with mixed. Two-thirds of urgency UI and 75% of mixed UI patients reported improvement; there was no effect on SUI. Four patients reported metrorrhagia and mastodynia. A 10 week crossover trial comparing quinestradiol 0.25 mg four times a day with placebo in 18 women in long-term care (type of UI not reported) found a mean 12% decrease in UI episodes vs. 22% increase with placebo [332]. The combination of conjugated oestrogen 0.625 mg/day and progesterone 2.5 mg/day was evaluated in a 6 month, placebo-controlled trial in 32 female NH residents with predominantly urgency UI, who also received prompted voiding [333]. In the 21 women who finished the trial, there was no difference in wet checks between drug and placebo despite increased serum oestrogen levels and partial oestrogen effect on vaginal cytology and pH in the women on drug. Two women on the drug developed vaginal spotting, and 10% developed breast tenderness. Similar lack of efficacy despite vaginal
changes were found in a case series of 9 frail women (mean age 83) with urgency or mixed UI using an oestrogen-implanted vaginal ring (Estring®) [334].

10. MISCELLANEOUS MEDICATIONS

Most of these agents are not widely used in clinical practice, and are included here for primarily historical purposes. **Emepronium bromide** had no significant effect on daytime or nocturnal UI among patients with chronic “organic brain syndrome” or chronic “functional psychiatric illness,” [335] similar to another RCT [336]. In 20 frail patients seen in a continence clinic (only 14 completed the trial), treatment with both **emepronium and flavoxate** for two weeks had no effect on UI or cystometric DO, but did increase in PVR [337]. **Propantheline** (15 mg three to four times daily) had no effect on daytime UI [338] or nocturia [339-341]. When the dose was increased to 30 mg four times daily, useful clinical effects were overwhelmed by antimuscarinic side effects [338]. In a similar small NH study, nocturia but not daytime UI improved with **concomitant propantheline and flavoxate** [342]. Titrated **imipramine** was no different than placebo in a small trial in ambulatory older persons also treated with habit training [343]. **Flavoxate** 200 mg at bedtime reduced nocturia in a small uncontrolled trial (n=40, age 51-79) [344]. An even smaller trial (6 “elderly” patients with urgency UI and cystometric DO) found no cystometric or clinical effect of a loading dose of 100 mg intravenous followed by 200 mg orally four times daily for 7 days [344].

**Flurbiprofen** 50 mg 4 times daily for four weeks decreased UI by nearly 50% (vs. no change with placebo) in 37 older persons (median age 78) with “idiopathic detrusor instability,” yet complete data were available for only 11 subjects [345]. **Procaine haematoporphyrin** 200 mg/day had only borderline effect in an 26 week RCT among 65 residents (mean age 85) of UK care homes with clinical “urge UI due to neurogenic bladder.” [346]. No studies were identified that evaluated **bethanechol chloride** specifically for frail elderly with UI and impaired detrusor emptying.

11. COMPARATIVE TRIALS

We found no studies that compared antimuscarinic agents in frail older persons.

5. SUMMARY OF THE EVIDENCE

1. Short-term treatment with oxybutynin-IR has small to moderate efficacy in reducing urinary frequency and urgent UI when added to behavioural therapy in long term care residents. (Level 2)

2. Low dose oxybutynin-ER does not cause delirium in cognitively impaired nursing home residents (Level 1)

3. Oxybutynin-IR has been associated with cognitive adverse effects in persons with dementia and/or Parkinson’s disease (Level 3), although the incidence and prevalence are unknown (Level 4)

4. Oxybutynin has been associated with tachycardia (Level 3), but not associated with QTc prolongation (Level 3) or ventricular arrhythmia (Level 2).

5. Oxybutynin is less effective in persons with impaired orientation, cerebral cortical under-perfusion, and reduced bladder sensation (Level 2).

6. There is insufficient evidence to determine the efficacy, tolerability, and safety of the following agents in frail elderly (Level 4):
   a. Intravesical oxybutynin
   b. Trospium
   c. Tolterodine
   d. Fesoterodine
   e. Darifenacin
   f. Solifenacin
   g. Duloxetine
   h. Oral and topical oestrogen
   i. Bethanechol

7. Tolterodine is associated with cognitive impairment and tachycardia (Level 3), although the incidence and prevalence are unknown. (Level 4)

8. There is evidence for lack of efficacy in the frail elderly for:
   a.Emepronium bromide (Level 2-3)
   b. Propantheline (Level 2)
   c.Imipramine (Level 2)
   d.Flavoxate (Level 3)

9. Combination of propantheline and flavoxate reduces nocturia but cannot be recommended because of unknown tolerability and safety (Level 4)

10. Flurbiprofen, propiverine, and procaine haematoporphyrin cause a small reduction in UI (Level 3) but tolerability and safety are uncertain (Level 4).

6. SURGICAL TREATMENT

a) Background

Very little is known about surgical treatment of UI in the frail elderly, likely reflecting a bias toward conservative therapy in a group with high prevalence of comorbidity and functional impairment. There are still very few studies of gynaecological surgery in women, surgical treatment for post-prostatectomy UI in frail men, minimally invasive procedures, or peri-operative care (including prevention of common post-operative complications) in urological and gynaeco-
logical patients. We reviewed the available data and general issues regarding peri-operative care which could improve surgical outcomes in this group. Surgical treatment of UI in healthy older persons is covered in Chapter 15: Surgery for Urinary Incontinence in Men, Chapter 16: Surgery for Urinary Incontinence in Women, and Chapter 17: Surgery for Pelvic Organ Prolapse.

An exhaustive review of surgical management of UI in the frail elderly is beyond the scope of this chapter. Therefore, in providing an evidence-based summary on this topic, we have taken advantage of the recent literature review and research recommendations from the American Geriatric Society, New Frontiers in Geriatrics Research: An Agenda for Surgical and Related Medical Specialties [347]. This project involved systematic literature reviews that were used to generate summary statements and recommendations for research. Their findings and recommendations pertinent to the frail elderly regarding surgical treatment of geriatric UI, [348] geriatric gynecological surgery, [349] and general care of the geriatric surgical patient [350] are included in the summary statements below. Data supporting these conclusions are available in the monograph [351].

b) Incontinence surgery in frail elderly women

Data on surgery rates in older frail women are difficult to find and overall appear very low. Several studies have used U.S. national hospital discharge databases to examine surgery rates, but unfortunately they either age-adjusted results [352] or used relatively younger cut-points (e.g., <50 years) [353]. Even in series that specifically looked at elderly women (mean age 78, range 68-90), most patients were cognitively intact (95%) [354]. Cognitive impairment appears to bias against having surgery: in one study, only 0.11% of operations for UI were done in women with dementia, cerebrovascular disease, or hemiplegia combined [353]. While absolute numbers of ambulatory UI surgery cases in women increased from 1994-1996, the percent done in those aged ≥80 years remained the same (4-5%), [355] and the results were similar for pelvic organ prolapse surgery (5%) [356]. In the US, surgery rates in elderly women vary by region of the country and race [355, 356].

One single-centre, community-based series of 54 patients aged 70 years and over provides a picture of this surgical population [357]. Twenty-eight percent of patients were aged >80, four resided in a nursing home or assisted living facility, 82% had significant comorbidity, and 32% were classified as American Society of Anaesthesiology class III risk. Intra-operative complications occurred in 11% of patients; post-operatively, 11% required intensive care monitoring, 6% had serious complications, 7% became delirious, and 9% had slow return of bowel function [357]. The authors concluded that discharge planning is especially important for these patients, and recommend pre-surgery planning of place of discharge and likely care assistance needs [357].

Although higher complication rates generally reflect the comorbidity common in frail elders (10.4% complication rate with comorbidity vs. 5.8% without it, p<.001), [353] some studies have found age protective (in one, age ≥73 years was associated with lower risk of vaginal cuff infection and recurrent prolapse following vaginal sacrospinous fixation [358]). Overall, the morbidity and mortality for geriatric patients undergoing anti-UI procedures are similar to those of other major non-cardiac surgical procedures [348]. Mortality is inconsistently associated with increased age, and most strongly related to cardiac or cancer complications [349]. Many studies do not uniformly control for the impact of comorbidity on mortality [348, 349]. Pre-operative administration of oestrogen appears ineffective in promoting wound healing [350]. Patient-controlled analgesia provides adequate pain control and sedation and increased patient satisfaction compared with standard fixed-dose and time-administered medications in cognitively intact geriatric patients [350]. Choice of anaesthetic agent may affect postoperative cognition [350] and urinary retention. The use of methylaltrexone to treat opioid-related urinary retention may become an important adjunct to surgical care in frailer patients [359]. Very few age-specific data on outcomes are available, and no studies systematically examine quality of life, functional outcome, and discharge site.

With the advent of newer “minimally invasive” procedures, there has come some modicum of testing in older, albeit, not frail, patients. Injection of bulking agents in women appears to be effective in older women, and age does not appear to correlate with outcomes [348]. In a randomized controlled trial of tension-free vaginal tape (TVT) versus 6-month wait-list control, [360] at 6 months the intervention group had a statistically significantly greater improvement in mean I-QOL score, patient satisfaction score, and urinary problem score. There was no objective measure of cure. Peri-operative complications were not insignificant, with bladder perforation by needle in one-in-five (22.6%) which required 24 hours of indwelling catheterization, urinary retention (12.9%), and less than 5% with either a urinary tract infection or new urinary urgency (3.2%). In an uncontrolled case series examining the use of the suprapubic arch (SPARC) sling procedure, the outcomes in 43 older women (ages 65-91) were separately examined. Objective cure rate was evaluated by clinical and urodynamic examination and subjective cure rate was assessed using a visual analogue score and a global patient impression questionnaire, all at 3, 6, and 12 months. At a mean follow-up of 36 months (range, 12-54 months), objective and subjective cure rates with
surgery were 91% and 95%, respectively [361]. There were statistically significant improvement in pad weight and pad numbers (from a mean of 5 to 0) and the visual analogue score. No severe intra- or post-operative complications were observed, and no patient developed de novo urgency UI.

c) Incontinence surgery in frail elderly men

No specific conclusions can be drawn regarding surgical treatment of UI in frail men. Typical studies of anti-UI surgery in elderly men are very small or fail to stratify results by age and/or comorbidity (e.g., see references [362, 363]). One small study (n=46) found that advanced age was not a risk factor for poor outcome after collagen injection for post-prostatectomy UI, [364] while another (n=12, mean age 80 years) of trans-urethral resection prostatectomy (TURP) for obstruction-associated urgency UI found that cognitively impaired men had the greatest UI improvement [365]. In a single-institution case series of men aged > 80 years old undergoing TURP (68% of whom had urinary retention), 80% were satisfied with their outcome. Of the men with retention, 80% were able to void with a small PVR by six weeks. Complication rates were 41% (early) and 22% (late) [366]. Urodynamic evaluation of post-prostatectomy UI is recommended prior to surgical treatment (see, for example, reference [363]).

d) General issues in surgical care of the frail elderly

Important factors in the surgical care of frail patients include: pre-operative risk stratification (e.g., American Society of Anaesthesiology class, Charlson index, Modified Cardiac Risk Index, [367] Burden of Illness Score [368]); ensuring adequate nutrition, especially when patients cannot take oral feeding or become delirious; proactive management of comorbid heart disease, diabetes, and pulmonary disease; prevention, [369, 370] recognition, [371] and treatment of post-operative delirium; [370, 372] adequate pain assessment and treatment, especially in cognitively impaired persons; [373] recognition of the hazards of prolonged bed rest [374] and the prevention [375] and treatment of functional impairment; use of specialised care units for the elderly; [376] and discharge planning regarding rehabilitation, need for assistance, and site of discharge. These issues should be factored into any plan of surgical care of frail elderly persons.

e) Summary of evidence

1. No studies were identified regarding gynaecological surgery in institutionalized elderly women. (Level 4)
2. Exogenous administration of oestrogen is ineffective in promoting wound healing after gynaecological surgery in older women. (Level 3)
3. Injection of bulking agents appears to be effective in older women, and age does not appear to correlate with outcomes. (Level 3)
4. No studies were identified that evaluated functional or quality of life outcomes after UI surgery in frail older persons (Level 4)
5. Risks of morbidity and mortality for frail patients undergoing anti-UI procedures are similar to those of other major non-cardiac surgical procedures. (Level 2)
6. Surgical mortality risks are still low in elderly persons, and often due to cardiac or cancer complications. (Level 2-3)
7. Operative mortality is inconsistently associated with increased age, and many studies did not uniformly control for comorbid conditions. (Level 2-3)
8. Patient-controlled analgesia provides adequate pain control and sedation and increased patient satisfaction compared with standard fixed-dose and time-administered medications in cognitively intact geriatric patients. (Level 2)
9. Choice of agent for patient-controlled analgesia may affect postoperative cognition. (Level 3)
10. Some case series and waitlist-controlled trials suggest that minimally invasive surgical approaches may be useful in older adults, yet these trials may have little to do with whether surgical treatments are appropriate in the frail elderly (Level 3)

VIII. URINARY RETENTION IN THE FRAIL ELDERLY

The association of both detrusor underactivity and bladder outlet obstruction with age, comorbidity, and medications makes urinary retention (UR), either acute or chronic, a potential problem in frail older adults. Although bothersome in younger and middle-aged persons, in older frail persons UR and acute UR (AUR) carry significant morbidity, including delirium, [377] bradycardia (possibly related to alteration in the reflex loop involving the vagal and the sympathetic nerves), [378] higher mortality in the year following hip fracture, [379] and persistent UI. [380] UR and elevated PVR have [380] and have not been [381] associated with an increased risk of UTI in this population. Data from the UK NHS data base found that the 1-year mortality in older men without significant comorbidity presenting with AUR was 12% (age 75-84) and 29% (age > 85); in men with comorbidity, the respective mortality rates were 27% and 43%, and rates were even higher in men with “precipitated” retention (not associated with BPO) [382]. Of concern is the fact that UR may be asymptomatic in frail elders, particularly women.[383].
1. QUALITY OF THE DATA

Studies of the prevalence of UR among frail elders suffer from lack of standardization of the definition of UR, which ranges from inability to void to PVR cutoffs as low as 50 mL. PVR is usually reported as a volume and not percent of bladder emptying; results often are based on a single measurement; and whether or not the patient strained is rarely reported. Many studies do not exclude patients with medical reasons for impaired emptying, such as advanced diabetes mellitus and anticholinergic medications. There is also extensive heterogeneity in the populations studied, and there is a relative paucity of data on UR in women. The 1996 US Agency for Health Care Policy Research consensus guidelines on UI in adults suggested that PVR > 200mL is abnormal, <50 mL normal, and 50-200 mL intermediate [172]. Using data from symptomatic patients referred for urodynamics, Madersbacher et al estimated that, starting at age 40, PVR increased by 13 mL per decade in men and 4 mL per decade in women [42]. In two studies of postmenopausal women without DO, both with and without LUTS, Pfisterer et al found median PVR to be < 20 mL [43, 49]. Efforts to establish normative means for PVR in women only compared those less than age 65 versus those older; only 25 were aged > 65, and their mean PVR was 34± 31 mL [384].

2. RESULTS

Frail elders in hospital and rehabilitations units may be at special risk for UR and impaired bladder emptying. Amongst 100 consecutive patients admitted to a geriatric hospital ward (mean age 81), 34% had PVR >50 mL, and they had greater functional impairment and subsequent mortality than those with smaller PVR [170]. UR (defined as PVR ≥ 150 mL) was present in 22% of older patients on admission to a subacute, predominantly geriatric, rehabilitation unit; [380] patients with UR were more likely to be male and have poor mobility, neurologic disorders (e.g., stroke or multiple sclerosis), cognitive impairment, UI, previous prostate problems, previous LUTS, take anticholinergic medications, or have a UTI diagnosed on admission. Other risk factors for UR in this population include previous history of UR, [385] faecal impaction, [386] and several classes of medications. [44] UR is common after hip fracture: in consecutive series of patients admitted to hospital with hip fracture, a PVR >300 was present in 79-97% on admission. [379,387] 36% immediately pre-operatively, 56% post-operatively, and 22% during the recovery phase [379]. Randomized trials have shown both short-term indwelling and intermittent catheterization to be effective in restoring normal voiding in frail elderly [44, 388].

Impaired emptying is common among nursing home residents. In separate case series, 35% of residents had a PVR ≥100 mL (n=150), [381] 11% had PVR ≥150 mL, [386] and 59% had urodynamic evidence of detrusor underactivity [171]. Less is known about the prevalence of UR in frail elders in the community. In a case series of 167 frail elderly outpatients, 11% had UR (two consecutive ultrasound PVR measurements ≥150 mL), which was independently associated with advanced age, use of anticholinergic medication, diabetes, and faecal impaction [386]. Women attending a Female Pelvic Medicine Clinic who were found to have a high PVR (≥100 mL) were significantly older than women with normal emptying (62±14 vs. 59±13 years, p=0.005) [389]. Studies involving older men focus on AUR. Cathcart et al evaluated AUR among men in the UK NHS data base, defining AUR by ICD-10 coding; men with TURP, prostatic cancer, multiple sclerosis, or Parkinson’s disease were excluded. AUR incidence rose sharply with age, even amongst the oldest old, from 9.13/1000 person-years among men aged 75-84, to 16.8/1000 person-years among men aged 85-100 [390]. AUR incidence in older men (aged 70-83) was also evaluated in a prospective observational study of over 6,000 American male health professionals without baseline history of TURP, prostate cancer, or AUR. The estimated AUR incidence over 3 years was 7.9/1000 person-years among men with no or only mild LUTS at baseline, and 11.3/1000 person-years among men with moderate to severe LUTS [391].

Intermittent catheterisation (ISC) can be helpful in the management of patients with UR with or without UI. ISC can be carried out by either the patient or a caregiver, with the frequency based on PVR. The assumption that older patients are unwilling or unable to manage UR with ISC has not been borne out [392]. The ability to reliably and safely use ISC to manage UR in hospital and long term care settings is highly dependent on staff availability and training. In addition, using ISC in institutional settings (where multi-resistant organisms are common) may yield an unacceptable risk of nosocomial infections, and use of sterile catheter trays are very expensive. Thus, it may be extremely difficult to implement such a programme in a typical nursing home setting.

3. SUMMARY OF EVIDENCE

1. There is no consensus regarding a standardized definition of UR in frail older persons (Level 4)
2. UR is common in hospitalized frail elders and long term care residents (Level 2), but not in healthy, asymptomatic older persons (Level 2)
3. Hip fracture and orthopaedic surgery are associated with very high rates of UR in older persons (Level 2)
4. Risk factors for UR in frail elders include male sex, impaired mobility, cognitive impairment,
The prevalence of two or more episodes among men has been reported to be as high as 90% for one episode per night in persons over age 80 [398-402]. The prevalence of nocturia increases with age, and there are limited data on optimal diagnostic assessment, and treatment of nocturia in the frail elderly. Similar to UI, nocturia is usually multifactorial in frail elderly persons. Thus, diagnostic assessment must be comprehensive, and multi-component interventions may be necessary for successful treatment.

2. QUALITY OF THE DATA

There are good epidemiological data from multiple cultures and countries on the prevalence of nocturia, but limited data on associated factors and impact. Studies of the pathophysiology of nocturia in the elderly have generally been small and highly focused on one aspect of potential underlying causes. As with UI, there are limited data on optimal diagnostic assessment, and therefore recommendations are generally based on expert opinion [19, 393]. Data on treatment in elderly patients are very limited. Although there are some treatment RCTs, they are small, include few very elderly subjects, and have focused primarily on vasopressin. We located no data on the effectiveness of multi-component interventions for nocturia in the elderly.

3. PREVALENCE AND IMPACT

The prevalence of nocturia increases with age, and has been reported to be as high as 90% for one episode per night in persons over age 80 [398-402]. The prevalence of two or more episodes among men between 70 and 79 is nearly 50 percent [403]. This increasing prevalence is largely due to age-related conditions that underlie the pathophysiology of nocturia (see below). Nocturia is more common in young adult women than in men, but the gender ratio reverses after age 60 [403]. Nocturia has been variably associated with chronic medical conditions such as hypertension and diabetes, [404, 405] advancing renal failure, [406] and cardiovascular disease [407, 408]. Nocturia in the frail elderly can cause accidental falls [409]. Frail elderly persons with nocturia, who also have gait and balance disorders and other risk factors for falls, are clearly at increased risk for injury and consequent morbidity, yet no nocturia treatment trials have evaluated any impact on fall reduction. Nocturia also has adverse effects on quality of life, including an increased risk of depression and poor self-rated health, probably as the result of the impact on sleep [410, 411]. Adults with nocturia also complain that nocturia “makes them feel old” and they worry about falling at night [412].

4. PATHOPHYSIOLOGY

In elderly persons, the pathophysiology of nocturia is usually multifactoral and can be related to one or a combination of three primary underlying causes, all of which increase with age: low bladder capacity usually as a component of OAB, DO, urgency UI, or BOO in men; nocturnal polyuria; and primary sleep disorders [395-397]. The proportion of 24-hour urine volume produced at night increases with age, even among healthy older adults free of overt comorbid conditions [413, 414]. Studies of frail elderly have shown that the proportion of urine produced at night is close to 50%, rather than less than 30% as in young healthy adults [415-417]. Nocturnal polyuria is more common in older compared to younger nocturics [418]. In some elderly persons, this is due to mobilisation of excess volume caused by peripheral oedema, which may be due to venous insufficiency, medications, and/or heart failure. Some studies have suggested that there is an abnormality in the secretion and/or action of arginine vasopressin (AVP) or a loss of its normal diurnal rhythm (with inappropriately low values at night) in many elderly patients with nocturia [419, 420]. Another, however, failed to find an association between AVP deficiency (detected by water deprivation testing) and nocturnal polyuria in a series of elderly persons with nocturia [421]. Other research suggests that some frail elderly persons with nocturia have high atrial natriuretic peptide (ANP) levels at night; [422, 423] however, these investigators did not use echocardiography or brain natriuretic peptide levels to detect occult heart failure. Sleep disordered breathing and sleep apnoea also have been associated with nocturia and nocturnal UI in the elderly [422, 424-426]. Whether this relates to increased ANP production, [422] mechanical forces on the bladder generated during apnoea events, [424] or other mechanism(s) is unknown.
5. DIAGNOSTIC ASSESSMENT

The approach to the assessment of nocturia should be similar to that for UI described above. Special considerations include:

- A frequency-volume chart of at least 24 hours duration that includes timing and volume of each void at night as well as during the day, as well as a specific indication of when the individual went to bed with the intention of going to sleep at night and awoke in the morning. Some patients may find this difficult to perform, [427] but face-to-face explanation of the procedure, a receptacle to place in the toilet to measure volumes, and involvement of carers may improve compliance and accuracy.

- Additional questions in the history that focus on the possibility of a primary sleep disorder, such as asking about sleep quality, daytime sleepiness, snoring, and leg movements at night (this history is enhanced by questioning the bed partner).

- Additional history and focused physical examination related to volume overload (e.g., lower extremity venous insufficiency, heart failure); in some cases additional testing such as an echocardiogram or a brain natriuretic peptide level may be helpful in ruling out the latter diagnosis.

6. TREATMENT

Treatment of nocturia in elderly patients should be based on individualized identification of all potential underlying causes. The most commonly used measure of nocturia treatment efficacy is a reduction in nocturia episodes. However, studies have not related the number of nocturia episodes to the hours spent in bed, which may vary considerably in older persons. The impact of three episodes of nocturia is considerably different in someone in bed for seven compared with twelve or more hours. Cure, or the complete resolution of nocturia, is infrequently achieved in either clinical practice or in research. Some trials have reported percent of trial participants achieving a 50% reduction in nocturia or the percent of individuals reporting one fewer nightly episodes of nocturia. It is important to recognize that most reports of treatment have shown only a small reduction in episodes of nocturia, ranging from 0 to 0.8 fewer episodes of nocturia versus placebo. Patient-based outcomes are important and may include general satisfaction questions, nocturia-related bother, and nocturia-specific quality of life. Most trials examining nocturia as an outcome were performed prior to the validation testing of the ICIQ-NQOL instrument [428]. An additional important target for therapy is reduction in bother due to nocturia.

Although no specific data are available on multi-component interventions, elderly patients with nocturia may benefit from an approach to treatment that combines behavioural strategies, therapy for medical and sleep disorders, and nocturia-specific drug therapy.

a) Behavioural approaches and treatment of comorbidity

There are no specific data on the impact of behavioural strategies (e.g. altering fluid or sodium intake, leg elevation for oedema) on nocturia in older patients. Using bedside commodes or urinals, and minimising the distance necessary to reach a toilet and providing a safe, adequately lit path may be helpful in reducing the risk of night-time falls related to nocturia, especially in those with underlying gait instability and other risk factors for falls. Reducing volume overload associated with lower extremity venous insufficiency or congestive heart failure with a late afternoon dose of a rapid acting diuretic may be helpful in reducing nocturnal polyuria and nocturia in selected patients [429, 430].

Treating sleep apnoea with continuous positive airway pressure can reduce nocturia severity, but these trials have not usually included the frail elderly [431]. Treatment with very short-acting benzodiazepines for patients with primary insomnia, and with dopaminergic agonists for patients with restless leg syndrome, may improve sleep quality, but there are no data to support these approaches. There is one secondary data analysis of a RCT which demonstrated that behavioural therapy, with an emphasis on pelvic floor muscle exercises and urgency suppression strategies, reduced nocturia in women with urgency-predominant UI [432].

The median reduction of 0.5 episodes per night was significantly more effective than antimuscarinic (0.3 episodes) or placebo (no reduction). There are no trials of pelvic floor muscle exercises or urgency suppression strategies with nocturia as the primary outcome.

There are several approaches to drug therapy for elderly patients with nocturia. Most of the published guidelines suggest targeting a "primary" or "principal" causes of nocturia (e.g., nocturnal polyuria). Because most older adults with nocturia have multiple potential causes, treatment often will require combination treatment.

b) Antimuscarinic therapy

In general, if the history, bladder diary, and physical examination suggest that nocturia is related primarily or in part to OAB/DO/urgency UI, then treatment with an antimuscarinic agent should be considered (see Pharmacological Treatment above). There are several trials examining the effect of antimuscarinics for nocturia reduction, including trials of oxybutynin-IR, [432] solefenacin, [318] and tolterodine [433, 434]. Even when these agents have shown statistically significant reductions in nocturia, the net benefit of reduction in nocturia (above that effect shown with placebo) is only 0.0 to 0.3 episodes. There is evidence to suggest that these agents may be best used in combination with other therapies [433] rather than as single modality therapy.
c) **Agents for benign prostatic obstruction**

Alpha-adrenergic blockers used in patients with symptoms suggestive of BPO have a modest impact on nocturia, with a mean reduction of slightly less than one episode per night [421]. 5-alpha reductase inhibitors have mostly shown no statistical benefit for nocturia [421] except in one study among a subset of participants age ≥70 [435]. This statistical advantage did not persist beyond one year, and the net benefit compared to placebo was a difference of < 0.2 fewer nocturia episodes. Among postmenopausal women, one uncontrolled trial of estradiol in combination with a progestational agent showed a dramatic reduction in nocturia over 6 months, [436] but this was not replicated in another RCT [437]. There are few studies that have focused on treatment of nocturia with the use of medications for sleep. One RCT evaluated melatonin for treatment of nocturia associated with BOO in older men [438]. Melatonin showed only a trend towards reduction in nocturia compared to placebo (-.03 and -0.05 episodes from baseline 3.1 episodes, respectively) but did significantly reduce reported bother from nocturia.

d) **Anti-diuresis treatment: Desmopressin**

A large number of studies over the last 20 years have examined the potential role of exogenous AVP (desmopressin or DDAVP) for the treatment of nocturia in older patients [439-451] (Table 9). The majority have been uncontrolled case series involving relatively small numbers of subjects, and the inclusion criteria, outcome measures, and route, dosing, and duration of DDAVP treatment varied considerably. The two largest studies were RCTs of oral DDAVP using essentially identical designs, one conducted in men [449] and the other in women [450]. Although they included some patients older than 75, the mean age of the participants was closer to “middle” rather than “old” age (65 and 57, respectively). Both found significant reductions in nocturia and nocturnal urine volume, and increases in mean duration of self-reported first night-time sleep episode. However, the trials’ designs were unusual: the randomised controlled portion was preceded by a dose-titration run-in, with the subsequent exclusion of subjects who did not experience >20% reduction in nocturnal urine volume or who were intolerant to the medication. Although this approach may be useful for targeting therapy in clinical practice, it raises questions about selection bias and the generalizability of the results.

Most individuals in DDAVP trials were titrated up to an oral dosage of 0.4 mg, [449, 450] yet older patients can have a significant reduction in night-time urine with much lower doses of 0.1 or 0.2 mg orally [452]. A major concern related to DDAVP treatment in elderly patients is fluid retention (which can exacerbate underlying cardiovascular disease) and hyponatremia. Many older persons may have pre-existent hyponatremia due to a variety of medical conditions and drugs. A recent review [453] found the incidence of hyponatremia with DDAVP in older persons to be 0-9% (depending on definition), with the exception of the RCT in men discussed above, in which the incidence of any hyponatremia was 22% (4% with sodium < 130 mmol/L). Because so few frail elderly were included in these trials, the actually incidence of clinically significant hyponatremia from DDAVP is unknown. A further review of pooled trial results found that the incidence of hyponatremia in subjects with normal baseline sodium was <1% (3/336 subjects) in persons < 65 and 8% (22/2760) in those ≥65, and 75% (6/8) in older patients with a low baseline serum sodium [454]. Pharmacodynamic studies in younger older men (aged 55-70) found that DDAVP had a prolonged half-life which was in part responsible for hyponatremia [455]. DDAVP is not useful in frail older persons in nursing homes with nocturia and/or night-time UI because of the lack of efficacy for reducing night-time voids and the very high rate of hyponatremia [452].

7. SUMMARY OF EVIDENCE

- Late afternoon administration of a diuretic may reduce nocturia in persons with lower extremity venous insufficiency or congestive heart failure unresponsive to other interventions. (Level 2)
- If OAB, DO, and/or urgency UI is felt to be a major contributor to nocturia, antimuscarinic agents should be considered. (Level 3)
- If nocturia is due to insomnia alone, then a very-short acting sedative hypnotic may be considered. (Level 3)
- DDAVP should not be used in frail elderly because of the risk of hyponatremia. (Level 1)

X. MODELS OF CARE FOR THE FRAIL ELDERLY WITH UI

1. BACKGROUND

Throughout the world, frail elderly persons are cared for in a variety of settings using many different models of care. While there continues to be very few studies that examine these models in relation to UI management, a discussion of selected models is useful in identifying the challenges and opportunities to improve continence care in this population. This descriptive section briefly outlines four models of UI care particularly relevant to the frail elderly: home care, continence nurse advisors, collaborative practices between advance practice nurses and physicians, and long term institutional care. comprehensive review of worldwide care models is outside the purview of this section. Of note, we located little new information since the 3rd ICI.

2. HOME CARE

Most care for the frail elderly who live at home is provided by spouses, children, other relatives, and in some cases neighbours or friends. Overall, there has been little research on UI interventions for this population. One trial found that behavioural interventions can be effective in selected frail homebound persons with UI and motivated caregivers [456]. Overall, however, the informal nature of care at home may lead to important barriers to effective continence care. First, caregivers may not be available 24 hours per day, and thus regular toileting assistance may only be intermittently available. Toileting programmes (e.g., prompted voiding) and intermittent catheterisation therefore may be impossible to implement consistently. Second, many caregivers for frail persons are in fact frail themselves. Spouses and even adult children may have medical illnesses and/or functional problems that make it physically difficult and stressful for them to provide continence care. Third, even among caregivers who are physically capable and available to assist with continence care, negative attitudes and lack of education may pose substantial barriers to providing the required care.

Trained, paid caregivers for frail elderly living at home are variably available throughout the world. Such services may include nurses to teach patients and caregivers UI care and management of intermittent or indwelling catheterisation; health aides who can assist with continence care; and provision of continence care supplies (e.g., pads and catheter supplies). In the US, for example, Medicare (health insurance for persons aged > 65) does not pay for ongoing UI care, only some catheter care and supplies period and need-based, home skilled nursing and physical therapy, and usually only on a limited basis and following hospitalisation... For patients who do not have access to continence home care and/or do not have an available and motivated caregiver, UI management remains pads and other protective products, which can be expensive if not provided or reimbursed through available health insurance. In these cases, some frail elders will devise homemade alternatives to pads, which are neither effective, comfortable, nor safe (especially for skin protection).

3. CONTINENCE NURSE ADVISORS

In many countries (e.g., UK, Australia, and Canada, among others), continence nurse advisors are available who can provide extremely valuable services for frail elderly with UI. Continence nurse advisors are highly trained in UI assessment and management. They are generally funded by the government and function as public health nurses for a region associated with one or more hospitals. They serve as advisors and provide education to physicians, nurses, and other health care professionals, as well as patients and their caregivers. They may also assist hospital staff in the assessment and management of UI in hospitalised frail elderly, and coordinate follow up care in the home or in an outpatient clinic. One Canadian study found that continence nurse advisors had a positive impact in improving management of UI in older persons [457].

4. COLLABORATIVE PRACTICES BETWEEN ADVANCE PRACTICE NURSES AND PHYSICIANS

In many countries, publicly supported continence nurse advisors are not available. However, other models have developed that generally involve collaborative practices between nurses with special interest, advanced training, and expertise in continence care and physicians (usually an urologist, gynaecologist, or geriatrician). These collaborations can be vital for providing optimal continence care for the frail elderly because of the multicomponent therapy required. Such nurses may provide reimbursable services in private offices and clinics; provide education, consultation, and/or direct services to nursing homes, other long term care facilities, and assisted living facilities; and assist with the assessment and management of UI for frail elders in their homes. Reimbursement for advance practice nurses and their ability to provide direct care independently of a physician varies across countries, and in some case within countries (e.g., in the US their scope of practice can vary by state). In some countries there are specialty organisations for this type of continence nurse (e.g., the US, Wound Ostomy Continence Nurses Society and Society of Urological Nurses and Associates). Although little data on the effectiveness of this model exist, it is becoming more widespread (e.g., Israel and Italy).

5. INSTITUTIONAL LONG TERM CARE

Long term care for the frail elderly is provided in a variety of types of institutional settings throughout the world. Continence care in these settings is dependent upon many factors, including: type of resident (only long-term care or also short-term rehabilitation post-hospitalization patients as well); physical environment; the organisational culture and leadership commitment to providing high quality care; the number, education, and motivation of direct care staff; access to physicians with interest and understanding of continence care; and financial and regulatory incentives to provide appropriate continence care. Nursing home staffing is a major barrier to translating research on prompted voiding and other interventions into practice (see Behavioural interventions above), and because resource constraints are stringent and will become more challenging with the rapid growth in the frail elderly population [267, 458].
The section on Interventions with Long-term Care Staff above reviews studies of interventions with nursing home staff to improve continence care. These interventions have generally met with limited success because they have not addressed the culture, staffing, and overall system of care in these facilities.

Three broad strategies have been employed to improve the quality of continence care for frail elderly nursing homes residents. The first are standardised approaches to identification, assessment, and management of UI. One is the Resident Assessment Instrument for nursing facilities, whose use is mandated in the US and other countries [460]. The Resident Assessment Instrument combines information from the Minimum Data Set (including data on individual resident demographics, medical conditions, function, cognition, and care needs) with Resident Assessment Protocols for specific conditions and impairments. The continence section of the Minimum Data Set is generally accurate in identifying incontinent patients, but not for determining the type or severity of UI or determining especially smaller changes in continence over time [459]. The original version of the Resident Assessment Protocol for UI was partially validated in a sample of approximately 100 frail, incontinent patients in one large academically-affiliated US nursing home [460]. Another approach is national guidance directives, such as that for surveyors who conduct yearly quality evaluations of all US nursing homes. A recent revision of the US guideline for UI attempted to replace the existing emphasis on nursing documentation of continence care plans with an emphasis on UI assessment and provision of patient-focused care [461]. However, a subsequent study found that both surveyors and nursing home staff did not understand this shift in emphasis, and that dissonance between these two groups in basic UI knowledge and elements of the guidance is a likely barrier to any change in quality of UI care [156]. The American Medial Directors Association (for nursing home physicians) publishes a clinical practice guideline for continence care, based on the US Agency for Healthcare Policy and Research guideline and the federal guidance mentioned above [462] yet its implementation and effectiveness has not been studied. However, despite the existence and dissemination of these approaches, several studies document an ongoing discrepancy between their recommendations and regulations and the continence care actually delivered in the US [166, 272, 463, 464] and UK [160]. The second strategy has been the use of principles of continuous quality improvement and total quality management developed for business management [465]. The key elements of these approaches are education and involvement of direct care staff, identification of a “continence champion” and team to implement the programme, and the continuous collection and analysis of quantitative outcome data using principles of statistical quality control. Quality assurance programmes using UI quality indicators have also be proposed [157]. One study successfully used a computerised assessment and quality improvement software programme and external oversight to maintain a 50% reduction in UI in eight diverse, geographically dispersed US nursing homes [273]. A second implemented a quality improvement programme in five diverse US nursing homes, but UI reduction was more modest (20-30%) in this effort to translate research into practice [309].

The third approach is a specialty practice exemplar model for continence care, with an academic nursing faculty member with expertise in the assessment and treatment of UI conducting a clinical UI practice in a long-term care facility (see Interventions with Long-term Care Staff, above). Graduate nursing students working with this individual focus on the Resident Assessment Protocol for UI. UI assessment and management skills are transferred to the facility nursing staff members through several mechanisms, including staff education and improved continence care systems [273].

Assisted living communities are social care residential models, in which older persons are provided primarily IADL assistance (meals, laundry, cleaning), are becoming more common (primarily in the developed world). There is substantial variation in the functional status and medical care needs of their residents, availability of nursing and physician care, reimbursement, regulation, and whether and how residents are allowed to age “in place” versus transferred to nursing facilities. In some countries and localities, assisted living residents may substantially resemble the nursing home population. There are no data on the quality of management of UI for frail elderly residing in assisted living facilities, or intervention trials specifically in this population. The US National Association for Continence (www.nafc.org) has published a “blueprint” for continence care in assisting living facilities, based primarily on expert opinion.

**XI. RECOMMENDATIONS FOR MANAGEMENT**

1. **BASIC ASSESSMENT** (SEE ALGORITHM FOR SPECIFICS)

   a. Active case finding for UI should be done in all older persons (Grade A).

   b. Screening for frailty is possible (Grade A) and encouraged (Grade C).

   c. The basic assessment of UI should focus on identification of potentially treatable conditions and factors that may cause or worsen UI, contribute to its burden, and impact management decisions (Grades A-C).

<tr>
<td></td>
<td>Improve intervention adherence by:</td>
</tr>
<tr>
<td></td>
<td>• Designing interventions feasible for most, and incorporating caregivers/care setting in that consideration</td>
</tr>
<tr>
<td></td>
<td>• Allowing flexible time frame for follow-up assessments</td>
</tr>
<tr>
<td></td>
<td>• Prioritising safety</td>
</tr>
<tr>
<td></td>
<td>• Providing transportation</td>
</tr>
<tr>
<td></td>
<td>• Preplanning alternatives to clinic-based follow-up (e.g., home visit, telephone)</td>
</tr>
<tr>
<td></td>
<td>• Establishing good relationship and incentives to participate for family, caregivers, and/or care setting</td>
</tr>
<tr>
<td></td>
<td>• Understanding priority rank and definition of important potential outcomes to patients, caregivers, and care settings</td>
</tr>
<tr>
<td></td>
<td>Anticipated attrition rates should not preclude attempts at long-term follow-up.</td>
</tr>
<tr>
<td>Exclusions that decrease generalizability</td>
<td>Principle exclusion should be factors that prevent participation.</td>
</tr>
<tr>
<td></td>
<td>Avoid exclusions for comorbidity.</td>
</tr>
<tr>
<td></td>
<td>Exclude only those persons whose cognition is not compatible with the specific intervention.</td>
</tr>
<tr>
<td></td>
<td>Use explicit procedures for consenting participants; involve a surrogate/proxy when needed. Include discussion of ethical concerns and how they were addressed in the report.</td>
</tr>
<tr>
<td>Problems using self-report to assess outcomes</td>
<td>Supplement self-report of primary outcomes with “hard” measures, e.g. assist with toileting.</td>
</tr>
<tr>
<td></td>
<td>Collect “objective” measures of function and proxy information in parallel, e.g. percent of wet checks, hours of caregiver time.</td>
</tr>
<tr>
<td></td>
<td>Set outcomes to be less sensitive to random fluctuations (e.g., end point of “50% decrease in UI”).</td>
</tr>
<tr>
<td></td>
<td>Use outcome measures specific to the target population: e.g., for quality of life, use established measures of social interaction [42] rather than existing UI-specific scales; re-validate existing UI-specific scales; for community-dwelling persons, transfer to setting with higher level of care (e.g., from home to residential/institutional care)</td>
</tr>
<tr>
<td></td>
<td>Include measures related to caregiver time commitment, burden, costs, morbidity, quality of life, and satisfaction with intervention (regarding the patient and themselves).</td>
</tr>
<tr>
<td></td>
<td>Assess possible caregiver(s) preference(s) for care.</td>
</tr>
</tbody>
</table>
2. PRINCIPLES OF MANAGEMENT

a. Initial management should be individualized (Grade B).

b. Decisions on specific management of frail older persons with UI should incorporate:
   i. Most likely type of UI (Grade C)
   ii. Patient and caregiver preferences for care (Grade B)
   iii. Patient-centred care goals of care (Grade C)
   iv. The chance that a specific treatment will achieve the patient’s/’career’s goals within the patient’s expected remaining life expectancy (Grade C)
   v. Understanding of the potential direct and indirect costs and benefits of treatment for the individual, their caregiver(s), and health systems (Grade C)

c. Decisions to use drug therapy and choice of specific agent should incorporate:
   i. Age-related changes in pharmacology (Grade B)
   ii. Adding to pre-existent polypharmacy (Grade B)
   iii. Drug-drug interactions (Grade A)
   iv. Drug-disease interactions (Grade B)

d. Management of UI in frail older men should incorporate consideration of gender differences in:
   i. Comorbidity and functional impairment (less in men) (Grade C)
   ii. Caregivers (men more likely to have living spouses) (Grade C)
   iii. The relationship between UI and cognition (less strong in men) (Grade C)
   iv. Benign prostate disease (Grade C)
   v. Prostate cancer (Grade C)

  e. No recommendation is possible regarding gender differences in the risk of urinary retention from antimuscarinic therapy (Grade D).

  f. No recommendation is possible regarding the cost-benefit, cost-effectiveness, or cost-utility of specific interventions (Grade D).

3. LIFESTYLE INTERVENTIONS

a. Fluid restriction should be avoided in long-term care residents and other frail elders who may not have ready access to fluids or accurately sense thirst (e.g., persons with dementia) (Grade C).

b. No recommendation can be made regarding other lifestyle interventions (Grade D).
4. BEHAVIOURAL THERAPY

a. Prompted voiding should be offered to nursing home residents and homebound older adults with UI who: are able to state their name or point to one of two named objects; transfer with a maximum assist of one person; and have less than four UI episodes during the day (Grade A).

b. Prompted voiding should be continued only in those frail elders who, after a three-day trial, demonstrate at least a 20% reduction in leakage or toilet appropriately at least two-thirds of the time (Grade A).

c. Efforts must be made to increase and maintain caregiver compliance with prompted voiding (Grade B).

d. Combined toileting and exercise programs should be considered for frail elderly with UI who are physically inactive, when there are resources to conduct and continue the intervention (Grade A).

e. No recommendation can be made for behavioural treatment of night-time UI (Grade D).

f. No recommendation can be made for habit retraining in frail elderly (Grade D).

g. No recommendation can be made for timed voiding in frail elderly (Grade D).

5. PHARMACOLOGICAL THERAPY

a. Antimuscarinic treatment should be considered for those frail persons with UI who have symptoms of OAB, urgency UI, or mixed UI, and who have been assessed for contributing comorbid factors (including existing medications), and who are appropriate for and have had a trial of behavioural treatment (Grade C).

b. Choice of specific antimuscarinic should be based on:

i. Age-related changes in pharmacokinetics that could affect the metabolism and clearance of a specific agent

ii. Likelihood of the agent causing any adverse effects the patient already experiences, such as pre-existing constipation, dry mouth, and visual impairment (Grade C)

iii. Potential drug-drug and drug-disease interactions (Grade C)

c. Drugs should be started at the lowest possible dosage (Grade C).

d. There should be proactive monitoring and re-evaluation of drug therapy for achievement of explicit efficacy goals, any adverse drug effects, and appropriateness of continued drug therapy (Grade C).

e. Oxybutynin-IR can be considered for additional benefit for frail elders with OAB, urgency UI, or mixed UI in whom behavioural therapy is feasible, with careful monitoring for adverse effects (Grade C).

f. Topical oestrogens (cream, tablet, ring) may be considered for adjunctive treatment of urogenital atrophy in women (Grade B).

g. No recommendation can be made for the use of oral or topical oestrogen for the treatment of UI in frail elderly women (Grade D).

h. No specific recommendation can be made for use of the following agents for the treatment of UI in frail elderly (Grade D):

i. Tolterodine

ii. Topical or extended-release oxybutynin

iii. Darifenacin

iv. Solifenacin

v. Trospium

vi. Fesoterodine

vii. Bethanacol

viii. Duloxetine

ix. Propiverine

x. Flurbiprofen

i. The following agents should not be used in the frail elderly:

i. Emepronium bromide (Grade B)

ii. Propantheline (Grade B)

iii. Imipramine (Grade B)

iv. Fluoxetine (Grade B)

v. Procaine haemtoporphyrin (Grade C)

J. Combinations of bladder antimuscarinics should not be used (Grade C).

6. SURGICAL THERAPY

a. Age alone is not a contraindication to surgical treatment of UI (Grade C).

b. Urodynamic evaluation should be done before considering surgical treatment of UI in frail older persons (Grade B).

c. Pre-operative risk should be stratified using established indexes (Grade A).

d. Insure adequate post-operative nutrition especially in patients who cannot take oral feeding or who become delirious (Grade C).

e. Programmes to prevent post-operative delirium should be used (Grade A) along with proactive use of established measures to diagnose delirium (Grade A).

f. Pain assessment in cognitively impaired persons
should use measures specially-designed for this population and not general pain scoring tools (Grade B).

g. Proactive preventative approaches to hospitalisation-related functional impairment should be used (Grade A).

h. Specialised care units may improve selective outcomes for frail older patients (Grade A).

i. Discharge planning should begin before surgery takes place (Grade C).

j. Patient controlled analgesia can be used in cognitively-intact frail older persons (Grade B).

k. Analgesic agents associated with delirium (e.g., meperidine) should be avoided (Grade B).

7. NOCTURIA

a. Older patients with bothersome nocturia should undergo a diagnostic assessment that focuses on identifying the potential underlying cause(s), including nocturnal polyuria, a primary sleep disorder, OAB/DO/urgency UI, or a combination of these conditions (Grade C).

b. Treatment of elderly patients with nocturia should focus on the underlying causes:

i. For patients with OAB/DO/urgency UI, consider an antimuscarinic agent. (Grade B)

ii. Patients with nocturnal polyuria must be evaluated and treated for contributing factors (peripheral oedema [and its potential medical and drug aetiologies], congestive heart failure, and type and timing of fluids [all Grade C], and sleep apnoea [Grade B]).

iii. In patients with nocturnal polyuria unresponsive to treatment of contributing factors or of uncertain cause, afternoon dose of a rapid-acting diuretic can be considered with careful monitoring of efficacy, volume status, and electrolytes and renal function. (Grade C)

iv. Patients with a primary sleep disorder should be treated for the underlying cause(s), and the impact of treatment on nocturia monitored. (Grade C)

v. For patients without cognitive impairment and nocturia inadequately responsive to the above approaches who remain most bothered by inability to achieve sleep after an episode of nocturia, a low dose of short-acting hypnotic may be considered, (Grade C)

c. DDAVP should not be used in frail elderly with nocturia because of the risk of hyponatremia (Grade B).

8. INTERVENTIONS WITH LONG-TERM CARE STAFF

a. Long-term care institutions should implement staff development programmes to increase knowledge and skills about continence care and the efficacy of behavioural methods (Grade C).

b. Computerised databases may help caregivers determine the effectiveness of UI programmes (Grade C).

c. Family caregivers need monitoring for and resources to counteract fatigue, social isolation, and other burdens related to continence care. (Grade C)

d. Use of mechanical lifts may help to reduce staff injury and increase adherence to toileting programmes (Grade C).

XII. RECOMMENDATIONS FOR RESEARCH

1. AETIOLOGY

a. Racial and ethnic differences in LUT- and comorbidity-related causes of UI

b. Aetiological models and translational research in the causes of UI in frail older persons, incorporating principles of concentric, interacting, multiple risk factors models of geriatric syndromes

c. Relationship between emerging models of frailty and vulnerability and development of UI

d. Relative roles of lower urinary tract disorders, medical conditions, hormonal factors, sleep disorders, and other conditions in the pathophysiology of nocturia in frail older persons

e. Longitudinal studies incorporating basic science as well as clinical measures

2. EVALUATION

a. Efficacy and effectiveness of current evaluation guidelines and recommendations across settings (home, clinic, assisted living, long-term care)

b. Development and validation of consensus standards for the definition of elevated PVR and UR for both frail elderly men and women, in both clinical and research settings

c. Development and validation of consensus standards for evaluation of nocturia in frail older persons
3. TREATMENT

a. Proactive incorporation of frailer, older-old persons in all UI intervention trials

b. New outcome measures relevant to geriatric care, including quality of life, socialisation, need for institutionalisation, impact on comorbidity, caregiver burden, and alternatives to wet-checks for long-term care residents

c. Outcome measures that are sensitive to differences across cultures and health care systems, e.g., reimbursement for continence services and supplies

d. Association between expectations, preferences, and outcomes

e. New approaches and tools to assess UI-specific quality of life in cognitively-impaired frail elderly

f. Increased understanding of the interaction between functional impairment and the impact of UI

g. Investigation of the utilities frail elderly and their caregivers assign to varying degrees of UI (with or without treatment intervention) versus “dryness”

h. Multicomponent interventions

i. Development and validation of predictive models for guiding treatment decisions

j. Family caregiver characteristics associated with and optimum interventions to improve their effective use of behavioural interventions for UI in the home

k. Racial-ethnic differences in UI treatment efficacy, tolerability, and safety in frail older persons across care settings (home, assisted living, long-term care, hospital)

l. Racial-ethnic disparities in UI treatment in frail older persons across care settings

m. Efficacy and effectiveness of policy and regulatory approaches to improve UI care quality in long-term care

n. Efficacy and tolerability of antimuscarinics in older-old and frail persons across care settings

i. Include adequate numbers of patients (including those with cognitive and/or functional impairment, and comorbid conditions common in this population); use outcome measures specific for this population and include impact on caregivers; stratify outcomes by age, comorbidity, function, and frailty; specify diagnostic methods; and continue interventions for clinically-relevant periods

ii. Determine the characteristics of frail older persons who respond to drug therapy

iii. Incidence, prevalence, and risk factors for adverse cognitive and functional effects, and optimum research and clinical measures to detect them

iv. Cost-benefit, cost-effectiveness, and cost-utility studies of UI treatments, using models incorporating the special issues of patient and caregiver preferences, definitions of “benefit” in this population, and a comprehensive approach to costs across a range of care settings

o. Inclusion of older-old and frailer patients in surgical studies, with stratification of outcomes by age, comorbidity, oestrogen status (women), and urodynamic findings

p. Prospective studies to determine the magnitude and severity of common geriatric complications following anti-incontinence surgery

q. Develop and validate guidelines for identifying frail elders who would benefit from gynaecological/urological anti-incontinence surgery

r. Efficacy and effectiveness of specific devices and procedures to prevent complications from long term indwelling catheters in frail elderly

s. Efficacy and effectiveness of multicomponent treatment for nocturia, including interventions targeted at comorbidity and drug therapy

t. Compare the efficacy of specific models of UI care for frail elderly around the world.

u. Determine the factors associated with the effectiveness of care models in countries with different health care systems

XII ALGORITHM

1. URINARY INCONTINENCE IN FRAIL OLDER MEN AND WOMEN

Healthy older persons should receive the similar range of treatment options as younger persons, but frail older persons require a different approach addressing the potential role of comorbid disease, current medications (prescribed, over-the-counter, and/or naturopathic), and functional and/or cognitive impairment in UI. The extent of investigation and management should take into account the degree of bother to the patient and/or carer, goals for care, cooperation, and overall prognosis and life expectancy. Effective management to meet the goals of care should be possible for most frail elderly.

2. HISTORY AND SYMPTOM ASSESSMENT

Active case finding and screening for UI should be done in all frail older persons (Grade A). History
should include comorbid conditions and medications that could cause or worsen UI. The physical should include rectal exam for faecal loading or impaction (Grade C), functional assessment (mobility, transfers, manual dexterity, ability to toilet) (Grade A), screening test for depression (Grade B), and cognitive assessment (to assist in planning management, Grade C). The mnemonic DIAPPERS (see algorithm) covers some of these comorbid factors, with two alterations: 1) atrophic vaginitis does not itself cause UI and should not be treated for this purpose (Grade B); and 2) current consensus diagnostic criteria for urinary tract infection (UTI) are poorly sensitive and specific in nursing home residents. The patient and/or carer should be asked about the degree of bother of UI (Grade B), goals for UI care (dryness, decrease in specific symptom[s], quality of life, reduction of comorbidity, lesser care burden) (Grade B), likely cooperation with management (Grade C), and the patient’s overall prognosis and remaining life expectancy (Grade C). Urinalysis is recommended for all patients, primarily to screen for hematuria (Grade C); treatment of otherwise asymptomatic bacteriuria/pyuria is not beneficial (Grade D), and it may cause harm by increasing the risk of antibiotic resistance and severe adverse effects, e.g., *Clostridium difficile* colitis (Grade C). Utility of clinical stress test in this population is uncertain (Grade D). Wet checks can assess UI frequency in long-term care residents (Grade C).

Postvoiding residual volume (PVR) testing is impractical in many care settings, and there is no consensus for the definition of “high” PVR in any population. Yet, there is compelling clinical experience for PVR testing in selected frail older persons with: diabetes mellitus (especially longstanding), prior urinary retention or high PVR; recurrent UTIs; medications that impair bladder emptying (e.g., opiates); severe constipation; persistent or worsening urgency UI despite antimuscarinic treatment; or prior urodynamics showing detrusor underactivity and/or bladder outlet obstruction (Grade C). Treatment of contributing comorbidity may reduce PVR. Trial with catheter may considered for PVR > 200–500 ml if the PVR is felt to contribute to UI or frequency (Grade C).

Assessment of frail elders with bothersome nocturia should identify potential underlying cause(s) including nocturnal polyuria (by bladder diary [frequency-volume chart] or wet checks or oedema on exam) (Grade C); primary sleep problem (e.g., sleep apnoea); and low voided volumes (e.g., from high PVR).

3. CLINICAL DIAGNOSIS

The most common types of UI in frail older persons are urgency, stress, and mixed UI. Frail elderly with urgency UI also may have detrusor underactivity and high PVR (without outlet obstruction), called detrusor hyperactivity with impaired contractility (DHIC). There is no evidence that antimuscarinics are less effective or cause retention in DHIC (Grade D).

4. INITIAL MANAGEMENT

Initial treatment should be individualized and influenced by goals of care, treatment preferences, and estimated remaining life expectancy, as well as the most likely clinical diagnosis (Grade C). In some frail elders the only possible outcome may be contained UI (managed with pads), especially for persons with minimal mobility (require assistance of ≥ 2 persons to transfer), advanced dementia (unable to state their name), and/or nocturnal UI.

Conservative and behavioural therapy for UI include lifestyle changes (Grade C), bladder training for more fit alert patients (Grade B), and prompted voiding for more impaired patients (Grade A). For select cognitively intact patients, pelvic muscle exercises may be considered, but there are few studies (Grade C). Antimuscarinics may be added to conservative therapy of urgency UI (Grade A-C, depending on agent). Alpha-blockers may be cautiously considered in frail men with suspected prostatic outlet obstruction (Grade C). All drugs should be started at the lowest dose and titrated with regular review until either care goals are met or adverse effects are intolerable. DDAVP (vasopressin) has a high risk of severe hyponatraemia in frail persons and should not be used (Grade B).

5. ONGOING MANAGEMENT AND REASSESSMENT

Optimal UI management is usually possible with the above approaches. If initial management fails to achieve desired goals, next steps are reassessment and treatment of contributing comorbidity and/or functional impairment.

6. SPECIALIZED MANAGEMENT

If frail elderly have either other significant factors (e.g., pain, haematuria), UI symptoms that cannot be classified as urgency, stress, or mixed, or other complicated comorbidity which the primary clinician cannot address (e.g., dementia, functional impairment), then specialist referral should be considered. Referral also may be appropriate for insufficient response to initial management. Type of specialist will depend on local resources and the reason for referral: surgical specialists (urologists, gynaecologists); geriatrician or physical therapist (functional and cognitive impairment); continence nurse specialists (homebound patients). Referral decisions should consider goals of care, patient/carer desire for invasive therapy, and estimated remaining life expectancy.

Age per se is not a contraindication to UI surgery (Grade C), but before surgery is considered, all patients should have:
Discussion (including the carer) to insure that the anticipated surgical outcome is consistent with goals of care in the context of the patient’s remaining life expectancy (Grade C)

- Adequate trial of conservative therapy (Grade C)
- Evaluation and treatment for any comorbidity, medications, and cognitive and/or functional impairments contributing to UI and/or which could compromise surgical outcome (e.g., dementia that precludes patient ability to use artificial sphincter) (Grade C)
- Urodynamic testing, because clinical diagnosis may be inaccurate (Grade B)
- Preoperative assessment and perioperative care to establish risk for and minimise common geriatric post-operative complications such as delirium and infection (Grade A) and dehydration and falls (Grade C).

INTRODUCTION

Conservative treatment is any therapy that does not involve pharmacological or surgical intervention. It includes principally, lifestyle interventions, physical therapies, scheduled voiding regimens, complementary and alternative medicines (i.e. those not considered part of the traditional biomedical model), anti-incontinence devices, supportive rings/pessaries for pelvic organ prolapse (POP) and pads/catheters. In some countries a combination of the first three is called “behavioural therapy” (defined as an approach that seeks to alter the individual’s actions or their environment in order to improve bladder control). Conservative therapies are usually low cost, and managed principally by the person with urinary incontinence (UI) with instruction/supervision from a health professional. They differ from other forms of incontinence and prolapse management, in that they have a low risk of adverse effects and do not prejudice other subsequent treatments. Consequently conservative measures should be included in the counselling of patients who suffer from either UI or POP regarding their management options. As the prevalence of UI and POP is high, and with the current constraints on most healthcare economies, conservative treatment constitutes the principal form of management at the primary care level. It is also indicated for those patients for whom other treatments, in particular surgery, are inappropriate, for example, those who are unwilling to undergo or who are not medically fit for surgery and women who plan future pregnancies (as these may adversely affect surgery). Other indications include patients awaiting surgery or who wish to delay surgery and those whose symptoms are not serious enough for surgical intervention.

To date, however, only a relatively small number of intervention studies of adequate size have been carried out to assess the effectiveness of conservative management of UI and POP. This chapter reviews the main types of conservative management (excluding anti-incontinence devices and pads/catheters; see report of Committee 20: Management using continence products) with regard to their ability to prevent and treat UI and POP effectively. Comment is also made on the effect of conservative management on other lower urinary tract symptoms (in addition to UI) and also factors affecting outcome, in particular age. This information will assist in the counselling of neurologically ‘normal’ adults regarding these treatment options (readers are directed to the chapters on children, the frail elderly and neuropathic patients for discussion on the effect of conservative management in these specific groups). A systematic review of the literature has been carried out, principally of randomised controlled trials (RCTs), resulting in some recommendations for practice based on the level of evidence available (see preface) and suggestions for future research.

Notes to the reader: For ease, all studies are cited using the first author and year. Where summary statistics are presented, the raw data from which these are derived can be found in the trial reports and systematic reviews cited in the chapter. Readers who are interested in the conservative management of faecal incontinence are referred to the chapter on faecal incontinence.

A. UI IN WOMEN

Female UI is a distressing condition with significant social implications. It is common – the median level of prevalence estimates gives a picture of increasing prevalence during young adult life (prevalence 20-30%), a broad peak around middle age (prevalence 30-40%), and then a steady increase in the elderly (prevalence 30-50%) (see report of Committee 1: Epidemiology). Although the proportions of different types of UI are difficult to estimate, approximately half of all incontinent women are classified as stress incontinent, a smaller proportion as mixed incontinent and urge urinary incontinence is the smallest category. The various types most likely reflect different pathologies and aetiologies.
Stress urinary incontinence (SUI) is thought to occur due to a lack of bladder neck support and/or poor urethral closure. As a result the urethral lumen is not closed effectively during activities that increase intra-abdominal pressure with consequent involuntary leakage during effort, exertion, sneezing or coughing. If during urodynamic assessment there is involuntary urine loss synchronous with a rise in intra-abdominal pressure and in the absence of an involuntary detrusor contraction this is described as urodynamic stress incontinence. Urge urinary incontinence (UUI) can be due to a rise in intravesical pressure due to involuntary detrusor contraction, a condition known as detrusor overactivity (DO). This is further subclassified as idiopathic (cause unknown) or neurogenic (where there is a known neurological cause for detrusor muscle overactivity). Some women experience urgency with or without leakage, usually with urinary frequency and nocturia. This constellation of symptoms is called the overactive bladder (OAB) syndrome. Mixed urinary incontinence (MUI) is used when the person has evidence of both SUI and UUI. This chapter addresses the effect of conservative management in women and men with stress, urge (idiopathic), and mixed urinary incontinence, and OAB syndrome.

Where able, the authors of the chapter have differentiated the effects of interventions by diagnosis (such as SUI, UUI, OAB, and MUI). This diagnostic distinction was not made or not reported in some of the studies reviewed; where it was not possible to distinguish effect by diagnosis the more generic term urinary incontinence (UI) is used in summaries and recommendations.

### I. LIFESTYLE INTERVENTIONS

Various lifestyle factors may play a role in either the pathogenesis or, later, the resolution of UI. While published literature about lifestyle factors and UI is sparse, alterations in lifestyle are frequently recommended by healthcare professionals and lay people alike. However, to date, most studies about lifestyle report associations only and do not assess the actual effect on UI of applying or avoiding the behaviour in question. Currently, only a relatively small number of RCTs have been carried out to assess the effect of a specific lifestyle change on UI. This section will examine the evidence for the association and use of lifestyle interventions in the management of female UI. A summary of the search strategy and inclusion/exclusion criteria is given in the appendix.

#### 1. PREVENTION

No RCTs assessing the effect of lifestyle interventions on UI prevention were identified.

#### 2. TREATMENT

Where RCTs are available, these are reviewed. Where there are no RCTs for a particular lifestyle intervention, other types of evidence are considered.

##### a) Weight loss

Two RCTs were found that specifically recruited incontinent women [1, 2]. Another RCT focused on the effect of intensive lifestyle intervention in overweight women with diabetes [3]; the bulk of this intervention was weight loss. Four prospective cohort studies [4-7] evaluated the effect of weight loss. Other study designs were cross-sectional [8-14], retrospective cohort [15], or case-control studies [16].

#### 1. QUALITY OF DATA

Sample sizes for the intervention studies were 12 [5], 138 [6], 10 [4], 48 [1], 338 [2], 1,957 [3] and 101 [7]. Sample sizes for observational studies that assessed the association between obesity and UI ranged from 193 [15], 3536 [13], 27,936 [11] to 83,355 [14]. The case control study had a sample size of 108 cases and 108 controls [16].

Participant blinding was not possible in any of the three RCTs. Of 48 randomized in one trial, 40 remained in the study at the time of assessment [1]. Another trial [2] is in abstract form and full details have not been published. In the large RCT with diabetes as the primary focus, 2191 women were enrolled and 234 were excluded because data about UI were not available; the number that dropped out before the endpoint is not detailed for this subpopulation of women.

The outcome measure in most studies was subjective, determined by either validated or non-validated questionnaires. Studies by Bump (1992) and Subak (2002, 2005, 2007) also used objective measures including urodynamics, bladder diary and a standardised fluid loss quantification test.

Follow-up periods for the interventional studies were one year after gastroplasty surgery [5] and laparoscopic Roux-en-Y gastric bypass [7], six months after completion of weight reduction, either by means of low calorie liquid or reduced calorie solid diet [4], three months after completion of a very low calorie liquid diet and exercise [1], six months after completing an intensive group weight intervention programme that included lifestyle and behaviour changes [2], mean 2.9 years after beginning the intervention [3], and not stated [6].

#### 2. RESULTS

Many researchers [8-11, 13-20] have reported an association between increased weight, or increased body mass index (BMI, kg/m²), and UI. This association held after controlling for age and parity. In one multivariate analysis, Brown (1996) reported that the prevalence of daily UI increased by an odds ratio of 1.6 per 5 BMI units. In a multivariate analysis
of a different population, Brown (1999) found that the prevalence of at least weekly SUI increased by 10% per five units BMI. Similarly, Foldspang (1995) reported an OR of 1.07 for UI prevalence per BMI unit, after controlling for other factors [21]. Hannestad (2003) described a dose-response type relationship between BMI and severe UI. Compared to women with a BMI < 25, OR’s for the following groups were: BMI 25-29, OR 2.0 (95% confidence interval (CI) 1.7 to 2.3); BMI 30-34, OR 3.1 (95% CI 2.6 to3.7); BMI 35-39, OR 4.2 (95% CI 3.3 to 5.3); BMI 40+, OR 5.0 (95% CI 3.4 to 7.3). Danforth (2006) reported that in women with a BMI of 30 or higher, the odds of severe UI were 3.1 times that of women with a BMI between 22 and 24. Similarly, Melville (2005) found that women with a BMI of 30 or higher had a 2.3 fold risk of UI compared to normal weight women.

Three groups [5-7] reported resolution of UI in the majority of cases after massive weight loss in morbidly obese women undergoing surgical weight reduction procedures. While obesity is commonly considered a risk for SUI, in Bump’s (1992) study, women with UUI were as likely to experience post-operative continence as women with SUI. In the Burgio (2007) study, mean BMI decreased from 48.9 (standard deviation (SD) 7.2) pre-surgery to 35.3 (SD 6.5) at six months and 30.2 (SD 5.7) at 12 months post-surgery. Prevalence of UI decreased from 67% pre-surgery to 41% at six months and 37% at 12 months (95% CI for change 18.6 to 40.0%, p<0.001). Reduction in prevalence of UI was significantly associated with decreases in BMI (p=0.01). Among incontinent women who lost 18 or more BMI points, 71% regained urinary continence at 12 months. In a cross-sectional study of 1800 Swedish women [12], incontinent women were slightly more likely than continent women to report at least a five kg weight loss in the preceding five years (15% versus 11%, respectively; p=0.05). This may be secondary to intentional weight loss as a treatment for UI, rather than some effect of weight loss itself.

In Subak’s pilot study (2002) of 10 women, all six of the women achieving a weight loss of at least 5% had at least a 50% reduction in incontinent episodes compared to one out of the four women with <5% weight loss. In the 2005 RCT [1] reporting on 48 participants, median baseline weight (95 kg) and number of incontinent episodes (21 per week) were similar between the groups. Compared to controls (wait list) that did not participate in a weight loss programme, women in the weight loss (liquid diet) group lost 15kg (SD 7) (compared to 0kg (SD 4)) and experienced a 60% reduction in weekly incontinent episodes (compared to 15%). The Programme to Reduce incontinence by Diet and Exercise (PRIDE) [2] randomised 338 overweight incontinent women in a 2:1 ratio to an intensive 6-month group weight intervention programme or usual care, consisting of four information sessions. Women in the intervention group lost a mean of 8kg compared with 2kg in the usual care group. Forty one percent of women in the intervention group decreased the weekly number of incontinence episodes by at least 70% compared to 22% in the usual care group.

The RCT from the Diabetes Prevention Programme [3] reporting on 1957 participants found that overweight diabetic women assigned to intensive lifestyle therapy (consisting of low-fat diet, moderately intense exercise for at least 150 minutes per week and a behavioural and educational curriculum) were less likely to be incontinent compared to those assigned to placebo drug with standard lifestyle advice or metformin alone (38.3% versus 45.7% and 48.1%, respectively; p=0.001).

**Summary**

Obesity is an independent risk factor for the prevalence of UI. Massive weight loss (15 to 20 BMI points) significantly decreases UI in morbidly obese women. (Level of Evidence: 2). Moderate weight loss also results in decreased UI. (Level of Evidence: 1).

**Recommendations**

For morbidly and moderately obese women weight loss is a useful treatment to reduce UI prevalence (Grade of Recommendation: A). Based on the current evidence, maintaining normal weight through adulthood may be an important factor in preventing the development of UI. Given the high prevalence of both UI and obesity in women, the dual issues of weight loss and prevention of weight gain should receive high research priority.

**b) Physical forces (exercise, work)**

No RCTs exist in which UI prevalence is compared between subjects assigned to heavy work or high impact activity versus sedentary activities.

1. **Quality of data**

A case-control study compared the incidence of surgery for UI and/or prolapse between 28,619 population based controls and 1,652,533 nursing aids [22]. Be (1989) and Nygaard (1994) evaluated the difference in UI prevalence between 305 and 144 women, respectively, engaged in high versus low impact activities [23, 24] Be (2001a) compared 572 athletes ages 15-39 years with 574 controls [25]. In a retrospective cohort study, Nygaard (1997) reported UI prevalence in 104 high-impact and low-impact former Olympic athletes [26]. Caylet (2006) compared UI prevalence between 157 elite female athletes and 426 women from the general population between ages 18 and 35 [27]. Kruger (2007) conducted a case-
control study exploring mechanisms by which athletes might be more likely to experience SUI and compared pelvic organ descent and pubovisceral muscle volume between 24 elite nulliparous athletes and 22 age and BMI matched controls [28]. Eliasson (2005) compared UI at 36 weeks gestation and one year postpartum between 665 primiparous women participating in high-impact, low-impact or no activity [29].

Several small case series described UI in women doing specialised activities. Davis (1996) described a series of nine women who became incontinent after parachute jumping [30]. Larsen (2007) compared UI and POP in 37 soldiers that completed parachute training versus 79 that completed other summer military training [31]. Benjamin (2000) studied the prevalence of UI in 25 women aviators exposed to high gravitational forces [32].

Several cross-sectional studies compared the prevalence of UI with the self-reported level of physical activity. The Norwegian EPINCONT study compared both any and severe UI in 27,936 women according to three levels of high impact physical activity [11]. Kikuchi (2007) compared UI prevalence in 676 men and women age 70 years and older participating in three physical activity groups; physical activity was assessed by a single-item questionnaire [33]. Nygaard (2005) compared UI prevalence and severity in 3,364 women according to physical activity level as assessed by the International Physical Activity Questionnaire [34].

Using women enrolled in the Nurses Health Study, two prospective studies assessed the risk of incident UI according to physical activity level, reported as metabolic equivalent task hours per week, in 2,355 women ages 54 to 79 years [35] and 30,135 women 37 to 54 years at risk of incident UI [36]. Another study measured physical activity by questionnaire and electronic motion sensor in 69 women before and one year after successful treatment for UI [37].

2. RESULTS

Minimal SUI is common in young exercising women [23, 38, 39]. College athletes participating in high impact activities are more likely to report the symptom of SUI during exercise than those participating in low impact exercise [24]. Bø (2001a) found no difference in UI prevalence between elite athletes and controls. Caylet (2006) found that 28% of elite athletes reported UI compared to 10% of controls. There was no difference in UI prevalence between physically active and sedentary controls. In the prospective study of pregnant and postpartum women, high-impact physical activity before pregnancy was associated with more urinary leakage one year postpartum compared to low-impact activity [29].

There is little available information on whether strenuous exercise or activity causes the condition of UI later in life. In a study of 104 women who were Olympians approximately 25 years ago, those who competed in gymnastics or track and field were not more likely to currently report daily or weekly UI than Olympians who competed in swimming [26]. Certain provocations may cause SUI; one report described nine nulliparous infantry trainees who developed SUI and pelvic floor defects for the first time during airborne training, which included parachute jumping [30]. The precise number of total trainees is unknown but is estimated to be approximately 500. Larsen (2007) found no difference in UI prevalence between female paratroopers and women that completed regular summer training, but paratroopers were more likely to demonstrate stage II prolapse on examination (OR 2.7; 95% CI 1.4 to 5.4). In 25 women aviators, self-report of UI was not found to increase at high gravitational forces [28]. Compared to a control group, athletes that participated in high-impact, frequent intense training had a higher mean diameter of the pubovisceral muscle, greater bladder neck descent and a larger hiatal area on Valsalva manoeuvre [28].

The EPICONT study reporting on 27,936 women found no difference in either any UI (that is, mild or greater) or severe UI in women that reported high impact physical activity one to two hours per week or three or more hours per week compared to those that reported exercising less than one hour per week (after adjusting for age, BMI, parity, coughing and wheezing) [11]. In contrast, Nygaard (2005) reported that UI with physical activity was more common among highly active than less active women (15.9% versus 11.8%; p=0.01). Additionally, after adjusting for age, parity, comorbidities and other factors, women with very severe UI were more likely to be insufficiently active than continent women (OR 2.64). In Kikuchi (2007), compared to people in the lowest physical activity group, those in the middle and high level activity groups were less likely to report UI (adjusted OR of 0.71, 95% CI 0.47 to 1.09, and 0.58, 95% CI 0.35 to 0.96 respectively).

In older women enrolled in the Nurses Health Study, total physical activity (i.e. top versus bottom quintile of metabolic equivalent task hours per week) was significantly associated with a reduced risk of new UI (OR 0.81) in analyses adjusted for confounders. Walking constituted about half of the total physical activity among the participants and was related to a 26% lower risk of developing UI. Total physical activity was not related to the incidence of UUI [35]. These findings were mirrored in younger women enrolled in the same study [36]: the risk of at least monthly UI decreased with increasing quintiles of moderate physical activity (relative risk (RR) 0.80, 95% CI 0.72 to 0.89 comparing extremes of quintiles). Note that few women in either study did strenuous physical activity. Stach-Lempinen (2004) found no difference in exercise habits after successful treatment for UI.

Surprisingly little information is available on the
relationship between stressors in the workplace and UI. Danish nursing assistants, who are exposed to frequent heavy lifting, were more likely to undergo surgery for genital prolapse and/or UI than women in the general population (RR 1.6, 95% CI 1.3 to 1.9); the study did not control for parity [22].

**SUMMARY**

Strenuous exercise is likely to unmask the symptom of SUI during the provocation. There is currently no evidence that strenuous exercise causes the condition of UI although in a small number of women without other known risk factors, extreme provocations such as parachute jumping may cause UI.

There is good prospective cohort information suggesting that moderate exercise decreases the incidence of UI in middle-aged and older women; this effect may be mediated by weight control (Level of Evidence: 2).

There are scant uncontrolled data that suggests that women engaged in occupations with heavy lifting may be predisposed to genital prolapse and/or UI (Level of Evidence: 3). In spite of the fact that healthcare professionals commonly advise restricting exercise and heavy lifting following UI or prolapse surgery, there is no published evidence that this improves surgical outcome.

**RECOMMENDATIONS**

Given the large proportion of women who are employed in various occupations that require heavy lifting and the paucity of data about the association of such exertions and UI, this association should be investigated further. Specifically, research must establish whether heavy exertion is an etiologic factor in the pathogenesis of UI, and whether changing exertions can alleviate established UI.

c) **Smoking**

Understandably, there are no RCTs investigating the effect of smoking on UI. There are no trials of the effect of smoking cessation.

1. **Quality of data**

One case-control study compared incontinent smokers with incontinent non-smokers [40], while a second compared smoking behaviour between continent and incontinent women [41]. Seven large cross sectional studies evaluated multiple risk factors for UI, including smoking [8, 11, 14, 42-45]. One case-control study evaluated smoking as a risk factor for failure of SUI surgery [46]. One trial of women planning surgery for SUI assessed the association between smoking and severity of UI, defined by mean number of Incontinence episodes per day on a bladder diary [47]. An in vitro study assessed the effects of nicotine on bladder muscle contraction [48]. Sample sizes were 189 [40], 1761 [42], 160 [41], 199 [46], 7949 [8], 7338 [43], 1761 [42], 3302 [44], 5488 [45], 27936 [11], and 83355 [14].

2. **RESULTS**

Smokers were more likely to report UI than non-smokers in some studies [11, 14, 41, 43, 44], but not in others [8, 42, 45]. Amongst women with SUI, current smoking was positively associated with UI severity after adjusting for confounders [47]. After adjusting for age, parity, type of delivery, and pre-pregnancy BMI, smokers had a 1.3 fold higher RR (95% CI 1.0 to 1.8) of reporting UI at 16 weeks gestation than non-smokers [43]. The adjusted OR for moderate or severe UI among women reporting UI was 1.38 (95% CI 1.04 to 1.82) in current smokers, after adjusting for perimenopausal status, BMI, diabetes and ethnicity [44]. In the large population based study by Hannestad et al [11], smoking increased the odds of severe UI (OR 1.4, 95% CI 1.2 to 1.6) but not of mild UI. In the case-control study, after adjusting for confounders, smoking was a protective factor (OR 0.26, 95% CI 0.09 to 0.81) against recurrent UI after anti-incontinence surgery [46]. Incontinent smokers were found to have stronger urethral sphincters and lower overall risk profiles than incontinent non-smokers [40]; therefore, it was proposed that more violent coughing promotes anatomic defects, which allow UI.

In potential support of nicotine as a risk factor for UI, Hisayama (1988) and Koley (1984) found that nicotine produces phasic contraction of isolated bladder muscle probes in vitro [48, 49]. However, Milsom (1993) reported an apparent paradoxical local estrogenic effect of nicotine on the vagina, resulting in a decrease in vaginal pH and an increase in lactobacilli [50].

**SUMMARY**

Current data suggest that smoking increases the risk of more severe UI (Level of Evidence: 3). Smokers may have a different mechanism causing their UI than non-smokers.

**RECOMMENDATIONS**

Further prospective studies are needed to determine whether smoking cessation prevents the onset, or promotes the resolution, of UI.

d) **Dietary factors**

No RCT was identified that addressed dietary changes. In a prospective questionnaire study, Dallosso (2004a) studied the impact of dietary risk factors on the one-year incidence of SUI [51] and OAB symptoms [52,
53] in women. Participants completed a 130-item validated food frequency questionnaire. Anecdotal evidence suggests that eliminating dietary factors such as artificial sweeteners and certain foods may play a role in continence; however, no treatment trials have tested this hypothesis.

In a large postal survey, 6037 men and women responded to questions about tea, soft drink and alcohol consumption, as well as whether or not they had UI [54].

One RCT [55] assessed the effects of a caffeine reduction intervention upon frequency, urgency and UUI. Subjects were those with urinary symptoms who consumed more than 100mg caffeine daily. Those randomised to the experimental group received bladder training and a caffeine-fading method to decrease caffeine intake to less than 100mg per day, while the control group also received bladder training but no caffeine reduction information. Another RCT [56] used a crossover design to evaluate the effect of caffeine restriction and of increasing and decreasing fluid intake on urinary symptoms over a four-week period in women with urodynamic SUI or DO.

One study compared women with DO with continent women who received caffeine tablets [57], while another compared caffeine intake between women with DO and those without [58]. The effect of decreasing caffeine intake in a small cohort of incontinent women was examined in a prospective fashion [59]. Large epidemiologic trials using multivariate analyses assessed the effect of coffee drinking [8], alcohol consumption [9] and tea, coffee, and alcohol intake and UI [11]. A smaller cross-sectional analysis assessed the association between symptoms and lifestyle factors, including caffeine intake [60].

In one RCT, women with UI were randomly assigned to one of three groups: increase fluid intake by 500 cc, maintain fluid intake at baseline level, or decrease by 300 cc. Participants kept fluid intake and output diaries for five weeks [61]. Wyman (1991) analysed the correlation between mean daily oral fluid volume intake and mean daily voids and incontinence episodes in 126 women aged 55 and older that kept diaries for one week [62].

1. QUALITY OF DATA

It was not feasible to blind participants in any of the three RCTs, with dropout rates of 22% (26/58) [55], 37% (41/110) [56], and 45% (25/58) [61]. The numbers completing each study were 30 [57], 32 [61], 34 [59], 69 [56], 74 [55], 126 [62], 159 [58], 297 [60] 2764 [9], 6037 [54], 7949 [8], 27,936 [11], and 6,424 women [52] and 4887 men [63].

2. RESULTS

(a) Diet: After adjusting for age, physical functioning, SUI at baseline, obesity, smoking and certain dietary factors, the incidence of SUI at one year was increased in women consuming more total fat, saturated fatty acids and monounsaturated fatty acids, as well as those that consumed more carbonated beverages, zinc or vitamin B12 at baseline [51, 52]. The incidence of SUI was reduced in those that ate more vegetables, bread and chicken at baseline [52]. Higher intake of vitamin D, protein and potassium were associated with decreased risk of onset of OAB in women [53].

(b) Caffeine: One RCT found a clinical effect of decreasing caffeine, while the other did not. Bryant (2002) reported that women in the intervention group decreased daily caffeine consumption to a mean of 96.5mg, compared to 238.7mg in the control group. The experimental group had statistically significant reduction in urgency episodes (61% versus 12%); the number of incontinence episodes decreased as well (55% compared to 26% in the controls) but this was not statistically significant (p=0.219). In contrast, while Swithinbank (2005) found effect of decreasing fluid intakes (see below), changing from caffeine containing to decaffeinated drinks produced no improvement in symptoms.

Other study designs generally found mixed effects of caffeine on bladder function. Following caffeine intake, women with DO had increased detrusor pressure on bladder filling, while continent women had no such abnormality [57]. In a population of 259 consecutive women presenting for urodynamics, 131 women with DO had a significantly higher mean caffeine intake (484mg/day, SD 123) than women without this diagnosis (194, SD 123) [58]. This association persisted after controlling for age and smoking. In 34 women with symptoms of UI (mostly mixed) who decreased caffeine intake (from 900mg/day to 480mg/day), episodes of daily urine loss also decreased (from 2.3 to 1.0 per day) [59]. In a multivariate analysis, Brown (1996) found no association between coffee drinking or alcohol drinking and daily UI. In the Norwegian EPINCONT study, tea drinkers had a slightly higher odds for all types of UI (OR 1.2, 95% CI 1.1 to 1.2) for up to two cups per day compared to none and OR 1.3 (95% CI 1.2 to 1.5) for three or more cups per day compared to none, while no association was found between either coffee (at any dosage) or alcoholic beverages (three or more drinks per two weeks compared to none to two drinks per two weeks) and UI [11]. Bradley (2005) reported that, after adjusting for confounders, coffee drinking was associated with bladder symptoms of difficulty emptying (OR 8.6, 95% CI 1.4 to 55.0) and weak stream (OR 5.3, 95% CI 1.5 to 19.0).

(c) Alcohol: After adjusting for age and gender, no association was found between UI and consumption of alcohol [54]. After adjusting for age and fluid intake, consumption of wine, beer or spirits did not increase the incidence of either SUI or OAB (there was a trend...

**SUMMARY**

Fluid intake plays a minor, if any, role in the pathogenesis of UI. Caffeine consumption is pervasive in many societies and may play a role in exacerbating UI. The data on caffeine intake and UI are conflicting. While large cross-sectional surveys indicate no association (Level of Evidence: 3), small clinical trials do suggest that decreasing caffeine intake improves continence. (Level of Evidence: 2).

**RECOMMENDATIONS**

Given the fact that decreasing fluids may lead to urinary tract infections, constipation, or dehydration, this intervention should be reserved for patients with abnormally high fluid intakes (Grade of Recommendation: C).

A reduction in caffeine intake is recommended for those with incontinence symptoms (Grade of Recommendation: B). Larger RCTs to assess the effect of caffeine and other dietary factors are feasible and important.

e) Constipation

No published RCTs were found which assessed the effect of regulating bowel function on UI. An observational study compared the self-report of straining as a child with urogynaecological symptoms as an adult [64]. Population-based studies assessed multiple risk factors for UI [65, 66].

1. **QUALITY OF DATA**

Sample sizes range from 73 for the observational study [64] to 213 in a study correlating the surrogate measures of perineal descent and pudendal neuropathy [67] to 1154 and 1051 in the population-based studies [65] respectively.

2. **RESULTS**

In a small observational study, 30% of women with SUI and 61% of women with uterovaginal prolapse reported straining at stool as a young adult, compared to 4% of women without urogynaecological symptoms [64]. In a large population-based study of 1154 women over age 60 years, those with UI were slightly more likely to report constipation than those who were continent of urine (31.6% vs 24.7%) [65]. After adjusting for demographic and obstetric confounders, women who reported straining at stool were more likely to report SUI (OR 1.9, 95% CI 1.3 to 2.6) and urgency (OR 1.7, 95% CI 1.2 to 2.4) [66]. There appears to be an association between straining and pudendal nerve function. The mean pudendal nerve terminal motor latency increased after straining, correlated with the amount of descent, and returned to resting by four minutes after a strain [68]. Others found evidence of pudendal neuropathy in only 25% of women with abnormal perineal descent; in this large group of patients with defecating dysfunction no relationship was seen between neuropathy and pelvic descent, leading to the conclusion that pelvic descent and neuropathy may be two independent findings [67].

**SUMMARY**

There is some evidence to suggest that chronic straining may be a risk factor for the development of UI. (Level of Evidence: 3). There are no intervention trials that address the effect of resolving constipation on UI.

**RECOMMENDATIONS**

Further research is needed to delineate the role of straining in the pathogenesis of UI. If the association holds, public education, particularly of parents and paediatricians, is needed to make an impact on the common problem of straining due to constipation in children.

f) Other

There are many other lifestyle interventions suggested either by healthcare professionals or the lay press for the treatment of UI, including reducing emotional stress, wearing non-restrictive clothing, utilising a bedside commode, decreasing lower extremity oedema, treating allergies and coughs, wearing cotton underwear, and increasing sexual activity. There is no evidence to support these interventions for UI; support for these interventions is all anecdotal in
outside of the laboratory setting.

1. Quality of data

In the urodynamics laboratory, 65 women underwent a series of standing cough stress tests in each of four postures: standing, crossing the legs, bending forward from the hips, and a combination of crossing legs and bending forward [69].

2. Results

The mean loss was 12.3g (95% CI 8.5 to 16.1) in the standing position; this was significantly reduced to 1.3g (95% CI 0.5 to 2.1, P<0.001) with crossed legs and to 4.7g (95% CI 1.4 to 7.7, P<0.01) by the combination of crossing the legs and bending forward. Bending forward alone did not reduce fluid loss (10.2g, 95% CI 6.5 to 13.9). No study has evaluated whether postural changes are a satisfactory form of treatment outside of the laboratory setting.

SUMMARY

Crossing the legs and bending forward may reduce leakage during provocation, but this has not been tested in a clinical environment (Level of Evidence: 3). There is no evidence about whether many other recommended lifestyle interventions prevent or are effective treatments for UI.

RECOMMENDATIONS

Crossing the legs and bending forward might be useful in reducing leakage during coughing or other provocation (Grade of Recommendation: C). High quality studies evaluating the effect of many other lifestyle interventions on UI are warranted.

3. Other LUTS

Most published data on the effect of lifestyle interventions (in particular, dietary factors) on other LUTS pertain to males only, and thus, are not included in this review. In one study of a geriatric population (n=128), there was a strong relationship between evening fluid intake, nocturia, and nocturnal voided volume; this relationship was weaker for diurnal intake and voiding [70]. Bladder training combined with caffeine reduction significantly reduced the number of voids in 24 hours compared to bladder training alone (35% versus 23%) [55]

Future work should separately evaluate the impact of lifestyle interventions on nocturia, diurnal frequency, urgency and UUI to delineate whether certain interventions preferentially affect different areas of OAB.

4. Factors Affecting outcome

RCTs are sparse in this field of lifestyles advice, and none of those available specifically describe the impact of age or any other variable on outcome.

II. Pelvic Floor Muscle Training (PFMT)

One of the principal therapeutic uses of pelvic floor muscle training (PFMT) is the prevention and treatment of UI. Because pelvic floor muscle (PFM) integrity appears to play an important role in the continence mechanism (see report from Committee 4: Pathophysiology), there is a biological rationale to support the use of PFMT in preventing and treating UI.

PFMT has been part of exercise programmes in Chinese Taoism for over 6,000 years [71]. It first entered modern medicine in 1936; a paper by Margaret Morris describing tensing and relaxing of the PFM introduced the use of PFMT as a preventative and treatment option for urinary and faecal incontinence to the British physical therapy profession [72]. However, PFMT as a treatment for SUI did not become widespread until the 1950’s after American gynaecologist Arnold Kegel reported on the successful treatment of 64 cases of female SUI using PFM exercises with a pressure biofeedback perineometer [73].

• Biological rationale for PFMT for SUI

The biological rationale is three-fold. Firstly, an intentional, effective PFM contraction (lifting the PFM in a cranial and forward direction) prior to and during effort or exertion clamps the urethra and increases the urethral pressure, preventing urine leakage [74]. Ultrasonography and MRI studies have demonstrated the cranial and forward movement of the PFM during active contraction and the resulting impact on the urethral position, which supports this rationale [75, 76]. Miller (1998) named this counter-balancing PFM contraction prior to a cough the ‘knack’ and assessed its effectiveness in an RCT [77]; they demonstrated that a voluntary PFM contraction before or during coughing can reduce leakage after only one week of training. Other published research, employing the term ‘PFM functional training’, recommends pre-contraction of the PFM not only during a cough but for any daily task that results in increased intra-abdominal pressure [78].

Thus, research suggests that the timing of a PFM contraction might be an important factor in the maintenance of urinary continence. However, the optimal strength required to clamp the urethra and prevent urine leakage has not yet been determined. In healthy continent women, activation of the PFM before or during physical exertion seems to be an automatic response that does not require conscious effort [79-81]. There is some evidence that this PFM ‘reflex’ contraction is a feed-forward loop and might precede bladder pressure rise by 200-240 milliseconds [82, 83]. For incontinent women, learning to rapidly
perform a strong, well-timed PFM contraction may actively prevent urethral descent during an intra-abdominal rise in pressure [84].

Secondly, the bladder neck receives support from a strong, toned PFM (resistant to stretching), thereby limiting its downward movement during effort and exertion, preventing urine leakage [74, 85]. Bø has suggested that intensive strength training may build up the structural support of the pelvis by permanently elevating the levator plate to a higher position inside the pelvis and by enhancing the hypertrophy and stiffness of its connective tissues [85]. In line with and supporting this hypothesis, differences in the anatomical position of the PFM have been demonstrated between continent and incontinent women [86, 87]. Additionally, dynamometric studies have shown that SUI and MUI women demonstrate less PFM tone, maximal strength, rapidity of contraction and endurance as compared to continent women [88, 89]. Further, in an uncontrolled MRI reconstruction study, a significant reduction in the internal surface area of the levator ani was observed after PFMT suggesting an increase in passive stiffness of the levator ani, which is indicative of the state of PFM tone [90]. Griffin (1994), using a pressure probe inside the vagina, also showed a significant difference in subjects’ PFM resting pressure three to four weeks after starting PFMT and increased resting pressure after PFMT was completed [91]. Furthermore, Balmforth (2004) reported increased urethral stability at rest and during effort following 14 weeks of supervised PFMT and behavioural modifications [92]. Thus, there is a growing body of evidence to support the rationale that PFMT improves PFM tone and that it may facilitate more effective automatic motor unit firing of the PFM, preventing PFM descent during increased intra-abdominal pressure, which in turn prevents urine leakage [93].

Thirdly, PFM may be activated with a transversus abdominus (TrA) muscle contraction; this has implications for coordination of muscle activity in and around the pelvis/abdomen during everyday activity. An increasing body of evidence suggests that the active contraction of the TrA muscle is associated with co-activation of the PFM. This has been demonstrated by US, EMG and MRI studies [94-98]. However, a TrA muscle contraction does not appear to elevate the PFM in all women [99] and when it does, it does not appear to be as effective as a direct PFM contraction [97, 98]. Recent studies suggest that the relationship between PFM and TrA muscle differs between continent and incontinent women with the PFM being displaced less during a TrA muscle contraction in SUI women as compared to continent women [98]. More research is needed to better understand the relationship between the TrA and the PFM muscles as well as the effect on incontinence of rehabilitating the interaction between TrA muscle and the PFM.

Given the above biological rationale, for SUI the objective of PFMT is usually to improve the timing (of contraction), strength and stiffness of the PFM.

• **Biological rationale for PFMT for UUI**

PFMT can also be used in the management of UUI. The biological rationale is based on Godec’s observation that a detrusor muscle contraction can be inhibited by a PFM contraction induced by electrical stimulation [100], and Burgio (1985) has demonstrated that detrusor contraction can be inhibited by a voluntary contraction of PFM [101]. De Groat (1997) demonstrated that during urine storage there is an increased pudendal nerve outflow response to the external urethral sphincter increasing intraurethral pressure and representing what he termed a ‘guarding reflex’ for continence [102]. Additionally, Morrison (1995) demonstrated that Barrington’s micturition centre excitatory loop switches on when bladder pressures are between five to 25mmHg while the inhibitory loop is predominantly active above 25mmHg [103]. Inhibition involves an automatic (unconscious) increase in tone for both the PFM and the urethral striated muscle.

Thus, voluntary PFM contractions may be used to control UUI. After inhibiting the urgency to void and the detrusor contraction, the patient can learn to reach the toilet in time to avoid urine leakage. However, the number, the duration, the intensity and the timing of the PFM contraction required to inhibit a detrusor muscle contraction is not known. This focus on urge suppression by voluntary PFM contraction, combined with PFMT, is commonly called behavioural training.

• **Principles of skeletal muscle strengthening**

The aim of any strengthening programme is to alter muscle morphology by increasing the cross-sectional area, increasing the number and frequency of motor neuron excitations, and improving tone and stiffness. When muscles engage in intense, repetitive tasks that exceed the normal demands of daily activities this stimulates an increase in the muscle fibre size (hypertrophy), which in turn increases muscle bulk [104]. However, hypertrophy is not immediately evident as a training response. An increase in strength is evident long before visible hypertrophy. Early improvements in strength result from neural adaptation, including a greater number of activated motor units, an increased rate of motor unit excitation, more synchronised motor unit firings and more persistent activation of type II motor units [105-107]. Hypertrophy begins only after a minimum of eight weeks of regular and intense strength training [108]. With increased overload, hypertrophy may continue for some years.

There are four principles of strength training: specificity, overload, progression and maintenance [93]. Strength training is specific to the muscle(s) being trained and requires overload (that is, exposing the muscle(s) being trained to a gradual increase in resistance,
repetitions or repetition speed). Progression is the extension, through increased resistance, intensity and volume of training, of the initial exercise programme. Finally, maintenance refers to the extent to which the muscle is able to maintain a continued level of strength. In order to achieve an effective strength training programme, the American College of Sports Medicine recommends that all these elements be addressed [109].

**Terminology and method of review**

In this section, PFMT is defined as any programme of repeated, voluntary PFM contractions taught by a healthcare professional. This definition allows for variations in the end-goal of PFMT, the supervision (e.g. individual or group sessions) and the exercise programme (e.g. variations in frequency, intensity, number of contractions and duration of training). Thus, PFMT in the context of this chapter may also include the use of pelvic floor muscle contractions for urge suppression, and preceding changes in intra-abdominal pressure to prevent stress leakage; interventions that may also be called behavioural training. PFMT is used in preference to other previously used terms such as Kegel’s Exercises, pelvic floor exercises and PFM exercises. The term ‘Kegel’s Exercises’ is no longer appropriate because it refers to his original exercise programme of 500 contractions per day [73]. Advances in strength-training research (see above) indicate that fewer contractions, with a higher load are more effective, making current PFM programmes very different from that which was originally prescribed by Kegel (1948). Terminology that fails to include a reference to the muscle also seems inappropriate, as it is the muscular component of the pelvic floor that is the primary focus of the training. Ideally, it should also be clear that it is the PFMs, not pelvic muscles in general, which are the target of the intervention. Further, training is viewed as a more appropriate word than exercise. The term exercise is commonly interpreted as one training episode or a single muscle action, whereas, training means repeated exercises over time. Therefore, the term Pelvic Floor Muscle Training (PFMT) is used throughout this chapter.

PFMT was the primary intervention in the studies discussed in this section; however, some also included PFMT complemented by additional strategies related to urge and/or frequency. Trials that combined PFMT with urge and/or frequency strategies were included unless these were clearly part of a bladder (re)training programme or a timed or scheduled voiding programme. Trials were excluded if the primary intervention was clearly a combination of two or more treatments (e.g. PFMT with bladder training, PFMT with oestrogen). The exceptions were biofeedback (BF) and intravaginal resistance devices as these adjuncts are not stand-alone interventions.

This section will examine the evidence for the use of PFMT in the prevention and treatment of UI in women. Questions addressed are:

- Is PFMT effective in the prevention of UI?
- Is PFMT better than no treatment, placebo or control treatments for treatment of UI?
- Is one PFMT programme better than another in the treatment of UI?
- Is PFMT better than other treatments in the treatment of UI?
- Does the addition of PFMT to other treatments add any benefit in the treatment of UI?
- What factors might affect the outcome of PFMT in the treatment of UI?
- What is the effect of PFMT on other lower urinary tract symptoms?

**Evidence for PFMT for UI in women**

A systematic search of studies to November 2007 was carried out (see appendix). Only papers published in English or in a language for which a translator could be found were included. Relevant systematic reviews and reports of RCTs and quasi-RCTs were included. Therefore, only Level 1 evidence is considered in this section. Recommendations are based on the findings of existing systematic reviews, where they were up-to-date, or systematic reviews and more recent RCTs.

In this section, the pre-specified primary outcomes of interest were 1) self-reported UI (for prevention studies), 2) self-reported cure or 3) cure and improvement in UI symptoms (for treatment studies). Secondary outcomes of interest were 1) leakage episodes (treatment studies) and 2) quality of life (prevention and treatment studies).

With regard to assessment of study quality the Consort Statement Checklist was used [110]. Empirical evidence indicates that two elements of trial quality, allocation concealment and double blinding, are important in estimating treatment effect with precision. Trials with inadequate or unclear concealment of allocation appear to overestimate treatment effect by about 30% and trials that are not double-blinded overestimate effect by about 15% [111]. Therefore, trials that reported adequate allocation concealment have been noted. Although it is often difficult or impossible to blind patients to PFMT, trials that reported blinding of the outcome assessment were also noted. Readers may wish to consider these factors in their interpretation of the data.

1. **PREVENTION AND TREATMENT (PREGNANT AND POSTNATAL WOMEN ONLY)**

This subsection specifically considers PFMT for the prevention and treatment of UI in pregnant and
postnatal women (called childbearing women in this section). As the physiological changes of childbearing can affect PFM function, it is possible that the effect of PFMT might differ in this group compared to non-childbearing women. 

Five systematic reviews investigating the effect of PFMT on the prevention and treatment of UI in childbearing women have been published [112-116]. The review by Hay Smith (2002) did not separate data from childbearing and other women. Critical evaluation of the trials included in the four reviews reveals that women were often recruited to trials without regard to previous continence status.

Based on these prior reviews, three main groups of trials in childbearing women are of interest: 1) trials of PFMT for prevention of UI; 2) trials where it was not possible to differentiate prevention from treatment effects; 3) trials of PFMT for treatment of UI. Based on the latest Cochrane review [116], the primary outcome of interest was self-reported UI. The secondary outcomes of interest were condition specific quality of life (e.g. King’s Health Questionnaire, Incontinence Impact Questionnaire), or any other quality of life or health status measure (for example Short Form-36); symptom severity and number of leakage episodes.

a) Is PFMT effective in the prevention of UI in childbearing women?

There are three grades of prevention: primary, secondary and tertiary [117]. Primary prevention aims to remove the causes of a disease. Secondary prevention focuses on the detection of asymptomatic dysfunction and provides treatment aimed at stopping its progression. Tertiary prevention focuses on existing symptoms to prevent the progression of the disease through treatment. This subsection addresses the question of PFMT effectiveness for primary and secondary prevention of UI in childbearing women. Clinically it can be difficult to effectively screen trial participants to ensure that a disease process is altogether absent (for primary prevention studies) or present, although asymptomatic (for secondary prevention). In many cases, there are no reliable and valid clinical tests. Trials investigating prevention of UI usually enrol people purely on the basis of the absence of symptoms. Thus, in all likelihood the trials in this section probably represent a combination of primary/secondary prevention effects. No attempt was made to distinguish between primary and secondary prevention effects.

Five trials addressed prevention of UI in childbearing women [118-122]. Two of these studies were combined prevention/treatment studies, but published or unpublished data were available for women who were continent at recruitment [118, 121]. In the study by Sampselle (1998), 54 of 72 women were continent based on a standing stress test at 20 weeks gestation. After drop outs, unpublished data were available from 37 previously continent women (16 PFMT and 21 controls). Mørkved (2003) published data for 207 of 301 women who were continent before pregnancy and at 20 weeks gestation. After dropouts, data were available from 193 previously continent women (94 PFMT and 99 controls). Neither study was powered to detect differences in the previously continent subgroup; the subgroup sizes were small.

Four studies recruited nulliparous or primiparous women during pregnancy, and one “pregnant women” [120]. Reilly (2002) recruited primigravid women without a pre-pregnancy or current history of UI, but with bladder neck hypermobility at 18 to 20 weeks gestation. Sampsele (1998), Mørkved (2003) and Gorbea Chavez (2004) also recruited primigravidae, at 18, 20 and 28 weeks gestation respectively.

In all five trials, PFMT began during pregnancy while controls received the usual antenatal care, which may have included advice on PFMT from their maternity caregivers [118, 119, 121] or were asked not to do PFMT [120, 122]. There were some variations in the PFMT parameters (intensity and supervision):

- Eight to 12 near-maximal voluntary PFM contractions, held for six to eight seconds with a six-second rest, followed by three to four fast contractions at the end of each contraction, twice daily from 20 weeks gestation. Also a weekly exercise class from weeks 20 to 36 [121].
- Eight to 12 PFM contractions, held for six seconds with a two second rest, three sets twice daily, from 18 weeks gestation. Also individual PFMT with physiotherapist during monthly visit [119].
- Up to 30 near-maximal PFM contractions per day from 20 weeks of gestation [118].
- 10 PFM contractions; held for eight seconds each followed by three fast one second contractions; a six-second rest between contractions; for up to 20 weeks. PFMT taught one-on-one with physiotherapist. Weekly clinic appointments (one hour each) for eight weeks, then weekly phone calls [122].
- PFMT not described. Participants were seen twice monthly throughout pregnancy, and every three months postpartum for one year [120].

Mørkved (2003), Sampselle (1998), and Gorbea Chavez (2004) stated that a correct voluntary PFM contraction was checked prior to training.

1. Quality of data

Allocation concealment appeared adequate in four trials [118, 119, 121, 122] and the outcome assessors were blind in four of the five trials [118-121]. Dropout rates ranged from 4% [121] to 14% [119] and 36% [118]. Stothers (2002) did not report any losses to
follow up. Markved (2003) and Reilly (2002) measured outcomes at 34 and 36 weeks gestation then at three months postpartum. Sampselle (1998) assessed women at 35 weeks gestation, then postpartum at six weeks and six and 12 months; the primary endpoint was 12 months. Gorbea Chavez (2004) measured outcome at 28 and 35 weeks gestation, and six weeks postpartum. Stothers (2002) measured outcome at six and 12 months postpartum. Reilly (2002) was the only trial with long-term follow up, at four years.

2. Results

i) Late pregnancy (34 weeks or later): Pooled data from three trials [118, 121, 122] showed that women in the antenatal PFMT group were 56% less likely to report UI than the controls (RR 0.44, 95% CI 0.31 to 0.65). Statistically significant heterogeneity was observed in this comparison. While the point estimates in all three studies favoured PFMT these differed considerably between the trials (RR of 0.86, 0.46 and 0.03 in the studies by Sampselle 1998, Markved 2003, and Gorbea Chavez 2004 respectively). A possible reason why the difference between PFMT women and controls is more pronounced in the study by Gorbea Chavez (2004) is that the comparison group was asked not to do PFMT, whereas in the other two studies the controls had usual care that might have included PFMT.

ii) Early postpartum (up to 12 weeks): Pooled data from two trials showed that PFMT women were around 50% less likely to report UI, compared to the controls (RR 0.50 95% CI 0.31 to 0.80; [118, 122]).

iii) Mid postpartum (three to six month postpartum): PFMT women were statistically significantly less likely than controls to report UI, although the difference in risk had reduced to about 30% (RR 0.71 95% CI 0.52 to 0.97; [118-121]).

iv) Late postpartum (up to one year postpartum): Based on the data from a previously continent subgroup of participants in Sampselle (1998), there was no difference in prevalence of UI between PFMT women and controls at 12 months postpartum. This trial had not shown a statistically significant effect of PFMT at any of the three previous time-points (late pregnancy, early and mid-postpartum periods), and was not powered to detect a difference in the previously continent subgroup.

v) Long term (more than one year): At four year follow up, Reilly (2002) reported seven of 42 PFMT women and 26 of 58 controls had symptoms of SUI. This advantage for the PFMT group needs to be viewed with caution as less than half of the original sample was followed up.

Regarding secondary outcome measures, four of the five trials reported symptom severity data such as frequency or amount of urine leakage. None of the measures, or the ways in which they were reported, were common to the four trials. The data suggested that PFMT women with symptoms of UI might have demonstrated less severe symptoms than the controls. Only Stothers (2002) noted adverse events; two of the 43 PFMT women withdrew due to pelvic floor pain.

Only two trials reported treatment adherence data. Gorbea Chavez (2004) reported that 84% of PFMT women attended seven or eight of the eight physiotherapy appointments offered. In the study by Reilly (2002), nearly half the women in the PFMT group exercised for 28 days or more; postpartum similar proportions of women in the intervention and control groups were doing occasional or no PFMT (28% and 34% respectively).

Summary

Pregnancy and birth appear to be important factors associated with the development of UI in women. Therefore, all women who have had a child or children might be considered ‘at risk’ of developing UI at a later date.

Continent pregnant women having their first baby who participated in a more ‘intensive and supervised’ PFMT programme than the PFMT provided as part of usual care were less likely to experience UI from late pregnancy up to six months postpartum (Level of Evidence: 1). There was not sufficient evidence available to be sure whether this benefit persists 12 months or more. There was no evidence investigating the preventive effects of PFMT in pregnant, previously continent, multiparous women.

Recommendations

Continent pregnant women having their first baby should be offered a supervised (including regular health professional contact) and intensive strengthening antepartum PFMT programme to prevent postpartum UI (Grade of Recommendation: A). The usual or standard approach to PFMT in pregnancy (which is commonly verbal or written instruction without confirmation of correct contraction or supervision of training) needs to be reviewed.

Based on the long term findings of one trial [119] health providers with limited resources may wish to consider whether supervised intensive training would be best targeted at those women who are continent at 18 weeks gestation, but have increased bladder neck hypermobility.

Further, large, good-quality RCTs are needed to investigate the effect of antepartum PFMT on preventing postpartum UI in multiparous women.
b) Is PFMT effective in the mixed prevention and treatment of UI in childbearing women?

Eight trials contributed to this comparison. In all these trials, some women did and some women did not have UI at the time of recruitment, i.e. in these studies the effect of PFMT included a mix of prevention and treatment.

Four trials randomised nulliparous or primiparous women to either supervised antepartum PFMT or usual antepartum care [118, 121, 123, 124]. The other four trials randomised nulliparous women during pregnancy [125] or postpartum [126-128] to either postpartum PFMT or usual postpartum care or no PFMT.

i) Antepartum PFMT versus usual care: The interventions of the trials by Mørkved (2003) and Sampselle (1998) in pregnant women have been described section B.2.1a. Hughes (2001) recruited nulliparous women at 20 weeks gestation and women randomised to PFMT attended one individual appointment then, between 22 and 25 weeks gestation, a group PFMT session (maximum six women) with a physiotherapist. No details of the training parameters were reported. Women with no palpable voluntary PFM contraction or a flicker of contraction were randomised. Controls received the usual community antepartum care. In Dannecker’s (2004) study, women in the PFMT group were trained to use an Epi-No device (an inflatable vaginal balloon connected to a pressure gauge for visual feedback), 15 minutes daily; for three to six weeks. Controls received no device. This trial was primarily interested in improving the elasticity of the PFM for delivery rather than continence outcomes.

ii) Postpartum PFMT versus usual care or no PFMT: Chiarelli (2002) restricted inclusion to women who had had forceps or ventouse deliveries, or had delivered a baby weighing 4000g or more. Ewings (2005) restricted inclusion to women who had already experienced UI and who were at high risk of UI following childbirth in accordance with the SIFCRAFT risk scale. The control groups received the usual postpartum care, which included an invitation to postpartum classes taught by physiotherapists in Chiarelli’s (2002) study; standard ante and postpartum care in Sleep’s (1987) study, no PFM re-education from two to 10 months postpartum in Meyer’s (2001) study and verbal promotion of PFM exercises supplemented by a leaflet in Ewings’ (2005) study. In PFMT groups, women were visited by a midwife or physiotherapist on the postnatal ward and were advised to train as follows:

- PFMT exercises as often as remembered and contractions integrated with daily living activities, plus midstream urine stop. Correct PFM contraction was checked on a second visit at eight weeks postpartum [126]
- PFMT exercises with three to six-second holds, three times a day. A variety of adherence strategies were employed (e.g. red stick-up dots, home or hospital visit after eight weeks) [127]
- PFMT programme including 12 visits with a physiotherapist between two and 10 months postpartum, including a 20 minute BF training session and a 15 minute electrical stimulation session [125]
- PFMT taught one to one with physiotherapist in hospital in addition to an invitation to attend PFMT class at two and four months postpartum; 21 of 284 women participated in the first class (18%) and only 5 (4%) attended both [128].

1. Quality of data

i) Antepartum PFMT versus usual care: Two of the four trials had adequate random allocation concealment [118, 121]. In the other two women were allocated at random but it was not clear if allocation was adequately concealed [123, 124]. Assessors were blinded in two of the four trials [118, 121]. Mørkved (2003) [121] randomised 301 women, Sampselle (1998) 72, Dannecker (2994) 144 and Hughes (2001) 1169 women. Dropout rates were 4% [121] at three months postpartum and ranged from 24% [124] to 34% [123] at six to seven months post-partum. At 12 months, the drop-out rate was 36% [118].

ii) Postpartum PFMT versus usual care or no PFMT: Random allocation concealment was adequate in the trials by Chiarelli (2002), Sleep (1987) and Ewings (2005), but inadequate in Meyer (2001) where alternate assignment was used. Blinding of outcome assessment was adequate in Chiarelli (2002). Sleep (1987) randomised 1,800 women; Chiarelli (2002) 720; Ewings (2005) 234, and Meyer (2001) 107. Both the Sleep (1987) and Chiarelli (2005) trials measured outcome at three months, with the loss of 191 (11%) and 44 women (6%) respectively. Ewings (2005) measured outcome at six months, with a loss to follow-up of 19%. Finally, Meyer (2001) measured outcome at 10 months with no withdrawal or loss to follow-up.

2. Results

i) Antepartum PFMT versus usual care: Pooled data from three trials [118, 121, 123] showed that women who were randomised to antepartum PFMT had about 10% less risk of UI in late pregnancy (RR 0.88, 95% CI 0.81 to 0.96). Statistically significant heterogeneity was observed in this comparison. While the point estimates in all three studies favoured PFMT these differed considerably between the trials (relative risks of 0.67, 0.81 and 0.93 in the studies by Mørkved 2003, Sampselle 1998, and Hughes 2001 respectively); the study by Hughes (2001) carried considerable weight in the pooled analysis; most likely because it was the largest study. One of the differences between the studies by Mørkved (2003) and the other two in this comparison was the PFMT intensity and
supervision as reported previously, being more ‘intense’ in the former.

Prevalence of UI was not statistically significant between PFMT and control groups in the early (RR 0.82, 95% CI 0.48 to 1.40; [118]), mid (RR 0.89, 95% CI 0.78 to 1.02; [118, 121, 123]) or late postpartum period (RR 0.96, 95% CI 0.70 to 1.32; [118, 124]).

Three trials reported data on symptom severity such as frequency or amount of urine leakage, but none of the data suggested that PFMT was superior to control or vice versa at the primary endpoint for each study [118, 123, 126].

ii) Postpartum PFMT versus usual care or no PFMT: There was no statistically significant difference in the prevalence of UI in women randomised to postpartum PFMT or control in the mid (RR 0.97, 95% CI 0.85 to 1.09 [126-128]) or late postpartum period (RR 0.94, 95% CI 0.75 to 1.16 [125, 127]). Statistically significant heterogeneity was observed in the combined data for the mid postpartum period, with one study favouring PFMT [127], one neither PFMT nor control [126] and one favouring the control condition [128]. Some potentially important clinical differences were noted between the studies. Firstly, Chiarelli (2002) recommended a PFM strength training programme; neither of the other two studies described their PFMT programme, so it is not possible to determine whether the latter studies could have had an effect or how different the PFMT and control conditions were. Further, Sleep (1987) found only a moderate difference in the proportion of PFMT women and controls doing some PFMT at three months postpartum (58% and 42% respectively) while at three month postpartum Chiarelli (2002) found that about half the controls were doing PFMT (58%) but an even greater proportion of the PFMT group (84%) were exercising. A second difference was that, Chiarelli (2002) recruited women at potentially increased risk of postnatal UI, such as those who had a large baby or a forceps delivery.

SUMMARY

The effect of antepartum PFMT or postpartum PFMT, in groups of women where some did and some did not have prior UI symptoms, varied by study with some studies showing a benefit of PFMT on UI prevalence whereas others did not (Level of Evidence: 2). The characteristics of the two studies, both methodologically robust, that demonstrated some effect were:

a) For antepartum PFMT: Mørkved (2003) recruited pregnant women having their first baby and used an intensively supervised strengthening PFMT programme; PFMT reduced UI prevalence in late pregnancy and three months postpartum but this was not evident six years after the index delivery.

b) For postpartum PFMT: Chiarelli (2002) recruited primiparous and multiparous women at potentially greater risk of postpartum UI after a large baby or forceps delivery, and used a strengthening PFMT programme; PFMT reduced UI prevalence at three months postpartum but not at one year.

RECOMMENDATIONS

Health providers should carefully consider the cost/benefit of population based approaches to health professional taught antepartum or postpartum PFMT; that is, health professional instruction to all pregnant or postpartum women regardless of their current or prior continence status (Grade of Recommendation: B).

Where a population approach is used, the ‘best’ evidence to date suggests the following: (a) an intervention comprising a daily home PFMT and weekly physiotherapist-led exercise classes for 12 weeks, starting from 20 weeks gestation for pregnant women having their first baby, and (b) an individually taught strengthening PFMT programme that incorporates adherence strategies for postpartum women who have had a forceps delivery or a vaginal delivery of a large baby (4000g or more) (Grade of Recommendation: C)

c) Is PFMT effective in the treatment of UI in childbearing women?

Four studies addressed the treatment of existing UI after delivery [129-132]. One study recruited incontinent women during pregnancy [132], while the other three recruited women three months or more after delivery. All four studies recruited a mix of primiparous and multiparous women.

The control groups in three studies [129, 130, 132] received standard care, which included ante and postpartum advice on PFMT, whereas the control group in Dumoulin’s (2004) study received, in lieu of training, relaxation massages at the same frequency as the PFMT treatments.

The PFMT interventions varied as follows:

- Wilson (1998) randomised women in the intervention group to either PFMT, or PFMT with vaginal cones, or vaginal cones (VC). PFMT comprised 80 to100 PFM contractions per day (a mix of fast and slow), with three home visits by a nurse, healthcare visitor or continence advisor. The VC group received 15 minutes per day of cone therapy while the combined PFMT/VC group received both interventions [129].
- The PFMT programme in Glazener (2001) was the same as Wilson (1998), supplemented by instruction from a physiotherapist on four occasions [130].
• In Dumoulin’s (2004) study PFMT included electrical stimulation (ESstim) with or without deep abdominal training. PFMT comprised weekly sessions supervised by physiotherapists for eight weeks with 25 minutes of PFMT and 15 minutes of ESstim (bi-phasic rectangular form; frequency 50Hz) [131].
• Woldringh’s (2007) study included four one to one and half hour sessions with a physiotherapist (three antepartum and one at six weeks postpartum) but details of the PFMT programme were not given [132].

1. Quality of Data

Random allocation concealment was adequate in three of the four trials [129-131] and outcome assessors were blind in two [130, 131].

There were 85 losses to follow-up in the trial by Wilson (1998) with high attrition rates noted in all intervention groups (20/39 PFMT, 24/38 PFMT/VC, 15/36 VC). Glazener (2001) reported 223 (30%) losses to follow-up and Woldringh (2007) 38%. In contrast, Dumoulin’s (2004) trial (which included weekly contacts with a physiotherapist for eight weeks) reported a 6% loss to follow-up. Wilson (1998) and Glazener (2001) measured outcome 12 months after delivery, and then 24 to 44 months post-delivery, and six years after the index delivery [133]. Dumoulin (2004) reported outcome nine weeks after intervention began. However as women were recruited at varying lengths of time following delivery (all more than three months postpartum) the data are presented alongside those from Glazener (2001), and Wilson (1998), as long-term post-natal data.

2. Results

In the one study of antepartum PFMT for treatment of UI, Woldringh (2007) did not find any statistically significant difference in the prevalence of UI between PFMT and control groups at 35 weeks, eight weeks postpartum, six months and 12 months postpartum. Pooled data from the three trials of postpartum PFMT found women were about 20% less likely to have UI after treatment compared to the controls (RR 0.79, 95% CI 0.70 to 0.90). Statistically significant heterogeneity was observed. The treatment effect in the study by Dumoulin (2004) was much greater than that in the other two studies. Possible reasons are that the controls in the study by Dumoulin (2004) were asked not to do PFMT, whereas controls in the other two studies received usual care and both interventions and control groups were also doing PFMT (a mean of 20 versus five PFM contractions per day in Glazener 200), and 86 versus 35 in Wilson 1998). Another difference was the intensity and supervision of the PFMT intervention; Dumoulin (2004) used a more intensive PFMT programme with adjunctive electrical stimulation and BF and physiotherapy appointments once a week for eight weeks, whereas in the other two studies [129, 130] women had three or four appointments with health professional over approximately six months and were asked to do PFMT on their own.

All four treatment trials reported some data on symptom severity such as frequency or amount of urine leakage. None of the measures, or the ways they were reported, was common to the four trials. The data suggested that PFMT women with symptoms of UI might have less severe symptoms than the controls, but this was not a consistent or clear-cut finding. Dumoulin (2004) stated that none of the women in the PFMT group reported any adverse events.

Three trials reported some data related to treatment adherence, one for antepartum PFMT [132] and two for postpartum PFMT [129, 130]. In the antepartum study, at 36 weeks gestation 37% of the PFMT women were exercising intensively compared to 14% of the controls [132]. Glazener (2001) and Wilson (1998) both reported the mean number of PFM voluntary contractions per day at 12 months postpartum. Respectively, the mean number of contractions was 20 (SD 29) and 86 (95% CI 69 to 104) per day in PFMT women, and 5 (SD 15) and 35 (95% CI 30 to 40) per day in the controls.

Glazener and colleagues followed up women six years after the index delivery. The effect of PFMT on UI was not sustained. At six years, 100 out of the 263 in the intervention group and 99 out of the 253 in the control group experienced UI at least once per week [133]. However, the women had had an average of 1.5 deliveries since the index delivery.

Summary

To date, only one trial has investigated the effect of PFMT for the treatment of UI in pregnant women [132]. This was a moderate-size study that did not report on allocation concealment or blinding of the assessors, and did not describe the type of PFMT programme employed. In the absence of any detail on the PFMT programme it is impossible to judge if the intervention had the potential to be effective. Postpartum women with UI who were randomised to PFMT taught and supervised by a health professional were less likely to be incontinent than controls (standard care or relaxation massage) six to 12 months following delivery (Level of Evidence: 1). Of the three trials, the one that used an intensively supervised strength training programme demonstrated the greatest treatment effect. It is unclear if the benefit of PFMT is maintained over time or with subsequent deliveries (Level of Evidence: 2). For women who have persistent symptoms of UI at three months postpartum PFMT is a more effective treatment than standard postnatal care or relaxation massage;
effects might be greater with supervised and intensive strengthening PFMT (with the addition of EStim). It is not clear if the effect can be sustained over the long-term; there is also no data on the effect of short periodic refresher sessions on long-term effect.

Recomendations

PFMT should be offered as first line conservative therapy to women with persistent UI symptoms three months after delivery (Grade of Recommendation: A); an ‘intensive’ PFMT programme (in terms of supervision and exercise content) is likely to increase the treatment effect (Grade of Recommendation: B).

There is a need for at least one large, pragmatic, well-conducted and explicitly reported trial with long term follow-up (five plus years) of postpartum PFMT that investigates the effect of ‘intensive’ treatment followed by periodic refresher sessions.

2. PREVENTION (OTHER WOMEN)

Hay-Smith and colleagues have previously reviewed trials of PFMT and other physical therapies for the prevention of UI [112]. Three main groups of trials were found. The first included trials that investigated the effect of PFMT on PFM activity in women, but did not measure continence related outcomes as so were not relevant for this chapter. The second recruited only childbearing women; these trials were considered in section B.2.1a, which addressed the prevention of UI in childbearing women. The third group included trials for prevention of post prostatectomy UI and these trials are considered in Section C.2.1.

No trials investigating the primary/secondary prevention effects of PFMT for UI in non-childbearing women were found.

3. TREATMENT (OTHER WOMEN)

a) Is PFMT better than no treatment, placebo or control treatments?

Recommendations in this section are based on the updated but as yet unpublished findings (Dumoulin and Hay-Smith 2008, personal communication) of a Cochrane systematic review [134]. Primary outcomes of interest were 1) patient-reported symptom cure or improvement and 2) symptom bother and incontinence specific quality of life assessment. Secondary outcomes of interest included the number of leakage episodes and other quality of life measures (not UI-specific, e.g. Short Form 36).

Seventeen RCTs comparing PFMT with no treatment for women with UI were found, of which five were excluded. Two were excluded because they compared supervised with unsupervised PFMT [135, 136]; for these trials see B.2.3b. One trial, reported only as a conference abstract, was excluded because it was unclear if it was a RCT and it lacked adequate data [137]. Finally, two more trials were excluded because the PFMT versus sham PFMT comparison was considered to be confounded by the choice of sham PFMT [138, 139]. In both trials, sham PFMT consisted of strong isometric hip abductor contractions and according to EMG, dynamometric and MRI studies, both hip abductions and external rotations result in a synergic contraction of the PFM [80, 97, 140]. These two trials probably compared a direct versus an indirect approach to PFMT; for this comparison see B.2.3b.

Of the 12 included trials, nine recruited women with SUI only [77, 141-148]. One included women with SUI, with or without UUI. However, the proportion with MUI was small (9%) and it was thus analysed with the SUI studies [149]. One included older women with UUI with or without SUI (with urge as the predominant type) [150]. The remaining study recruited women with a range of diagnoses [151].

Four studies gave no details about the PFMT programme used [142, 143, 146, 148]. Of the eight remaining trials, five stated that a correct voluntary PFM contraction was confirmed prior to training [77, 141, 145, 147, 150] and in all cases PFMT was taught by a health professional. Based on the description of training programmes, two trials had PFMT programmes that clearly targeted coordination [77] or strength training [145]. It was more difficult to categorise the other PFMT programmes, because they were either a mixed (i.e. strength and endurance) programme or did not provide enough information on the exercise parameters.

The ‘control’ groups received no treatment, [77, 141, 142, 146, 147, 149] placebo drugs, [150] sham EStim, [143], sham PFMT with placebo drug [148] or a non-active control intervention such as the use of an anti-incontinence device [149] or advice on incontinence pads [143].

The potential to consider the combined results from individual studies was limited by: 1) lack of consistency in the choice of outcome measures chosen by the researchers and because many did not use any of the pre-specified outcomes of interest for the review; and 2) poor reporting of outcome data (i.e. mean reported without a measure of dispersion) which meant the data could not contribute to a pooled analysis.

1. Quality of Data

The brevity of the reporting in three trials, which were published as conference abstracts, made it difficult to assess the quality [142, 146, 148]. Only Bø (1999) reported adequate random allocation concealment. Seven trials reported using blinded outcome assessors [77, 144-146, 149-151].

1042
2. Results

Twelve RCTs, involving 670 women, compared PFMT (353 women) with no treatment, placebo, sham or other non-active control treatments (317 women). In the six trials contributing data, the two comparison groups comprised 175 and 184 women, respectively. Two trials reported data on cure and both found that PFMT women were statistically significantly more likely to report cure [145, 150]. The size of effect was quite different in the two trials; SUI women receiving PFMT were about 17 times more likely to report cure compared to controls (RR: 16.80, 95% CI 2.37 to 119.04) [145], whereas PFMT women in the study with urge predominant UI were about two-and-half times as likely to report cure (RR: 2.34, 95% CI 1.11 to 4.94) [150].

With regard to patient-perceived cure or improvement the two trials in women with urodynamic SUI [143, 145] suggested more likelihood of cure or improvement than the single study in women with UUI with or without urodynamic SUI [150].

Two trials in women with urodynamic SUI used psychometrically robust questionnaires for the assessment of symptom impact. Be (1999) used the Bristol Female Lower Urinary Tract Symptoms Questionnaire (B-FLUTS), but only the lifestyle and sex-life domains were reported. Fewer women in the PFMT group reported that UI symptoms interfered with activities or were problematic. Schagen van Leeuwen (2004) reported a mean change in Incontinence Quality of Life score (I-QoL), but it was not clear if the difference in favour of the PFMT group was important as the means were presented without a measure of dispersion.

Four studies used urinary diaries to count leakage episodes. Effect size was greater in the Lagro-Janssen's (1991) trial (MD -2.92, 95% CI-3.74 to -2.10); a possible explanation may be inadequate random allocation concealment, with a resulting overestimate of treatment effect. The point estimates in the other three trials (MD -1.29, 95% CI-2.24 to -0.34) [149], (MD -0.77, 95% CI-1.22 to -0.32) [150], (MD -0.80, 95% CI-1.60 to -0.00) [145] were similar and all were statistically significant. PFMT women experienced, about one less leakage episode per 24 hours compared to the controls.

Few trials had long-term follow up. In all trials, supervision of PFMT stopped at the end of the treatment period except where the controls were then offered supervised training. Because of this ‘crossover’ of controls to training, follow up data were usually presented for all women in the trial, rather than by group allocation. Three trials have published long-term follow up results, at three and six months [149], nine months [141], and one and five years [152]. Burns (1993) found that those experiencing mild leakages were more likely to have a return of symptoms in contrast with those experiencing moderate to severe leakages, who were more likely to continue to improve with PFMT. At nine months Henalla (1989) reported that three of the 17 women (from the 25 originally allocated to PFMT) had recurrent symptoms. Lagro-Janssen reported data from 88 women of an original 110 [152]. The proportion of continent women was the same after five years (25%), but more had severe UI (increased from 3% to 18%). Leakage had also increased significantly (p = 0.009), with a mean increase of 2.7 episodes per week (95%; CI 0.7 to 4.6). Two thirds (67%) remained satisfied with the outcome and did not want further treatment, although women with UUI or MUI were less likely to be satisfied and SUI women were less likely to report that their condition had worsened. Nearly half (43%) who had done PFMT were no longer training at all, while 39% were training daily or “when needed”.

Summary

PFMT is better than no treatment, placebo drug or inactive control treatment for women with SUI, UUI, or MUI (Level of Evidence: 1). Women treated with PFMT were more likely to report cure or improvement and have fewer leakage episodes per day than the controls. Condition-specific quality of life might also be better after PFMT, but this finding needs confirmation through further studies. The trials suggested that treatment effect might be greater in SUI women who tended to be younger (in their 40s and 50s) and participated in a supervised PFMT programme for at least three months. These hypotheses need further testing. The limited evidence from follow up after treatment means that the long-term outcomes of PFMT are less clear, although continued treatment effect is probably associated with continued training.

It seems likely that treatment effect will be enhanced if PFMT is based on sound muscle training principles: such as, specificity, overload and progression, correct contraction confirmed prior to training, and if women are supported to maintain treatment adherence (Level of Evidence: 4).

Recommendations

Supervised PFMT should be offered as first line conservative therapy for women with stress, urge or mixed urinary incontinence (Grade of Recommendation: A).

b) Is one PFMT programme better than another?

A number of factors may influence the outcome of the PFMT programme, such as the way in which it is taught and supervised, the exercise parameters, and adherence to training. In this section, different
Twenty-eight trials were identified, and three were excluded for the following reasons. In one study, electrical stimulation (EStim) was added to the biofeedback arm only, and in a second study EStim was added to both treatment arms. In both studies the addition of EStim rendered the trial ineligible for inclusion [137, 153]. Another study reported outcomes by diagnosis and not by intervention group [154]. The included trials compared:

- Health professional supervised PFMT versus self-directed PFMT [135, 136, 155];
- Direct versus indirect (such as PFM contractions facilitated through abdominal or gluteal muscle work) PFMT [138, 139, 156, 157];
- Different exercise parameters (such as strength versus endurance training) [158-160];
- PFMT with repeated episodes of BF versus PFMT without BF [147, 149, 161-167].
- PFMT with intravaginal resistance versus PFMT without resistance [168];
- PFMT with adherence strategy (such as alarm or diary) versus PFMT without strategy [169, 170];
- PFMT with more versus less health professional contact [171-173].

i) Health professional (HP) supervised PFMT versus self-directed PFMT: Three trials made this comparison. Burgio (2002) compared written instruction on PFMT and urge suppression strategies (no HP contact) versus HP taught and supervised PFMT with urge strategies and anorectal BF versus HP taught and supervised PFMT with urge strategies but without BF. Treatment duration was eight weeks for all three treatment arms with four HP visits in the supervised arms. Goode (2003) compared written instruction on PFMT versus HP taught and supervised PFMT; treatment duration was 10 weeks in both arms with four HP visits in the supervised arm. Williams (2006) compared written instruction on PFMT along with fortnightly nurse visits versus HP taught PFMT with fortnightly visits for 10 weeks.

ii) Direct versus indirect PFMT: Four trials compared direct with indirect approaches. One arm of each trial was PFMT. The other arm was hip abductor contractions in two trials [138, 139]; Pilates in one trial [157] and ‘Paula method’ in another [156]. The ‘Paula method’ focuses on strengthening the circular muscles (such as the pubococcygeal muscle, the anal sphincter, and grip) based on the hypothesis that all sphincters in the body work simultaneously. Thus, exercising circular muscles in one area of the body might strengthen other sphincters. Treatment duration was 12 weeks in both arms of all four trials.

iii) Different exercise parameters: Three trials made this comparison; each comparison was different. Johnson (2001) compared near maximal (10 minutes three times a day at 90% of maximal PFM) versus sub-maximal PFMT (15 minutes three times a day at 60% of maximum contraction intensity) for six weeks. Hay-Smith (2003) compared motor relearning PFMT (being PFM contractions in different body positions, preceding and sustained during different provocative activities) versus motor relearning with strengthening PFMT programme (10-12 near maximal PFM contractions, six to eight second hold with equivalent rest, three times a day, at least three days a week). Both groups trained for 18 to 20 weeks. Borello-France (2006) compared 12 weeks of twice daily PFMT in supine versus the same programme performed in supine, sitting and standing.

iv) Addition of BF (Figures 1 and 2): Studies used either home or clinic based BF. Potentially, home based BF offers women more opportunity to make use of this adjunct and it might be expected that any BF effects would be greater in these studies. Clinic and home based BF trials were therefore considered separately.

Five trials used clinic based BF. In four of them the home PFMT programme was the same in both groups, with the addition in one arm of clinic BF once a week [149, 163], twice a week [167], or three times a week [162]. Treatment durations in both arms were four weeks [162, 163], eight weeks [149] and 12 weeks [167]. In the fifth trial there were some differences in the PFMT as well as the addition of clinic based BF in one arm. Pages (2001) compared PFMT (group PFMT five times per week for four weeks and daily home PFMT) versus daily home PFMT and clinic BF five times per week for four weeks; in both groups this was followed by eight weeks of home PFMT. flewind (1996) had a greater amount of supervisory HP contact with the BF group than with the PFMT alone group.

Four trials used home-based BF. In all of them the home PFMT programme was the same in both groups, with the addition in one arm of home BF. Treatment durations in both arms were six weeks [161], eight weeks [147], 12 weeks [164], and six months [166].

v) Addition of intravaginal resistance (IVR): One trial compared daily home PFMT versus PFMT daily at home with intravaginal balloon device for resistance; treatment duration was six weeks in both arms [168].

vi) Addition of adherence strategy: Two trials investigated the use of adherence strategies. In both trials the daily home PFMT programme was the same in both groups, with the addition in one arm of an
adherence strategy or device. These were a device that beeped in the rhythm that contractions were to be performed and participants pressed a button on this device to record their PFM contractions [170], or audiotape of exercise instructions, counting aloud 25 consecutive PFM contractions [169]. Treatment duration was four to six weeks [169], or eight weeks [170].

vii) More versus less health professional (HP) contact: Three trials contributed to this comparison. In all three studies both groups did the same daily home PFMT programme with the addition in one arm of a weekly 45 minute group exercise sessions [171], weekly supervised training session in groups of five [173], or twice weekly phone calls from a registered nurse monitoring progress [172]. Treatment duration was four to six weeks [169], or eight weeks [170].

1. Quality of data

i) HP supervised PFMT versus self-directed PFMT: One trial reported adequate random allocation concealment [155]. Outcome assessment was blind in Burgio (2002). The number of women allocated to each group was between 60 and 80 in all three trials. Dropouts were 7/75 for the self-directed group, 11/73 and 9/74 in the HP led groups in Burgio’s (2003) study. In Goode’s (2003) study, 25/67 in the self-directed group and 12/66 in the HP led PFMT group withdrew. In Williams’s (2006) study, 3/79 in the self-directed group and 3/79 in the HP group withdrew.

ii) Direct versus indirect PFMT: Two of the four trials reported adequate random allocation concealment [139, 157] and two reported blind outcome assessment [139, 157]. The number of women allocated to each group was less than 10 [157], between 20 and 30 [138, 156] and between 40 and 50 [139]. Losses to follow-up were less than 10 % in three trials [138, 156, 157] and was 20% in one [139].

iii) Different exercise parameters: One trial reported adequate allocation concealment and blind outcome assessment [159]. Two trials randomised less than 25 women to each group [158, 160] and Hay-Smith (2003) randomised about 60 per group. Four percent of women withdrew from the trial by Hay-Smith (2003), while14% dropped out from Johnson’s (2001) trial and 18% in Borello-France’s (2006) trial.

iv) Addition of BF: Of the five clinic based BF trials, two had adequate random allocation concealment [162, 167] and two had blinded outcome assessors [149, 162]. Two trials randomised between 25 and 50 women to each comparison group [149, 167] while others randomised less than 25 women per group [162, 163, 165]. There were no withdrawals or losses to follow up in one trial [162] less than 10% in one [149], less than 15% in two [163, 167], and 22% in the other [165]. In the latter trial all the dropouts were from the BF group [165]. All women were assessed post-treatment; further follow up was conducted by Burns and co-workers [149] at three and six months, and by Glavind (1996) at three months and two to three years.

Of the five home based BF trials, random allocation concealment was adequate in just one [166], and outcome assessors were blind for some or all of the outcomes in three trials [161, 166, 174]. The number of women allocated to the comparison groups was 20 or less in three trials [147, 161, 174]. Laycock (2001) randomised women in a ratio of 2:1, so there were 40 women in the BF group and 20 in the PFMT only group. Mørkved (2002) randomised 50 women or more to each group. Three trials had complete data sets on trial completion [147, 161, 174], Mørkved (2002) reported 9% withdrawal, and 33% dropped out of the trial by Laycock (2001). One trial reported a one-year follow up [175].

v) Addition of IVR: It was not clear if allocation concealment was adequate or outcome assessors were blind. There were 10 women in each intervention group and it seemed there were no dropouts. Women were assessed post-treatment and followed up at 12 to 24 months [168].

vi) Addition of adherence strategy: Both trials had inadequate allocation concealment, and neither stated if outcome assessors were blind to treatment allocation.
There were no statistically significant differences between the groups for self-reported cure/improvement (RR 0.25, 95% CI 0.03 to 2.21), cure/improvement (RR 0.88, 95% CI 0.59 to 1.31), or the number of leakage episodes in 24 hours (MD −0.2, 95% CI −0.55 to 0.15). Nor were there consistent differences in the nine domains of the KHQ. Johnson (2001) compared near maximal PFM contractions (strengthening programme) with sub-maximal PFM contractions (endurance programme) for women with urodynamic SUI. After six to seven weeks of training there was no statistically significant difference between the groups in the number of leakage episodes per day (MD −0.36, 95% CI −1.85 to 1.13). Borello-France (2006) compared PFMT in lying versus lying and upright positions for SUI women. There was no statistically significant difference in improvement in Incontinence Impact Questionnaire (IIQ) scores between the two groups, or differences in the weekly reduction in leakage or amount of urine lost during the pad test.

For the home BF trials, it was difficult to interpret or combine the data, principally because data were not reported in useful ways. Pooled data from Shepherd (1983) and Mørkved (2003) found no statistically significant differences between the groups for self-reported cure (RR 1.54, 95% CI 0.95 to 2.50) or self-reported cure/improvement (RR 1.17, 95% CI 0.93 to 1.47). Both trials recruited women with urodynamic SUI. Interestingly, at one-year, cure/improvement was 68% in the home BF group compared to 53% in the PFMT group; this difference did not reach significance.
[175]. Markved (2003) did not find any statistically significant differences between the groups on the Social Activity Index post treatment. Markved (2003) stated that no women reported an adverse event, while Aukee (2004) found that a small number of women could not use a vaginal probe due to discomfort or reported discomfort with PFMT without a probe.

v) Addition of IVR: The single trial did not collect any data for the pre-specified outcomes of interest.

vi) Addition of adherence strategy: Sugaya (2003) found that SUI women who used an electronic device to cue PFMT were more likely to be satisfied with treatment outcome (RR 3.17, 95% CI 1.02 to 9.88), but there was no difference between device and no device groups for the number of leakage episodes per day post treatment (MD –0.50, 95% CI –1.55 to 0.55). Gallo’s (1999) study did not measure any continence outcomes although an interesting finding was that SUI women who used the audiotape of exercise instructions were more likely to be performing the PFMT exercises twice daily as per instruction (RR 7.05; 95% CI 2.78 to 17.88).

vii) More versus less HP contact: Be (1990) found no statistically significant difference in the proportion of SUI women reporting cure (RR 6.25, 95% CI 0.31 to 124.10). Pooled data from two trials found SUI women having more HP contact were more likely to report cure/improvement (RR 1.80, 95% CI 1.34 to 2.43) [171, 173]. Konstantinidou (2007) found that SUI women in the more contact group had significantly fewer leakage episodes in 24 hours (MD -1.39, 95% CI -2.04 to -0.73) and were less likely to report high scores on a study specific UI quality of life score (RR 0.55). Gallo’s (1999) study did not measure any urinary outcomes of interest although an interesting finding was that SUI women who used the audiotape of exercise instructions were more likely to be performing the PFMT exercises twice daily as per instruction (RR 7.05; 95% CI 2.78 to 17.88).

SUMMARY
Considering the number of trials that compared one approach to PFMT versus another it is disappointing there were so few data for analysis. Many trials collected no data for the pre-specified outcomes of interest, collected data for only one of these outcomes, and/or did not report the collected data appropriately (e.g. presented mean without measure of variance).

With regard to HP supervised PFMT versus self-directed PFMT women were more likely to report cure/improvement, fewer leakage episodes and better quality of life if PFMT was taught and supervised by a HP (Level of Evidence: 1). Although women in self-directed PFMT programmes reported improvements, improvements in the HP led group were greater.

The four trials that compared direct versus indirect PFMT methods made different comparisons; none found an indirect method better than direct PFMT (Level of Evidence: 2).

Three trials also compared different exercise parameters, but none made the same comparison. For SUI women there may be no difference in the number of leakage episodes per day after six weeks of strength versus endurance PFMT; the training period was probably not long enough to be sure about the lack of difference (Level of Evidence: 2). For SUI women, combination strength/motor relearning PFMT versus motor relearning PFMT alone as well as supine versus a combination of supine, sitting and standing exercises seemed equally effective (Level of Evidence: 2). With regard to clinic based BF it seemed that there were no statistically significant differences between BF assisted and non-BF groups for self-reported cure, cure/improvement, or leakage episodes per day or quality of life (Level of Evidence: 1). This pattern appeared to be consistent across trials that recruited SUI women only, women with urodynamic SUI, MUI, or OAB. There were a similar number of trials addressing the effect of home BF, but fewer data. In a single robust trial, there were no statistically significant differences between home BF and non-BF groups for self-reported cure, cure/improvement, or quality of life for women with urodynamic SUI (Level of Evidence: 2).

Based on a single poor quality trial, SUI women might be more satisfied with the outcome of PFMT if accompanied by an exercise cue, this may not be reflected in differences in number of leakage episodes (Level of Evidence: 2).

Self-reported cure or cure/improvement in SUI women was more likely with more HP contact during PFMT (Level of Evidence: 1). More contact also appeared to lead to better quality of life and fewer leakage episodes for UI women. Based on follow up from a single trial, the initial benefit of intensively supervised PFMT may not be maintained 15 years later when training adherence is low.

RECOMMENDATIONS
Clinicians should provide the most intensive HP led PFMT programme possible within service constraints because HP taught and supervised programmes are better than self-directed programmes, and more HP contact is better than less (Grade of Recommendation: A). There does not appear to be any benefit of adding clinic (Grade of Recommendation: A) or home based BF (Grade of Recommendation: B) to a PFMT programme.
There are many hypotheses that need further testing, such as:

- Whether any indirect method of PFMT (Paula method, transversus abdominus training, hip abductor or adductor exercise) might be as effective as direct PFMT, or add benefit to a direct PFMT programme.
- Different types of PFM exercise (strengthening, endurance, co-ordination, functional training) may be as effective as each other.
- BF may benefit certain women, such as those with a weak PFM or with difficulty contracting the PFM in isolation.
- IVR adds benefit to PFMT. Given the evidence for the effect of vaginal cones on UI (see B.3) and the fact that PFMT most commonly aims to strengthen the PFM, there seems to be some biological rationale for the use of IVR devices.
- Cues to exercise are useful.

**c) Is PFMT better than other treatments?**

Trials were considered for inclusion in this section if they compared PFMT with another stand-alone intervention, e.g. vaginal cones, bladder training, drug therapy. Thirty RCTs comparing PFMT with another stand-alone treatment were found. Four trials were excluded. Two were reported as conference abstracts and contained no useable data [177, 178], one was reported in two conference abstracts with inconsistent data [179], and the fourth compared PFMT and vaginal cones versus electrical stimulation [180].

The 26 trials addressed the following comparisons:

- PFMT versus vaginal cones (VC) [129, 145, 155, 164, 177, 181-183]
- PFMT versus electrical stimulation (EStim) [141, 143, 145, 167, 184-187]
- PFMT versus bladder training (BT) [151, 188, 189]
- PFMT versus drug [139, 141, 142, 150, 190, 191]
- PFMT versus surgery [192]

**i) PFMT versus VC:** Eight trials compared PFMT with VC in women with SUI [129] or urodynamic SUI [129, 145, 155, 164, 177, 181-183]. Three trials recommended using VC once a day for 10 minutes [164] 15 minutes [181] and 20 minutes [145]. Four trials asked women to use cones twice a day for 15 minutes [129, 177, 182, 183]. The remaining trial suggested using cones two to three times a day for 10 to 15 minutes at a time [155]. All the VC programmes asked women to retain the heaviest cone possible, and programmes were progressed by increasing the cone weight. The lightest cone weights were 10g [155], 20g [129, 145, 177, 183] or 50g [181, 182] progressing to 60g [155], 70g [145, 177, 182], 80g [181] or 100g [129, 183]. Laycock (2001) did not describe the cone weights or progression. One study also asked women to perform 20 maximal PFM squeezes with a 65g weight once a day, progressing after two months to 100g [181].

The PFMT programmes varied too, as follows:

- 50 maximal PFM contractions per day [183].
- 10 daily sessions of five PFM contractions [177].
- 10 brief forceful PFM contractions and 10 sustained PFM contractions for 10 seconds, repeated as able [182].
- 100 fast and slow PFM contractions daily [129].
- eight to 12 near-maximal PFM contractions with six second hold and six to eight second rest, with three to four fast contractions at the end of every contraction, thrice daily, and a weekly group session [145].
- 20 maximal PFM contractions, 15 sub-maximal PFM contractions, and one static two minute sub-maximal contraction, twice daily [181].
- 10 minutes of personalised fast and slow PFM contractions [164].
- personalised individual PFMT four times a day [155].

Treatment duration was the same in both arms of all studies, and ranged from four weeks [183], to 10 weeks [177], 12 weeks [155, 164, 182], four months [181], six months [145] and 12 months [129]. The number of HP contacts was the same in both groups in Arvonen (2001), Laycock (2001), Haken (1991), Wilson (1998), greater in the VC than PFMT groups in Peattie (1988), Cammu (1998), but greater in the PFMT than VC group Be (1999) and Williams (2006).

**ii) PFMT versus EStim:** Eight trials compared PFMT with EStim in women with UI [186], SUI [145, 184, 185], urodynamic SUI [141, 143], mixed UI [187] or OAB [167]. There were different PFMT and EStim protocols in each study.

Two trials used interferential current. Laycock (1988) compared interferential (two to three times weekly, 30 minutes, 10-50Hz) to PFMT (weekly PFM exercise courses and daily home exercises), for four to six weeks. Henalla (1989) compared interferential (20 minutes weekly for 10 weeks, 0-100Hz, at maximal tolerated intensity) to PFMT (five PFM contractions with five second holds, hourly, every day for 12 weeks). Another trial used external (extra-vaginal and lumbar) electrodes to deliver an unknown type of current (10 minutes, three times weekly, intensity increased until noticeable PFM contraction and patient added voluntary PFM contraction) versus PFMT (no details given), for six weeks [143].
The remaining trials all delivered the stimulation using a vaginal electrode. The comparisons were, in approximately ascending order of duration of EStim:

- 20 minutes, twice weekly, biphasic symmetric intermittent current at 10Hz, pulse duration 400 microseconds, duty cycle 10 seconds on and five off, maximum tolerated intensity, versus PFMT (no details given), for 12 weeks [167].

- 30 minutes, three times weekly, biphasic intermittent current at 50Hz, pulse duration one millisecond, two second contraction, duty cycle one to two, at maximal tolerated intensity up to 100 mA (for predominant SUI) or the same stimulation at 20Hz (for predominant UUI), versus PFMT (no details given), for eight weeks [186].

- 30 minutes daily, biphasic intermittent current at 50Hz, pulse duration 0.2 milliseconds, individualised duty cycle depending on ability to hold PFM contraction, at maximal tolerated intensity up to 120mA, versus PFMT (three times daily, eight to 12 near-maximal PFM contractions with six second hold and six to eight second rest, with three to four fast contractions at the end of every contraction in addition to weekly exercise class), for six months [145].

- up to 60 minutes, twice daily, symmetric balance biphasic intermittent current at 12.5 and 50Hz, pulse duration 300 microseconds, five second contraction time with two second ramp up and one second ramp down, duty cycle one to two, intensity to 80mA, versus PFMT (daily, 60 slow and quiet PFM contractions), for four months [187].

- six to eight hour per night, intermittent current at 12, 20 or 50Hz, versus PFMT (six to eight times daily, five to 10 maximal PFM contractions with five second hold and five seconds rest, and one sub-maximal contraction with 30 to 40 second hold), for six months [184].

Amount of HP contact was the same for both groups in one trial [141], greater for EStim in two [143, 185], and greater for PFMT in another [145]. Any differences were not clear in the other four trials.

**iii) PFMT versus BT:** Three trials compared PFMT with BT in women with SUI [189], SUI and/or DO [188] or UI [151]. BT was not described in the conference abstract of the study by Sherburn (2007); in both the other trials BT comprised a voiding schedule with weekly progression. Wyman (1998) also included urge inhibition techniques (affirmations, distraction and relaxation).

Sherburn (2007) did not describe PFMT. In the other two trials BT was compared with:

- PFMT with clinic based BF, and a twice daily home PFMT programme of five fast (three second holds) and 20 sustained (10 second holds with 10 second rests) PFM contractions, PFM contraction for urge suppression and with increases in intra-abdominal pressure [188].

- PFMT with clinic based BF, and daily home PFMT of 30 PFM contractions for strength and endurance (12 second holds) [151].

Treatment duration, and amount of HP contact, was the same in both arms of all three trials, with treatment duration ranging from eight weeks [151], to 12 [188] and 20 weeks [189].

**iv) PFMT versus drug therapy:** Six trials compared PFMT to drug therapy in women with UUI [150], SUI [139, 141, 142, 190, 191].

The trials by Henalla (1989, 1990) compared Premarin (conjugated equine oestrogens) 2g per night for six [142] or 12 weeks [141] versus PFMT. In Henalla (1989) the PFMT comprised a daily home programme of five PFM contractions with five second holds per hour, but in Henalla (1990) PFMT was not described. All the other trials used different drugs.

Wells (1991) compared phenylpropanolamine hydrochloride (50mg qd for two weeks, increasing to bid for two weeks if leakage continued) for four weeks versus six months of PFMT (90 to 160 PFM contractions with 10 second hold and 10 second rest distributed throughout the day). Ishiko (2000) compared clenbuterol (20mg bid) versus PFMT (10 minutes daily), for 12 weeks.

Ghoniem (2005) compared duloxetine (4mg bid, plus sham PFMT) versus PFMT (four times weekly, three sets of 10 six to eight second contractions and two sets of 10 one to two second contractions), for 12 weeks. Burgio (1998) compared oxybutynin chloride (2.5mg tid, progressed to maximum 5mg tid) versus PFMT (15 PFM contractions thrice daily, 10 second hold, plus PFM contraction with increased intra-abdominal pressure and urge strategies), for eight weeks.

Four trials had the same amount of HP contact in drug and PFMT groups [139, 141, 150, 190]; in Henalla’s (1990) trial, this was not clear. Wells (1991) assessed treatment effect after four weeks in the drug group, and six months in the PFMT group.

**v) PFMT versus surgery:** Only one trial compared PFMT and surgery. For women randomised to surgery, Klarskov (1986) chose a surgical technique based on the type of defect identified; Burch colposuspension for anterior suspension defects and vaginal repair for posterior bladder descent.

Women with both defects had a combined Burch and vaginal repair procedure. No details on the PFMT parameters were provided; women had five or more group sessions with a physiotherapist.
1. Quality of data

**i) PFMT versus VC:** Bø (1999), Cammu (1998), Wilson (1988) and Williams (2006) reported adequate allocation concealment. Bø (1999) stated that outcome assessors were blind, and in the trials by Wilson (1988) and Williams (2006) some but not all outcome assessment was blind. Bø (1999), Cammu (1998) and Williams (2006) randomised 29, 30 and approximately 80 women per comparison group, while Wilson randomised 39 to the PFMT group and 36 to the VC group. There were dropouts from both PFMT and VC groups in all trials except Cammu (1998), where all the dropouts were from the VC group. Drop out rates were higher in the VC group for Arvonen (2001), Cammu (1998), Haken (1991) and Laycock (2001) but higher in the PFMT group for Bø (1999), Peattie (1988), Wilson (1988) and Williams (2006). None of the trials reported follow up beyond the post treatment evaluation.

**ii) PFMT versus ESTim:** Of the eight trials, two reported adequate random allocation concealment and blinding of outcome assessors [145, 167]. Three trials randomised approximately 10 women per comparison group [143, 184, 187], and the remaining trials between 20 and 35 women per group. Four trials appeared to have no dropouts [141, 143, 184, 187], with 5% [186], 12% [145], 13% [167] and 19% [164] reported in the others. All women were assessed post treatment; Henalla (1989) and Hahn (1991) also followed-up longer term, at nine months, and one to four years respectively.

**iii) PFMT versus BT:** Sherburn (2007) reported adequate random allocation concealment. Yoon (2003) and Sherburn (2007) reported blinding of outcome assessors while Wyman (1998) stated that outcome assessors were not blinded. Sherburn (2007) randomised 43 women to PFMT and 41 to BT, and Wyman (1998) randomised nearly 70 women per group. The trial by Yoon (2003) was smaller with approximately 15 to 20 women per group. Dropouts were approximately 4% for Wyman (1998) and 12% for Yoon (2003) and not mentioned by Sherburn (2007). All women were assessed post treatment, and Wyman (1998) followed-up three months later (i.e. six months after treatment began).

**iv) PFMT versus drug therapy:** Random allocation was concealed in only one of the six trials [139]. Outcome assessors were blind in the Burgio (1998) and Ghoniem (2005). Three trials randomised 25 women or fewer per group [141, 142, 190]. Ghoniem (2005) randomised approximately 50 per group. The two largest trials randomised about 80 [191] or 85 women per group [150]. Dropouts were not reported [142], none [141], 14% [150], 16% [190], 25% [191] and 36% [139]. All women were assessed post treatment, and Henalla (1989) also followed-up nine months later by questionnaire.

**v) PFMT versus surgery:** It was not clear if random allocation was adequately concealed, or if the outcome assessors were blinded [192]. Klarskov (1986) randomised approximately 25 women to each comparison group. It appears there were no dropouts at four months (post treatment assessment). There was further long-term follow-up at one year, then four to eight years.

2. Results

**i) PFMT versus VC:** Results of the individual studies were inconsistent. For cure, the trials favoured PFMT (RR 0.39, 95% CI 0.16 to 0.94, Bø 1999), neither PFMT nor VC (RR 1.00, 95% CI 0.56 to 1.81, Wilson 1998; RR 1.73, 95% CI 0.53 to 5.67, Williams 2006), or VC (RR 9.47, 95% CI 0.55 to 164.35, Arvonen 2001). Pooled data from the four trials showed no statistically significant difference in cure (RR 0.98, 95% CI 0.63 to 1.52); the pooled data showed statistically significant heterogeneity. For cure/ improvement, pooled data showed no statistically significant difference (RR 0.99, 95% CI 0.84 to 1.16, in five trials). PFMT was better than cones in terms of daily leakage episodes (WMD -0.61, 95% CI -1.05 to -0.16, three trials). Williams (2006) reported on the cost of intervention; PFMT was more expensive than VC, £338 versus £305 per person because of the amount of time spent with the therapist. With regard to adverse events, Arvonen (2001) and Williams (2006) stated that no women using VC reported any, while Bø (1999) and Cammu (1998) found that VC were associated with adverse events such as inability to use cones, pain, vaginitis, bleeding, and women finding cones unpleasant to use.

**ii) PFMT versus ESTim:** Pooled data from three trials in SUI women found self-reported cure was more likely with PFMT (RR 2.67, 95% CI 1.53 to 14.26) [145, 184, 187], although only Bø (1999) found a statistically significant difference when data from the trials was considered individually. It was not clear if the cure data reported by Hofbauer (1990) were derived from a symptom scale or a voiding diary; these data were therefore excluded. Pooled data from three trials in SUI women also found self-reported cure/improvement was more likely in PFMT women (RR 1.72, 95% CI 1.05 to 2.81) [145, 184, 185]; again only Bø (1999) found a statistically significant difference when trial data were considered individually. Only Bø (1999) measured leakage episodes and quality of life (Social Activity Index). There was no statistically significant difference between the groups for either outcome. At nine months post treatment, Henalla (1989) found that three out of 17 PFMT women and one out of eight in the ESTim group reported recurrent symptoms. Three trials reported side effects related to ESTim, including vaginal irritation and/or bleeding [145, 184, 187]. Spruijt (2003) recruited women with SUI, UUI or MUI,
and did not find a statistically significant difference between the groups for self-reported cure/improvement (RR 0.99, 95% CI 0.45 to 2.16). The trialists reported that EStim produced “physical and emotional stress” in the elderly women in their sample. Wang (2004) recruited women with UI, and did not find any statistically significant difference between the groups for self-reported cure (RR 0.74, 95% CI 0.38 to 1.42) or cure/improvement (RR 0.84, 95% CI 0.48 to 1.46). PFMT women had statistically significantly fewer leakage episodes per day (MD –1.22, 95% CI –2.37 to –0.07). On the KHQ there were no statistically significant differences in general health perception, incontinence impact, role limitation, physical limitation, social limitation, and personal relationship, but the EStim group had statistically significantly better scores for emotions, sleep/energy and severity measures. Some women using EStim reported discomfort during treatment.

**iii) PFMT versus BT:** Unfortunately, Yoon (2003) did not report any data for the outcomes of interest. Wyman (1998) recruited women with SUI, UUI or MUI. While more women in the PFMT group reported symptomatic improvement or fewer leakage episodes the difference did not reach statistical significance post-treatment (RR for symptomatic improvement 1.73, 95% CI 0.83 to 3.60; MD for leakage episodes –0.14, 95% CI –0.83 to 0.55) or three months later (RR 1.96, 95% CI 0.97 to 3.94; MD –0.09, 95% CI –0.73 to 0.55). Nor were there statistically significant differences in Incontinence Impact Questionnaire (IIQ) or Urogenital Distress Inventory (UDI) between the groups at either time point. Sherburn’s (2007) trial recruited women with SUI only. However, Sherburn (2007) found in SUI women, a significant difference between the two groups in the ICI-Q SF (p=0.003), leakage episodes (p=0.03) and the VAS (p=0.009) in favour of the PFMT group, although the generic health related QOL did not differ between the two groups. No adverse event data were reported in either trial.

**iv) PFMT versus drug:** Neither of the two trials comparing vaginal oestrogens versus PFMT in urodynamic SUI women reported data for the outcomes of interest [141, 142]. Of those that responded to a follow-up questionnaire at nine months, three out of 17 PFMT women and three women using oestrogens reported recurrent symptoms. Adverse events were not reported in either trial.

Two trials compared an adrenergic agonist and PFMT in women with SUI or MUI. Ishiko (2000) did not find any statistically significant difference in the proportion of women reporting no leakage episodes (cure) after treatment (RR 0.68, 95% CI 0.41 to 1.15), and Wells (1991) did not find any statistically significant difference for self-reported cure/improvement (RR 0.92, 0.77 to 1.10). Wells (1991) reported data for leakage episodes per day in SUI women only; PFMT women had statistically significantly more leaks per day than women in the drug group (MD 0.08, 95% CI 0.02 to 0.14). Ishiko (2000) reported that the drug side effects were sufficient for some women to withdraw; others discontinued the drug, but remained in the trial. Wells (1991) did not report data on drug side effects.

In the comparison of PFMT and oxybutynin in women with DO (DO), or DO with urodynamic SUI, Burgio (1998) reported no statistically significant difference for the number of women who were dry (cured) (RR 1.31, 95% CI 0.73 to 2.34), but PFMT women were more likely to report they were much better than women receiving the drug treatment (RR 1.46, 95% CI 1.08 to 1.97). PFMT women also had fewer leakage episodes per day (MD –0.41, 95% CI –0.80 to -0.02). Some women taking oxybutynin reported side effects (dry mouth and inability to void in particular).

Ghoniem (2005) reported that duloxetine had a significantly greater impact in decreasing Incontinence episodes than PFMT (57% versus 35% median decrease in UI episode frequency between drug and PFMT respectively, p=0.004), but there were no significant differences between the treatments with respect to Incontinence Quality of Life (i-QoL).

**v) PFMT versus surgery:** At four months PFMT women with urodynamic SUI were less likely to report cure than women who had surgery (RR 0.20, 95% CI 0.07 to 0.61), although there was no statistically significant difference in the proportions reporting cure/improvement (RR 0.80, 95% CI 0.60 to 1.07). At 12 months, 10 out of the 24 women from the PFMT group were satisfied with the initial therapy, versus 19 out of the 26 women randomised to surgery. Long-term data (four to eight years) were not presented by group allocation. All reported adverse events were associated with surgery; women reported new UUI, retropubic or pelvic pain, or dyspareunia [192].

**Summary**

Eight trials compared PFMT with VC in SUI women. No consistent pattern emerged in the data; data on self-reported cure were inconsistent (four trials), there was no difference in pooled data from four trials for self-reported cure/improvement, but there were fewer leakage episodes per day with PFMT in pooled data from three trials (Level of Evidence: 1). Treatment with VC may be inappropriate in some cases due to side effects such as bleeding, and some women appear to find them unpleasant to use.

Eight trials compared PFMT with EStim in SUI women. Pooled data demonstrated that self-reported cure and cure/improvement were more likely in PFMT than in EStim groups (Level of Evidence: 1). It is worth noting that only one trial individually demonstrated a statistically significant difference in these outcomes and there was more health professional contact in the PFMT arm. There were no statistically significant differences between PFMT and EStim groups for
leakage episodes or quality of life, based on a single trial (Level of Evidence: 2). In the one trial that recruited women with SUI, UUI or MUI self-reported cure/improvement rates were not statistically significantly different (Level of Evidence: 2). Self-reported cure and cure/improvement rates were not statistically significantly different in a trial in women with UUI, although PFMT women had fewer leakage episodes per day, and women in the EStim group had better quality of life in three of the nine domains measured (Level of Evidence: 2). Some women reported adverse events attributable to ES.

Three trials compared PFMT and BT, but only two reported data of interest. In women with SUI symptomatic improvement, leakage episodes and quality of life were statistically significantly better in the PFMT group (Level of Evidence: 2). In contrast the study that recruited women with SUI, UUI and MUI did not find statistically significant differences between the groups for these outcomes (Level of Evidence: 2).

In the absence of useful data there is insufficient evidence to determine if PFMT is better than vaginal oestrogens. Neither trial that compared an adrenergic agonist with PFMT in women with SUI or MUI found a difference in self-reported cure/improvement, although in one study women who took the drug had fewer leakage episodes per day (Level of Evidence: 2). Adrenergic agonist side effects were sufficient to discontinue treatment in some women. One trial of PFMT versus oxybutynin in women with DO or DO with urodynamic SUI found PFMT women were more likely to report improvement and had fewer leakage episodes per day after treatment (Level of Evidence: 2). Some women taking oxybutynin reported drug-related side effects. One trial compared a serotonin-norepinephrine reuptake inhibitor (duloxetine) with PFMT and while women who took the drug had fewer leakage episodes, there was no difference in terms of quality of life between the two groups (Level of Evidence: 2). Serotonin-norepinephrine reuptake inhibitor drug side effects were sufficient to discontinue treatment in some women.

Based on one trial it seemed self-reported cure was more likely after surgery than PFMT for women with urodynamic SUI; although there was no statistically significant difference in the proportion of women reporting cure/improvement (Level of Evidence: 2). There was insufficient detail about the PFMT programme to make a judgment about how effective it might have been.

**Recommendations**

For women with SUI:

- PFMT is better than EStim as first line conservative therapy, particularly if PFMT is intensively supervised (Grade of Recommendation: B).
- PFMT is better than BT as first line conservative therapy (Grade of Recommendation: B).
- PFMT and duloxetine are both effective in first line therapy, although PFMT is better because of the side effects experienced with the drug (Grade of Recommendation: C).
- PFMT and surgery are both effective therapies, although PFMT is better as first line therapy because it is less invasive (Grade of Recommendation: C).

For women with SUI or MUI:

- PFMT is better than VC as first line conservative therapy (Grade of Recommendation: B).
- PFMT is better than clenbuterol or phenylpropanolamine hydrochloride as first line therapy because of the side effects experienced with the medications (Grade of Recommendation: B).

For women with UUI or MUI:

- PFMT and BT are both effective first line conservative therapy (Grade of Recommendation: B).
- PFMT is better than oxybutynin as first line therapy (Grade of Recommendation: B).

Larger, good quality trials are needed to address each of the above comparisons if these are of interest to women. In planning comparisons researchers should consider carefully the potential impact of different levels of supervisory intensity between groups, particularly in comparisons of conservative therapies. A comparison of surgery and PFMT might be least useful, because PFMT is usually first-line therapy with surgery reserved for those in whom PFMT was unsuccessful or is not the treatment of choice.

**d) Does the addition of PFMT to other treatments add benefit?**

To be included, trials needed to investigate the effects of PFMT combined with therapy A versus therapy A alone, to address the additive benefit of PFMT over therapy A. Nine RCTs were found, and of these three were excluded. Jeyaseelan et al (2002), a conference abstract, did not report any useable data [178]. Millard (2004) included men and women and the data were not reported separately by sex [193]. Dowell (1997) used a combination BT/PFMT programme [194].

**j) PFMT/VC versus VC:** Two trials, in women with urodynamic SUI [195] or SUI [129], compared combined PFMT/VC versus VC. In both arms of each study the recommended VC regime was twice daily for 15 minutes, with cone weight progressing from 20g to 70g [195] or 100g [129]. Both PFMT programmes asked women to do 100 PFM contractions per day; Wise (1993) recommended 10 contractions 10 times a day, and Wilson (1998) recommended a combination of fast and slow contractions. Treatment duration was 12 weeks in both arms of both studies.
(ii) PFMT/EStim versus EStim: In women with urodynamic SUI, Hofbauer (1990) compared EStim (10 minutes, three times weekly, sufficient intensity to provoke a visible contraction to which the patient added their own PFM contraction, extravaginal and lumbar electrodes) to PFMT/ES (daily PFMT home programme (not specified) and a twice weekly exercise class plus the same ES programme). Treatment duration was six weeks in both arms.

(iii) PFMT/BT versus BT: In women with urodynamic SUI, or urodynamic SUI with DO, Wyman (1998) compared BT (progressive voiding schedule, advice on urge inhibition techniques such as affirmations, distraction and relaxation) to PFMT/BT (twice daily PFMT, maximum of 10 fast contraction with three second holds and 40 sustained contractions with 10 second holds in addition to bladder training as above). The combined PFMT/BT group began with BT and added PFMT in the 3rd week of the intervention. Women in both groups received the same preliminary education programme and treatment duration was 12 weeks in both arms.

(iv) PFMT/drug versus drug: Two trials compared PFMT/drug to drug alone in women with SUI [139, 190]. Ishiko (2000) compared drug (oral beta(2)-adrenergic agonist (clenbuterol) 20mg bid) to PFMT/drug (clenbuterol as above plus daily 10 minutes of PFMT contraction programme, no further detail of training was given), Ghoniem (2005) compared drug (duloxetine, 4mg twice daily plus sham PFMT) to PFMT/drug (duloxetine as above plus PFMT four times a week comprising three sets of 10 long contractions held six to eight seconds and two sets of 10 rapid contractions held one to two seconds). Treatment duration was 12 weeks in both arms in both studies [139, 190].

1. Quality of Data

i) PFM/VC versus VC: Wilson (1998) reported adequate allocation concealment and some outcome assessment was blind. Neither of these was clearly reported in the study by Wise (1993). There were approximately 39 women in each comparison group in Wilson (1998) and approximately 20 women in each comparison group in Wise (1993). In Wilson (1998) 63% of the women in the PFM/VC group dropped out compared to 41% in the VC group while in Wise (1993) 30% of the PFM/VC group dropped out compared to 9% in the VC group only.

ii) PFMT/EStim versus EStim: It was not clear if random allocation concealment was adequate or whether assessors were blind [143]. There were only 11 women in each comparison group. There did not appear to be any dropouts.

iii) PFMT/BT versus BT: It was not clear if random allocation concealment was adequate and outcome assessors were not blind [188]. There were 68 women in the BT group and 67 in combination therapy. There were fewer than 10% dropouts after 12 weeks of treatment. Further follow-up was reported at six months and approximately three years after study entry.

iv) PFMT/drug versus drug: Although adequate allocation concealment and blinded assessors where used in Ghoniem (2005) it was not clear in Ishiko’s (2000) trial. In Ishiko’s (2000) trial, there were 18 women in the drug group, and 23 in the combination therapy group. Five (27%) and four (17%) women dropped out of these groups respectively, principally because of drug-related side effects. Ghoniem (2005) randomised approximately 50 SUI women to each group; some 30% of whom dropped out of both treatment groups.

2. Results

i) PFM/VC versus VC: In this comparison, neither of the two trials identified any statistically significant differences between the groups (for patient reported cure, improvement as measured by a Visual Analogue Scale or pad test) and all of the confidence intervals were wide [129, 195].

ii) PFMT/EStim versus EStim: Although Hofbauer (1990) reported cure/improvement, it was not clear whether this was based on data from a symptom scale or a urinary diary. There were no data reported for the other outcomes of interest.

iii) PFMT/BT versus BT: Wyman (1998) did not find a statistically significant difference between the combination versus single therapy in the number of women reporting they were much better, however more in the combination group reported they were much better, six months after treatment began (RR 0.61, 95% CI 0.39 to 0.94). There was no statistically significant difference in the number of leakage episodes per day between the groups after treatment or at six months. With regard to quality of life the combination therapy group had statistically significantly better scores on UDI (MD 31.10, 95% CI 13.26 to 48.94) and IIQ (MD 25.50, 95% CI 1.05 to 49.95) after treatment, but there was no statistically significant difference in either measure six months after treatment had begun. Approximately three years later, a similar number in each group had sought further treatment for UI (19 of 48 BT, 18 of 48 PFMT/BT). Of the women who had not sought further treatment, fewer were free of leakage episodes in the BT group (four of 22 in BT group versus eight of 16 in the combination group). Adverse events are not mentioned.

iv) PFMT/drug versus drug: Ishiko (2000) did not report data for any of the primary outcomes of interest. They did state that 10 of the 13 women in the drug group, and 17 of the 19 in the combination therapy group had no leakage episodes per week post treatment, and some women reported drug-related side effects sufficient enough to withdraw from
treatment. Ghoniem (2005) reported that the combined treatment was not significantly different from the drug-only-treatment in terms of frequency of incontinence episodes, quality of life (IQOL) and Patient Global Impression of Improvement Scale.

SUMMARY

There were few trials addressing the effect of adding PFMT to another therapy, and only three of the eight studies reported useful data. The findings of Wilson (1988) and Ghoniem (2005) did not suggest any benefit of adding PFMT to VC or duloxetine respectively in women with SUI (Level of Evidence: 2). The study of Wyman (1998) suggested there is a benefit to adding PFMT to BT for women with USI or USI with DO in the short term (three months), but it is not clear if this benefit persists at six months or more (Level of Evidence: 2). There is not sufficient evidence to be sure if there is any benefit in adding PFMT to EStim.

RECOMMENDATIONS

For women with SUI or MUI a combination of PFMT/BT may be better than PFMT alone in the short-term (Grade of Recommendation: C). If a woman is taking duloxetine or using VC, it may not help to add PFMT (Grade of Recommendation: C). However, these recommendations are based on single trials of variable quality and larger, good quality trials are needed to address each of the above comparisons if these are of interest to women.

4. OTHER LUTS

Only two of the many trials included above reported data for other LUTS, e.g. frequency, nocturia, bladder pain.

Lin (2004) looked at the effect of a PFMT programme on frequency, nocturia and urgency in women with MUI [172]. Based on self report of symptom bother both frequency and nocturia improved significantly more in the PFMT group (OR for frequency 0.57, 95% CI 0.35 to 0.95; OR for nocturia 0.52, 95% CI 0.30 to 0.93), while urgency persisted (OR: 0.73, 95% CI 0.456 to 1.17).

A secondary analysis of Burgio (1998) looked at the effect of PFMT versus drug therapy on nocturia in older women with UUI or MUI [150]. The PFMT group reduced nocturia by a median of 0.5 episodes per night; this was significantly more effective than drug treatment (median reduction 0.03 episodes per night; p = 0.02).

5. FACTORS AFFECTING OUTCOME

Apart from differences in effect attributed to PFMT or comparison interventions, there might be other factors affecting treatment outcome. Of particular interest is the effect of older age; this and other factors are considered here.

a) Age

Firstly we looked for trials included above that specifically recruited older woman; there were six. Women were aged 55 or more [135, 149, 150, 191], or 65 or more [186, 189]. The average age of women in these trials was between 60 and 70 years [135, 149, 150, 191], or over 70 years [186, 189], compared with a mean age of 40 to 55 in most other included studies. It was not possible to compare the data from older women with data from younger women for the following comparisons: PFMT versus EStim [186], PFMT versus drug [150, 191], and PFMT versus BT [189].

For three comparisons (PFMT versus no treatment, [149] PFMT versus placebo/sham/control, [135, 150] BF assisted PFMT versus PFMT alone, [149] there were no clear differences in the size or direction of effect when the data from the trials in older women were compared with data from other trials. The recommendations arising from these comparisons appear to apply to older women. Namely, that PFMT should be offered, as first-line therapy, to all women with SUI, UUI or MUI, and that there does not appear to be added benefit of BF assisted PFMT over PFMT alone.

Secondly, the methods of included trials were checked for use of regression or other methods to investigate association between baseline characteristics (specifically age) and outcome. The literature search also located some papers that reported secondary analysis of data from the included trials. Papers that reported an association between age and outcome, but did not describe the methods of testing association are not discussed here.

Two reports detailed the testing of independent associations between patient characteristics (including age) and outcome [159, 196]. Burgio (2003)[196] used data from PFMT groups in three RCTs [135, 136, 150]. The individual trials restricted entry to women 55 years and older [135, 150] or 40 years and over [136]. In multivariate analysis, age was not a significant predictor of reduction in leakage episodes for PFMT women with SUI, UUI or MUI. Hay-Smith (2003) investigated the associations between leakage on paper towel test and patient characteristics using data from a trial that compared two approaches to PFMT for SUI women. Older age was associated with more leakage in univariate models, but was not significant in multivariate analysis.

One further trial [188] used correlation methods, and one study [197] categorised women as successes or failures, to investigate the association between age and outcome. In a secondary analysis of data from the trial by Wyman (1998) there was no statistically
significant correlation between age and reduction in leakage episodes or change in PFM activity after PFMT or BT in women with SUI, UUI or MUI [198]. Be characterised participants in the intensive PFMT group from the Bø (1990) trial as treatment responders or non-responders [197]. Treatment responders were statistically significantly older than borderline responders; there were no non-responders.

Considering the number of included trials, there were few that restricted entry to older women and/or investigated the association between age and treatment outcome. Only two studies have used the most appropriate methods to test independent associations. More research is needed to investigate the association between age and treatment outcome. Neither study using multivariate models found an association between age and outcome, nor was there a reported correlation in another. The two studies that categorised women as treatment successes or failures had conflicting results.

**Summary**

There is no good evidence to date to suggest that ‘healthy’ older women with UI do not benefit from PFMT as much as younger women.

**b) Other**

Aside from age, other factors have the potential to mediate treatment outcome, e.g. baseline UI severity and duration of symptoms. Trial reports, and subsequent publications of the included trials, were checked for methods investigating the association between baseline characteristics and treatment outcome. Some of the included studies reported predictors of outcome that appeared to be based on researcher observation, but did not describe the methods for checking the association; these data are not discussed here. Seven reports of interest were found [149, 159, 191, 196-199]. A wide range of patient characteristics were considered in these papers; it is not clear whether it is more important to know which baseline characteristics might be predictors of outcome, or which ones might not. To eliminate long lists of non-significant associations, a pragmatic choice was made to report only significant associations although this creates a false impression of some consistent associations. None of the variables discussed here has demonstrated a consistent association with outcome, and all are worthy of further investigation.

Two reports described the testing of independent associations between patient characteristics and outcome [159, 196]. Burgio (2003) used data from PFMT groups in three RCTs [135, 136, 150]. In multivariate analysis of data from PFMT women with UUI or urge predominant MUI, a 75% reduction in leakage episodes was more likely if women did not use protection (e.g. pads) prior to treatment. Continence (100% reduction in leakage episodes) was more likely if women had fewer Incontinence episodes at baseline and had a lower educational level, but less likely if they had prior UI surgery. For PFMT women with SUI or stress predominant MUI a 75% reduction in leakage episodes was less likely if women had previously been evaluated for UI or had more than 10 leakage episodes per week pre-treatment. Hay-Smith (2003) investigated the associations between patient characteristics and two outcomes (leakage on paper towel test, self-reported improvement) using data from a trial that compared two approaches to PFMT for SUI women. In multivariate models increasing parity was associated with less improvement in leakage symptoms and more risk of leakage on a paper towel test. Shorter symptom duration and higher body mass index were both associated with more improvement in symptoms. Leakage once or more per day was associated with greater risk of leakage on a paper towel test; the reverse was true for women with a history of constipation.

Theofrastous (2002) used correlation methods to investigate the association between patient characteristics and outcome in a secondary analysis of data from the trial by Wyman (1998). There was no statistically significant correlation between any of the baseline characteristics listed and the two outcomes (reduction in leakage episodes or change in PFM activity). One study categorised women as successes or failures, to investigate the association between patient characteristics and outcome. Bø (1992) characterised participants in the intensive PFMT group from the Bø (1990) trial as treatment responders or non-responders. Treatment responders had statistically significantly longer symptom duration, higher body mass index, stronger PFM, and were more motivated (clinician judgement) than borderline responders; there were no non-responders.

Few included studies investigated the association between patient characteristics and treatment outcome. Even fewer used appropriate methods. More research is needed to test for independent associations between patient characteristics and outcome. No consistent pattern emerged from the available data. Given the few data available, and the methodological limitations of some papers, any patient characteristic described above that was associated with outcome should be considered as a possible rather than established prognostic factor.

**Summary**

It is not clear if there are any reliable predictors of PFMT outcome. Too few trials have appropriately investigated the association between patient characteristics and outcome to be sure.
Weighted vaginal cones (VC) were developed by Plevnik as a method for testing PFM function and to provide overload for PFM strengthening exercises [183, 200]. The cones are inserted into the vagina, above the PFM. Theoretically, when a cone is inserted into the vagina, the sensation of ‘losing the cone’ provides strong sensory feedback prompting the PFM to contract in order not to let the cone slip. Starting with a weight held inside the vagina for at least one minute in the standing position, women train by building up to the ability to keep the cone in place for at least 20 minutes. When the woman is able to walk around for 20 minutes without losing the weight, she then moves on to progressively heavier weights, advancing towards overload of the muscles over the course of the exercise programme [183, 200].

Since their introduction, a variety of cones have been developed encompassing different sizes, shapes and weights (Figure 3). However, the effectiveness of the VC training method has been questioned over the years. First, the PFM contraction is not the only reason why the cone stays in place. As the orientation of the vagina is not vertical, it is possible for some women to retain the cone without contracting the pelvic floor; the transverse lie of the cones has been shown by radiology [201]. Moreover, depending on the axis of her vagina, a woman will need to produce different force intensities to retain the cone. Therefore, using the cone as a measurement of PFM function does not appear to be valid. Additionally, retaining the cone in the vagina for 15 minutes requires sustained low load contractions, which is not congruent with the principles of strength straining used in most pelvic floor rehabilitation [84]. Conversely, VC training may actually favour endurance, which could be important in retraining the pelvic floor. Finally, for some women, it may be impossible to insert the cone because of narrowed vaginal opening or to retain it because of either an enlarged vaginal opening or insufficient PFM contraction to hold even the lightest cone.

This section will examine the evidence for the use of VC for the prevention and treatment of UI in women. Questions addressed are:

- Are VC better than no treatment, placebo or control for the prevention of UI?
- Are VC better than no treatment, placebo or control for the treatment of UI?
- Are VC as effective as any other treatment for the treatment of UI?
- Are VC combined with PFMT better than PFMT alone for the treatment of UI?

To address these questions, the literature was searched for reports of relevant systematic reviews, RCTs and quasi-RCTs. Therefore, only Level 1 evidence is considered in this section. Recommendations are based on the findings of two systematic RCTs reviews undertaken by Hay-Smith (2002) on UI prevention and by Herbison (2004) who reviewed management of UI with cones [112, 202].

### 1. PREVENTION

No trials investigating the primary/secondary prevention effects of training with VC for women with UI were found. The literature search revealed two reviews on the prevention of UI [113, 203]. Only Hay-Smith (2002) considered VC prevention trials, but none of the trials measured the effect on UI; all the measures were of PFM activity. Because no continence related outcomes were measured, these trials were not reviewed here. The current Cochrane review of VC does not consider prevention [202], and our own searching has not revealed any new RCTs on VC for prevention.

### 2. TREATMENT

The literature search revealed one systematic review that specifically addressed the effects of VC in the treatment of UI in women [202]. The review, together with one RCT published after the review, is the basis of this subsection [155].

#### a) Are VC better than no treatment, placebo or control treatments?

Three RCTs compared VC with control treatments for women with UI [129, 145, 155]. Wilson (1998) compared VC with standard postnatal care in women with symptoms of UI three months postpartum (controls were requested to continue with their normal postnatal PFMT programme).

Bø (1999) compared VC with a control treatment (use of Continence Guard, Coloplast AG) in women with urodynamically proven SUI.
b) Are VC as effective as any other treatment?

VC have been compared with PFMT, and with EStim, but not with other therapies such as drugs, BT or with surgery.

i) VC versus PFMT: Eight trials compared VC with PFMT [129, 145, 155, 164, 177, 181-183]. This comparison has been addressed previously and for details of the trials (quality and results) readers are referred to section B.2.3d.

ii) VC versus EStim: Four trials compared VC with EStim [145, 195, 204, 205]. Important differences were noted in all the VC and EStim interventions. Delneri (2000) compared VC (25 to 35 minutes daily progressing through cone weights of 20 to 70g) to EStim (30 minutes daily with a low-frequency bipolar current of 50 Hz, 0.2ms pulse width at an intensity of between 0-120 mA). Treatment duration was six months in both arms. Bø (1999) compared VC (20 minutes daily progressing through three cone weights of 20, 40 and 70g) to EStim (30 minutes daily with a low-frequency bipolar current of 50 Hz, 0.2ms pulse width at an intensity of between 0-120 mA). Treatment duration was four weeks in both arms. Bø (1999) compared VC (20 minutes daily progressing through cone weights of 20 to 70g) to EStim (30 minutes daily with a low-frequency bipolar current of 50 Hz, 0.2ms pulse width at an intensity of between 0-120 mA). Treatment duration was four weeks in both arms. Wise (1993) compared VC (15 minutes twice daily progressing through cone weights of 20 to 100 grams) to EStim (15 minutes, three times per week with interferential current of 0-100 Hz, at maximum tolerated intensity); treatment duration was four weeks in both arms. Wise (1993) compared VC (15 minutes twice daily progressing through cone weights of 20 to 70g) to EStim (20 minutes daily of continuous stimulation of 20 MHz frequency and 0.75ms pulse width at the maximum tolerated intensity of 0-90 mA). Treatment duration was 12 weeks in both treatment arms.

1. Quality of data

All trials reported adequate randomisation concealment and blinded outcome assessors. Two randomised about 30 women to VC; however, while Be (1999) randomised a similar number to the control group, Wilson (1998) had around 100 women in the control group (factorial design). Williams randomised about 80 women in each group.

Dropout rates were 3% [155], 12% [145] and 40% [129]. There were more dropouts from VC (42%) than the control group (22%) in the latter.

2. Results

Pooled data from all three trials for self-reported cure showed suggested women in the VC group were more likely to report they were cured than controls (RR 1.98, 95% CI 1.21 to 3.23).

Pooled data from two trials for self-reported improvement or cure showed statistically significant heterogeneity. Individually, one trial favoured VC (RR 18.89, 95% CI 2.68 to 132.58 [145]) and the other neither control nor VC (RR 0.95, 95% CI 0.76 to 1.19 [155]). Be (1999) also reported that VC were better than the control for the Leakage Index but there were no statistically differences in the 24 hour pad test or the Social Activity Index.

Summary

There is evidence from three good RCTs suggesting that VC is better than control treatments (for subjective reporting of cure or cure/improvement) in the treatment of SUI (Level of Evidence: 1). Treatment with VC may be inappropriate in some cases due to side effects such as bleeding, and some women appear to find them unpleasant to use.

Recommendations

For women with SUI, VC can be offered as first line conservative therapy to those who can and are prepared to use them (Grade of Recommendation: B); VC may be inappropriate in some cases due to side effects and discomfort.
**SUMMARY**

In summary, eight trials compared PFMT with VC in SUI women. No consistent pattern emerged in the data; data on self-reported cure were inconsistent (four trials), there was no difference in pooled data from four trials for self-reported cure/improvement, but there were fewer leakage episodes per day with PFMT in pooled data from three trials (Level of Evidence: 1).

Pooled data demonstrated no statistically significant differences between VC and EStim groups for self-reported cure, cure/improvement or leakage episodes (Level of Evidence: 1). Both VC and EStim groups reported adverse events. Two trials had to exclude some women prior to randomisation because they could not use VC (e.g. wedging of the cone).

**RECOMMENDATIONS**

PFMT is better than VC as a first choice for conservative therapy, because some women cannot or do not like to use cones (Grade of Recommendation: B). VC and EStim seem equally effective in the treatment of SUI and MUI, but the usefulness of VC and EStim in practice might be limited because of side effects and discomfort (Grade of Recommendation: B).

c) Are VC combined with PFMT better than PFMT alone?

Two trials compared a combined PFMT/VC to PFMT alone [129, 206]. Pieber (1995) compared PFMT (100 PFM contractions daily supplemented by an initial visit with a physiotherapist and additional visits at intervals of two to four weeks) versus PFMT/VC (the same PFMT programme combined with 15 minutes of VC daily progressing through cone weights of 20 to 70g). Treatment duration was 12 weeks in both treatment arms. Wilson (1998) compared PFMT (100 fast and slow PFM contractions daily supplemented with one training session and three follow up visits) versus PFMT/VC (the same PFMT programme combined with 15 minutes of VC twice daily progressing through three cone weights of 20 to 100g). Treatment duration was 12 months in both treatment arms. None of the outcomes used in the two trials overlapped.

**1. QUALITY OF DATA**

Wilson (1998) reported allocation concealment and some outcomes had blinded assessors, but neither was clearly reported by Pieber (1995).

**2. RESULTS**

No statistically significant difference detected for cure (RR 1.21, 95% CI 0.63 to 2.32) [129], cure/improvement after six weeks (RR 1.41, 95% CI 0.81 to 2.45) [206], cure/improvement after 12 weeks (RR 0.92, 95% CI 0.51 to 1.64) [206], but confidence intervals were wide. Dropout rates were higher in the combined PFMT/VC group in both trials.

**SUMMARY**

The limited evidence available suggested no benefit from adding VC to PFMT for SUI women (Level of Evidence: 2).

**RECOMMENDATIONS**

If the combination of VC with PFMT is an intervention of interest for women, then more research is needed to confirm or refute the effect of this combination.

**3. OTHER LUTS**

None of the trials included in this section on VC reported other LUTS data.

**4. FACTORS AFFECTING OUTCOME**

None of the included trials addressed the effect of age or any other factors on outcome of VC training. However, it is worth noting that in the 16 trials included in this section on average 23% of the women being treated with VC (range 0 to 63%) withdrew or dropped out. Although few trials examined the reasons for dropping out, those who did reported low compliance, motivation problems, unpleasantness, aesthetic dislike, discomfort, bleeding and vaginal prolapse. However none of these were predominant.

**IV. ELECTRICAL STIMULATION (EStim)**

The literature concerning EStim in the management of UI is very difficult to interpret, due to the lack of a well-substantiated biological rationale underpinning the use of EStim. However, the theoretical basis of stimulation interventions is emerging with increasing understanding of the neuroanatomy and physiology of the central and peripheral nervous systems. It is also becoming clear that the mechanisms of action may vary depending on the cause(s) of UI and the structure(s) being targeted by EStim, e.g. PFM or detrusor muscle, peripheral or central nervous system. In general, the aim of EStim for women with SUI appears to be to improve the function of the PFM, while for women with UUI the objective seems to be to inhibit DO (DO). Overall, studies poorly report the biological rationale underpinning the application of EStim being tested [207, 208].

EStim is provided by clinic based mains powered machines or portable battery powered stimulators.
EStim also offers a seemingly infinite combination of current types, waveforms, frequencies, intensities, electrode types and placements (Figure 5). Without a clear biological rationale it is difficult to make reasoned choices of EStim parameters. Additional confusion is created by the relatively rapid developments in the area of EStim and a wide variety of stimulation devices and protocols have been used even for the same condition. For example, in the last 25 years or so women with SUI have been treated using anything from a single clinic based episode of maximal EStim under general anaesthetic for 20 minutes with vaginal and buttock electrodes [209], to 10 sessions of interfential current at 10 to 40 Hz with perineal body and symphysis pubis electrodes [180], to eight weeks of home-based stimulation using a “new pattern of background low frequency and intermediate frequency with an initial doublet”, for an hour a day [210, 211], to six months of low intensity stimulation at 10 Hz using a vaginal electrode [212].

Finally the nomenclature used to describe EStim has been inconsistent. Stimulation has sometimes been described on the basis of the type of current being used (e.g. faradic, interferential), but is also described on the basis of the structures being targeted (e.g. neuromuscular), the current intensity (e.g. low-intensity, or maximal stimulation), and the proposed mechanism of action (e.g. neuromodulation). In the absence of agreement of how best to classify EStim the authors of this chapter have made no attempt to do so. The authors were also reluctant to use any existing system to group the EStim protocols as many were poorly described and could therefore be erroneously classified.

In this review only non-surgical or non-invasive EStim (i.e. stimulation without implanted electrodes) is considered. The questions to be addressed are:

- What evidence is there that EStim can prevent UI?
- What is the most appropriate EStim protocol for treatment of UI?
- Is EStim better than no treatment, placebo or control treatments for UI?
- Is EStim better than other treatments?
- Does the addition of EStim to other treatments add any benefit?
- What is the effect of EStim on other LUTS?
- What factors might affect the outcome of EStim?

This section is underpinned by a Cochrane review of non-invasive EStim (submitted, Berghmans et al, personal communication) and four published systematic reviews [93, 112, 213, 214]. The review reported here is based on the trials included in prior systematic reviews with addition of trials completed after publication of the reviews and/or located through additional searching (see appendix). To be included in this section a study needed to (a) be a RCT, (b) include women with UI, and (c) address one of the questions listed above. Published abstracts were included but reports of trials in progress were excluded.

1. PREVENTION

It seems EStim has not been investigated for either the primary or secondary prevention of UI or LUTS; no published trials were found.

2. TREATMENT

a) What is the most appropriate EStim protocol for treatment of UI?

On the basis of trial reports to date it appeared that there was considerable variation in EStim protocols with no consistent pattern emerging. EStim protocols are often poorly reported, lacking detail of stimulation parameters, devices and methods of delivery. Therefore, one plausible explanation for differences in the findings of trials included in this section may be differences in the effectiveness of the wide range of protocols that have been tested. Equally it may be that some populations or subgroups of women benefit from EStim more than others. For example, anecdotal
evidence suggests that EStim is used with particular effect for women who are unable to perform a voluntary PFM contraction on initial assessment. However, this observation has not been investigated to date. Interestingly, there are also clinical questions about EStim that have not yet been investigated in trials, such as whether ‘active’ EStim (i.e. the patient voluntarily contracts the PFM during stimulation) is better than ‘passive’ EStim.

As the biological rational and purpose of EStim might be different depending on diagnosis, the EStim protocols from the trials included in this section are presented below for women with SUI (Table 1), women with urgency, UUI or DO (Table 2), and trials that recruited women with SUI or UUI or MUI (Table 3). There was a single trial in women with MUI only [215].

Amaro (2006) used a vaginal electrode to deliver an alternating current at 4Hz, with a bipolar square wave, 0.1msec pulse duration, a 1:2 duty cycle (2 seconds on and 4 off), at maximum tolerable intensity, for 30 minutes, three times a week for seven weeks.

It is clear there is no consistency in the EStim protocols used for women with SUI, or UUI, or MUI, or DO. It was not possible to identify an optimal set of EStim parameters. Some approaches to treatment are now rare, such as the use of faradic current or external electrodes. There seems to be a trend to use maximal tolerable current intensity, and in women with SUI some trials used a combination of EStim with a voluntary PFM contraction.

Rather than repeating the detail of stimulation parameters throughout this section, readers are referred back to these tables.

- **Comparison of EStim protocols**

Three studies compared one approach to EStim versus another, one in women with SUI [212], two in women with DO and sensory urge [218, 222].

### 1. Quality of data

Random allocation concealment was adequate in one [212] of the three trials. Blinding of assessors and patients was reported in one trial [222], but not in the

other two. Fewer than 25 women were allocated to each comparison group in all three trials; in Bower (1997) sample size was based on a power calculation. Bower (1997) had no dropouts or losses to follow up, with 12% [218] and 19% [212] lost to post-treatment follow-up in the other two studies. Two trials had longer term follow up, one [218] to six months [212] after treatment ended; in the latter 28% had dropped out by six months.

2. RESULTS
   
i) Women with SUI: In a small trial comparing maximal clinic based (n=20) versus low intensity home based (n=19) EStim in women with SUI, Knight (1998) found a significant difference in patient perceived recovery (OR 4.44, 95% CI 1.08 to 18.36) and pad test (WMD -12.40, 95% CI -16.64 to -8.16). After treatment more women in the low intensity home based EStim group reported cure or great improvement (80% home versus 47.3% clinic for cure, p=0.034; 85% versus 44.8% for improvement, p=0.009), although intention to treat analysis reduced the apparent success of treatment (66.7% versus 36%).

   Long term follow up (12 months) suggested that women in both groups continued to improve subjectively, and this was most noticeable in the group of women who had received low intensity stimulation.

   ii) Women with DO or urgency: Bower (1997) compared 10 Hz (sacral electrodes) versus 150 Hz (symphysis pubis electrodes) in women with DO (n=49) or sensory urgency (n=31). The same proportion (44%) of women in each stimulation group demonstrated a ‘stable’ bladder post stimulation and only the 150 Hz group showed a statistically significant improvement in the threshold volume (p=0.037).

   Lobel (1998) did not find any statistically significant differences in leakage episodes and quality of life between the groups. Although more than half the women in the study were improved symptomatically, only 25% were sufficiently satisfied with outcome that they did not wish for further treatment.

   SUMMARY

There were three small trials comparing different EStim protocols; the clinical heterogeneity meant it was not appropriate to pool the data from the studies. Based on a single trial low intensity home based stimulation may be more effective than maximal clinical based stimulation (Level of Evidence: 2). The other two studies did not find clinically important differences between stimulation groups; the studies were small and may have been underpowered. Further comparisons of EStim protocols are needed.

RECOMMENDATIONS

For women with SUI low intensity home based EStim daily for six months might be better than 16 sessions of maximal clinic based EStim (Grade of Recommendation: C). There is a need for studies to elucidate the purpose and biological rationale for EStim in different diagnostic groups, so these can then be tested and compared in clinical trials.

b) Is EStim better than no treatment, sham or control treatments for treatment of UI?

• EStim versus no treatment, or control treatment

Three trials were included [141, 145, 228]. Data were also gathered from two conference abstracts [214, 230] of the full publication by Berghmans (2002).

1. QUALITY OF DATA

Random allocation concealment was adequate, and outcome assessment was blind, in two of the trials [145, 228]. Henalla (1989) stated that outcome assessors were not blind. In two studies the size of the study population was based on a power calculation [145, 228]. Group sizes were less than 25 women per group in Berghmans (2002), and from 25 to 49 in the other two studies [141, 145]. The proportion of dropouts was less than 10% in one trial [141], and about 12% in the other two [145, 228]. Henalla (1989) followed women up beyond the post treatment evaluation for six months.

2. RESULTS

i) Women with SUI: Henalla (1989) compared interferential stimulation with no treatment. In addition to the EStim and no treatment arms there were two other arms in the study. Eight of the 25 women receiving EStim were had a negative pad test or more than 50% reduction in pad test at three months, versus none of the 25 controls. Be (1999) compared 50Hz daily EStim for six months versus the offer of the Continence Guard (Coloplast AS); the Continence Guard was used by 14 out of 30 women. There was no statistically significant difference between the groups for women reporting symptoms were “unproblematic” after treatment; 28/30 controls and 19/25 in the EStim group wanted further treatment. Two of 30 controls were cured (< 2g leakage) on pad test with standardised bladder volume compared to 7/25 in the EStim group, and the EStim group had less pad weight gain than controls (MD -6.60g, 95% CI -8.60 to -4.60). Leakage Index score was better in the EStim group (MD -1.60, 95% CI -1.79 to -1.41), but did not retain significance with intention to treat analysis. In Henalla (1989) no side effects were reported, but Be (1999) reported that two out of 25 women in the EStim group had smarting and/or discomfort.

**ii) Women with DO:** In a four arm RCT in 68 women with DO, Berghmans (2002) investigated the effect of no treatment (n=14) versus nine weeks of 4 to 10Hz twice daily EStim at home (n=17). There was more improvement in Detrusor Overactivity Index score (DAI, lower score better) in the EStim group compared to controls (p=0.032), and less self reported symptom impact on the Dutch Incontinence Impact Questionnaire (DI-QOL). There were no reports of side effects or adverse events.

**SUMMARY**

Single trials suggest that EStim might be better than no treatment in women with SUI, and women with DO (Level of Evidence: 2). These findings need to be confirmed in further trials.

**RECOMMENDATIONS**

For women with DO nine weeks of 4 to 10Hz twice daily EStim at home, and for women with SUI six months of 50Hz daily EStim at home, might be better than no treatment (Grade of Recommendation: C). However, these are single small studies, and the recommendation should be viewed with caution until the findings are supported or refuted in further trials; it would be particularly useful if further trials used a validated and reliable quality life measure as a primary outcome.

- **EStim versus sham EStim**

  Fourteen trials were included. The sham stimulation comprised a device that:
  - delivered a limited output that the trialists considered would have no treatment effect [187, 210, 220, 221].
  - appeared to be working but there was no electrical output [180, 209, 217, 219, 222, 224, 227-229].

  In the remaining trial placebo stimulation was not described at all [231].

  Eight of the 14 trials specifically reported that some attempt was made to remove the participants’ expectations of the physical sensations that might accompany stimulation in an effort to mask participants to their allocation to active or sham stimulation [180, 217, 219, 221, 222, 224, 228, 229]. In one trial the stimulation was delivered under general anaesthesia [209].

**1. QUALITY OF DATA**

Random allocation concealment was adequate in seven of the 14 trials [209, 210, 217, 219, 221, 228, 229]. Blinding of assessors was clearly stated in eight trials [209, 219-224, 231]. One trial stated that outcome assessors were not blinded [180].

In six studies the size of the study population was based on a power calculation [210, 215, 219, 221, 222, 229]. Two trials randomised more than 50 women to each comparison group [209, 217]. In three trials the group sizes ranged from 25 to 49 [219, 221, 224], and the remaining nine trials allocated less than 25 women to each comparison group.

Three trials had no dropouts or losses to follow up [180, 187, 222]. The proportion of dropouts was less than 10% in two trials [220, 223] and in the remainder it varied from 11% [210] to 12% [209, 224] to 21% [226, 227].

Eight trials followed women up beyond the post treatment evaluation [180, 187, 209, 215, 220, 223, 224, 229]. The length of follow-up varied from six weeks [209] to six months [187, 220, 229]. Yamanishi [223, 224] only followed up those participants who had improved with treatment, monthly for several months.

Readers should note that the trial by Yamanishi (1997) included men and women with UI. It is possible that the effects of stimulation might be different between sexes (due to difference in electrode placement for example) so this study has not contributed to the analysis where the trialists did not differentiate the effects of treatment in women versus men.

**2. RESULTS**

- **i) Women with SUI:** Eight trials compared EStim with sham stimulation in women with urodynamic SUI [143, 180, 210, 219-221], or men and women with urodynamic SUI [223], or reported a subgroup analysis of women with SUI [217]. Blowman (1991) compared EStim plus PFMT versus sham EStim plus PFMT and for the purposes of analysis this trial was considered to be a comparison of EStim with placebo EStim, as there is currently no evidence that PFMT enhances the effect of EStim. Two trials contributed no data to the analysis. Hofbauer (1990) provided minimal detail of participants, methods and stimulation parameters, and it was not clear how ‘cure’ was defined (self report or urinary diary). Yamanishi (1997) did not report any subgroup data for women.

  Two trials were reasonably similar with regard to EStim. Both Sand (1995) and Luber (1997) used twice daily alternating current at home for 12 weeks at 50Hz [219] or 12.5 and 50Hz [219]. Sand (1995) found that the EStim group had significantly greater changes in patient perceived recovery (OR 2.76, 95% CI 0.66 to 11.44), but Luber (1997) did not find any statistically significant difference between EStim and sham (OR 0.81, 95% CI 0.21 to 3.10). The same two trials also had contradictory findings for leakage episodes; Sand (1995) reported a statistically significant difference in the number of leakage episodes in 24 hours (MD 0.90, 95% CI 0.83 to 0.97) whereas Luber (1997) did not (MD 0.10, 95% CI -0.87 to 1.07). A third study, that also used twice daily home stimulation but at 20 Hz (rather than 50) and for eight weeks (rather than 12),
had similar findings to that of Sand (1995) with a significant difference in patient perceived recovery (OR 2.63, 95% CI 1.11 to 6.20) and fewer leakage episodes (MD 2.80, 95% CI 1.06 to 4.54) in favour of EStim; this was a subgroup analysis of 60 women with SUI in a larger trial [217]. Finally, Luber (1997) did not find any statistically significant difference between active and sham groups for health status (SF-36).

Two trials used daily home alternating current for six weeks [210], at 10 and 35Hz [220] or a “low” frequency (to target the slow twitch fibres) and “intermediate” frequency (to target the fast twitch fibres). Neither study found a statistically significant difference in leakage episodes between active and sham groups, nor did Jeyaseelan (2000) find statistically significant difference in pad test findings or UDI scores.

Laycock (1993) used clinic based, short-term (10 treatments) maximal stimulation with an interferential current, and did not find a significant difference in leakage episodes between the groups post treatment.

With regard to side effects, three studies collected this data but no adverse events or side effects were reported [219-221].

### ii) Women with DO or UUI:
The three trials were sufficiently heterogeneous with respect to EStim and sample populations their results are described separately. A fourth study reported a subgroup analysis of women with DO from a larger trial [217].

Abel (1996) randomised 28 postmenopausal UUI women to maximal anal or vaginal alternating current for 20 minutes once a week for 12 weeks, or sham. In both groups there was a significant improvement in subjective parameters (VAS) but not in objective measurements (24 hour pad test and incontinence episodes per day).

Bower (1997) in a three arm study used a single stimulation episode of alternating current (either 10 Hz, sacral electrodes or 150 Hz, symphysis pubis electrodes) given after the voiding phase of cystometry and before repeat bladder filling.

The results were reported separately for women with DO and those with urgency. In DO both stimulation groups showed statistically significant improvements in urodynamic measures when compared with sham although the clinical relevance of this in terms of benefit felt by patients remains unclear. In women with urgency between group comparisons were not reported.

Yamanishi (2000a) investigated maximum intensity alternating current delivered daily for four weeks in men and women with DO. For the one outcome reported separately for women, more women in the EStim group reported cure/improvement than women in the sham group (p=0.0091).

In a subgroup analysis of 61 women with DO (DO alone, or DO with urodynamic SUI), Brubaker (1997) found that after bipolar alternating current 16 of 33 women with pre-treatment DO had post treatment DO. In contrast 24 of 28 women in the sham group had persistent DO, although there were no statistically significant differences between the EStim and sham groups with respect to post treatment urodynamic diagnosis of DO (p=0.22).

### iii) Women with SUI or UUI or MUI:
Amaro (2006) compared intravaginal EStim with sham in 40 women. Leakage was evaluated using a 60 minute pad test, and was statistically significantly reduced in both groups (mean 6.9g SD 3.5 and mean 1.1g SD 0.5 before and after EStim respectively; mean 3.1g SD 3.6 and mean 1.1g SD 0.5 before and after sham respectively).

Although the authors stated that there was no significant difference between groups, our re-analysis revealed a small difference, favouring EStim (MD 3.89, 95% CI 2.58 to 5.20). There were fewer micturitions in 24 hours in the EStim group than sham group post treatment (MD 3.00, 95% CI 1.74 to 4.26). Eighty percent of the EStim group and 65% of the sham group were satisfied with their final result.

### iv) Women with SUI or UUI or MUI:
EStim and sham stimulation were compared in two trials that included women with symptoms of SUI (n=42), UUI (n=26) or MUI (n=39) [209] or urodynamic diagnoses of SUI (n=60), UUI or DO (n=28) or MUI (n=33) [217].

Shepherd (1984) suggested a slightly higher likelihood of patient perceived cure in the EStim group than in the sham group (MD 1.38, 95% CI 0.59 to 3.20), although neither trial found any significant differences between the stimulation and sham groups for a range of outcomes including frequency, number of leakage episodes, quality of life.

### SUMMARY

Due to the clinical heterogeneity of the studies, in terms of EStim protocols and diagnoses, it is difficult to interpret the findings of trials comparing EStim with sham. For women with urodynamic SUI the findings of two trials using similar stimulation protocols were contradictory (Level of Evidence: 2). There was insufficient evidence (small trials, different EStim protocols) to determine if EStim was more effective than sham in other groups of women.

### c) Is EStim better than other treatments for UI?

EStim has been compared with magnetic stimulation (MStim), PFMT, VC, and drugs. The comparisons of EStim versus PFMT, and EStim versus VC, have been addressed previously (see B.2.3d and B.3.2b respectively). Two of the trials comparing EStim with another treatment included men and women [225,
226], and these studies have not contributed to the analysis where they did not differentiate the effects of treatment in women versus men.

• ESTim versus MStim

In the single, small trial intravaginal ESTim was compared with MSTim; stimulation was applied continuously at 10 Hz in both groups [225]. Neither of the interventions was well described.

1. QUALITY OF DATA

Random allocation concealment was adequate. It was not clear if outcome assessors were blind or if there were any dropouts or losses to follow up.

2. RESULTS

Bladder capacity at first desire to void and maximum cystometric capacity increased significantly in both groups, and maximum cystometric capacity was statistically significantly greater in the MSTim group (114.2ml SD 124.1 versus 32.3ml SD 56.6).

SUMMARY

With only one single small trial comparing ESTim with magnetic stimulation there is insufficient evidence to determine if ESTim is better than magnetic stimulation in women with DO.

• ESTim versus medication

Henalla (1989), in a four arm trial, compared ESTim (interferential) versus vaginal oestrogen (Premarin) in 104 women with urodynamic SUI [141]. Smith (1996) compared ESTim with propantheline bromide in 38 women with OAB [187].

Soomro (2001) compared transcutaneous electrical nerve stimulation (TENS) with oxybutynin in both men and women with DO in a crossover design [226]. Results were not separately presented by gender, which meant it was not possible to draw any conclusions from this study about the effect of TENS in women with DO.

1. QUALITY OF DATA

Outcome assessment was not blind in either trial, and random allocation concealment was unclear in one study [141] and inadequate in the other [187]. There were few dropouts in either study, and Henalla (1989) followed women up at nine months.

2. RESULTS

i) Women with SUI: Eight of 25 women in the ESTim group reported they were cured or improved versus 3/24 in the oestrogen group [141]. Nine month follow-up found that one of the eight women in the ESTim group who had reported cure/improvement post treatment had recurrent symptoms, as did all three women in the oestrogen group once oestrogen therapy ceased. Differences in leakage on pad test, and maximum urethral closure pressure did not reach statistical significance. There was no report of side effects or adverse events.

ii) Women with DO: There was a statistically significant difference in patient perceived recovery in favour of the ESTim group (OR 0.38, 95% CI 0.10 to 1.49), but no difference in leakage episodes [187].

SUMMARY

With only single trials, with small numbers per comparison group, there is insufficient evidence to determine if ESTim is better than vaginal oestrogens in women with SUI, or propantheline bromide in women with DO.

d) Does the addition of ESTim to other treatments add benefit for the treatment of UI?

• ESTim with BF assisted PFMT versus BF assisted PFMT alone

One study was found, investigating ESTim with BF assisted PFMT versus BF assisted PFMT alone in women with SUI, or MUI [136].

1. QUALITY OF DATA

Random allocation concealment was adequate; blinding of assessors was not reported. Goode (2003) reported a power calculation and randomised more that 50 patients to each group. The dropout rate was 22.5%.

2. RESULTS

Intention-to-treat analysis showed similar perception of improvement between the comparison groups (OR 0.98, 95% CI 0.06 to 16.08), and there was no difference between the groups for leakage episodes. The authors reported no adverse events, but there were side effects in four women; problems were vaginal irritation, slippage of the ESTim probe resulting in a pinching sensation, and reaction to the conduction gel which resolved after changing brands.

SUMMARY

A single trial found that the addition of ESTim to a BF assisted PFMT was no more effective than BF assisted PFMT in women with SUI, or MUI (in which stress leakage was the predominant symptom) (Level of Evidence: 2). A few women experienced side effects with ESTim.

RECOMMENDATIONS

The addition of ESTim to a BF assisted PFMT programme does not appear to add benefit (Grade of Recommendation: C); this hypothesis needs to be investigated further with high quality trials if it is a clinical/research question of interest to women.
• EStim with PFMT versus PFMT alone

Four trials compared EStim combined with PFMT versus PFMT alone in women with SUI [143, 179, 212, 216]. Tapp (1987, 1989) used faradic stimulation in combination with PFMT in two small trials reported in conference abstracts, and another small trial gave minimal detail of participants, methods and stimulation parameters [143]. Knight (1998) combined clinic based maximal intensity alternating current with PFMT. In a four arm RCT with 68 women with proven DO Berghmans (2002) investigated the effect of PFMT alone, alternating biphasic EStim alone, and EStim in combination with PFMT in comparison with no treatment [212, 228].

1. Quality of Data

Of the five trials random allocation concealment was adequate in two [212, 228], a blind outcome assessment clearly stated in just one [228]. The trials were generally small, with only Berghmans (2002) reporting a power calculation. Group size was less than 25 in four [143, 212, 216, 228] of the trials, and between 25 to 49 in the fifth [179]. Two trials had no dropouts or losses to follow up [143, 216], and two followed women up six months post treatment [143, 212].

2. Results

i) Women with SUI: Three of the four trials were small and poorly reported; none of them reported statistically significant differences between the groups receiving combined ES/PFMT and PFMT alone [143, 179, 216]. The fourth trial was also small although better reported [212]. In this study 10 of 21 women in the PFMT group and 16/24 in combination therapy group reported cure or great improvement; a difference in favour of combination therapy (OR 0.23, 95% CI 0.05 to 0.93), but there were no statistically significant differences in improvement in pad test or vaginal squeeze pressure. Neither Hofbauer (1990) nor Knight (1998) recorded any adverse events from stimulation.

ii) Women with DO: No data were provided on the comparison of combined PFMT/EStim versus PFMT. No women had any side effects or adverse events.

Summary

For comparisons of EStim with PFMT versus PFMT alone the reporting was very poor in three of the four trials in women with SUI, and only a single trial that did not report any data for the comparison of interest was found for women with DO. There is insufficient evidence to draw any conclusion about the effect of adding EStim to PFMT.

3. OTHER LUTS

No studies were identified that analysed the effect of EStim on lower urinary tract symptoms alone, i.e., frequency of voiding, urgency and/or nocturia.

4. FACTORS AFFECTING OUTCOME

a) Age

This section considers the effect of EStim in older age, from studies recruiting independent, community dwelling elderly; the frail elderly are considered in the chapter on the elderly.

Only one of the trials in this section on EStim specifically recruited older women [186]. Spruijt (2003) compared the effectiveness of eight weeks of vaginal EStim in women aged more than 65 years with symptoms of SUI, UUI or MUI with a daily pelvic floor muscle training (PFMT). This comparison of EStim and PFMT was considered in the section on PFMT (see B.2.3d). No statistically significant differences between the groups were found for leakage or self reported improvement, but this study was small (n=37) and a post hoc power analysis suggested that the study was underpowered. In view of the likelihood of type II error, the finding of no difference should be treated with caution. In the study report, Spruijt (2003) observed that EStim does not appear to have any serious side-effects in the elderly (apart from interfering with pacemaker activity), but can give an unpleasant vaginal, anal and perineal sensation which can easily lead to a lesser degree of cooperativeness, informed consent and motivation, especially in the elderly. Nevertheless, in general, EStim seems to be a well tolerated and acceptable treatment modality in the older person [186].

One other study included in this section completed a secondary analysis on the basis of age. In a double-blind RCT, Yamanishi (1997) studied EStim compared to a sham device in 68 patients with UUI [223]. EStim was delivered by surface, anal, or vaginal electrodes 15 minutes twice daily for four weeks, using 10Hz and a maximum output current of 60mA. Mean age was 70 years (SD 11) and the secondary analysis considered the effect of treatment in ‘older’ and ‘younger’ patients. There was no difference in treatment outcomes based on age (older or younger than 60 years).

In a moderate sized prospective study of 3198 women treated with home-managed EStim in Norway during 1992-1994, there was no association between self-reported improvement and age, although the physicians thought success rates were higher in younger patients [232].
SUMMARY

On the limited evidence available it seems older women may respond to EStim as well as younger women. On this basis there is no reason to exclude older women from studies of EStim, or not to offer EStim as part of a conservative management programme, except where recognised contraindications such as a cardiac pacemaker are present. More trials need to consider investigating the association between age and treatment outcome.

b) Other

Aside from age, other factors have the potential to mediate treatment outcome, e.g. diagnosis and underlying cause of UI. A range of other factors are considered below.

1. Diagnosis and underlying cause of UI

It is not clear whether one diagnostic group may benefit more than another from EStim. It has been hypothesised that, in women with SUI who cannot voluntarily contract the PFM to begin a PFMT programme, EStim might help initiate or substitute for a voluntary contraction. However, most studies focusing on the efficacy of EStim do use EStim to initiate or substitute for a voluntary PFM contraction [233]. To date, there has been no trial addressing this hypothesis.

2. Patient selection

EStim is reported to be unsuccessful in patients with major descent of the vagina and prolapse of the uterus [219]. Also denervated PFM muscles might not respond to EStim [234]. This means that in patients with no or reduced integrity of the relevant nerve pathways EStim provides no or little chance of cure/improvement [207]. It has also been reported that EStim will fail if EStim does not increase urethral pressure profile [235], although age, oestrogenisation, and urethral mobility are also affect urethral pressure profile and may influence therapeutic outcome [235]. It is unfortunate that it is difficult to assess patients easily in the clinical setting with regard to integrity of the sacral arc, and other factors, to determine the suitability of EStim as a treatment modality.

3. Treatment adherence

As with all conservative therapy modalities one of the key factors to success or failure of EStim is treatment adherence. Three trials made some comment about adherence or reported adherence data. Barosso (2004) stated that adherence to EStim was satisfactory, and attributed this to the ability of the doctor to motivate patients to continue with EStim if the considered stopping prematurely. Bø (1999) found that adherence to EStim (75%) was less than that for PFMT (93%), and the reasons for non-adherence to EStim were a lack of motivation (four women) and smarting or discomfort (two women). Sand (1991) reported that 80% adherence was achieved by 61% of the active EStim group and 89% of the sham group.

One of the main factors that may influence adherence is side effects of the treatment. Some of the studies included in this section noted some women had side effects attributable to EStim, others stated no side effects were reported by women, and some trials did not mention side effects at all. None of the side effects reported were serious, and all could be resolved with cessation of treatment or some other treatment adaptation (such as change of conduction gel). In a prospective study of about 1300 women in Norway, Indrekvam (2001) found that the most common side effects of EStim included pain (20%), soreness/local irritation (26%), and psychological distress (7%) were the most common side effects but none of the side effects reported was serious [232]. It seemed users of maximal stimulation experienced more pain than users of long-term stimulators (25% versus 15%).

SUMMARY

It is possible that diagnosis, other factors such as neural pathway integrity, and treatment adherence, will affect treatment outcome. None of these have been adequately investigated to date.

V. MAGNETIC STIMULATION (MSTIM)

MStim has been developed for stimulating both central and peripheral nervous systems noninvasively [236]. MStim for the treatment of UI was reported for the first time in 1999 by Galloway (1999) [237]. In contrast to EStim, extracorporeal magnetic innervation (more commonly called magnetic stimulation) stimulates the PFM and sacral nerve roots without insertion of an anal or vaginal probe [238, 239]. For treatment, the patient is positioned in a chair. Within the seat is a magnetic field generator (therapy head) that is powered and controlled by an external power unit (Figure 6). A concentrated steep gradient magnetic field is directed vertically through the seat of the chair. When seated, the patient’s perineum is centred in the middle of the seat, which places the PFM and sphincters directly on the primary axis of the pulsing magnetic field (Figure 7). Because of this all tissues of the perineum can be penetrated by the magnetic field. Galloway (1999) says that no electricity, but only magnetic flux enters the patient’s body from the device. Goldberg (2000) has suggested that, in contrast to electrical current, the conduction of magnetic energy is unaffected by tissue impedance, creating a theoretical advantage in its clinical application compared to EStim as structures such as sacral roots or pudendal nerves can be magnetically stimulated without patient discomfort or
Conventional magnetic stimulators deliver, at frequencies of 10 to 50 Hz, repetitive pulses of current lasting less than 100 µsec [238] and 275 µs [237] in duration. Size and strength of the magnetic field is determined by adjustments of this amplitude by the therapist [237].

Possible advantages of MStim are that it is performed through full clothing, needs no probes, skin preparation, or physical or electrical contact with the skin surface. On the other hand, the need for repeated clinic based treatment sessions is a potential disadvantage. In contrast to EStim, MStim lacks portability, although in 2003 But reported the development of a small electromagnetic device (Pulsegen) for home use [240]. Further, because both the depth and width of magnetic field penetration is proportional to coil diameter, the present technology is still best suited for stimulation of a field, rather than a narrowly focused target as the sacral roots or the pudendal nerve [238].

MStim of the sacral nerve roots and pelvic floor is said to be effective for both UUI and SUI [238], although the mechanism of action is not fully understood [241]. Some authors have suggested that in SUI stimulation of the PFM causes external sphincter contraction [242], acts as a passive Kegel exercise [243], and increases maximal urethral closure pressure [240]. In UUI, MStim might suppress DO through activation of pudendal nerve afferents blocking parasympathetic detrusor motor fibres at the spinal reflex arc, activation of inhibitory hypogastric sympathetic neurons, or a combination of both mechanisms [244]. Stimulation of sympathetic fibres maintaining smooth muscle tone within the intrinsic urethral sphincter and modulation of pudendal nerve afferent branches stimulating an inhibitory spinal reflex at the S3 nerve root, are also suggested to play a role in this mechanism of action [244].

This section will examine the evidence for the use of MStim for the prevention and treatment of UI in women. Questions addressed are:

- Can MStim prevent UI?
- Is MStim better than no treatment, placebo or control treatments for UI?
- Is one type of MStim better than another?
- Is MStim better than other treatments?
- What factors might affect the outcome of magnetic stimulation?

A literature search for reports of relevant systematic reviews and reports of RCTs and quasi-RCTs, e.g. alternate assignment (see appendix) was performed. No other types of study design were considered.

1. PREVENTION

No trials investigating the primary or secondary prevention effects of MStim for women with UI were found.

2. TREATMENT

The literature search revealed three reviews, two in English and one in the German language, that addressed the indications for and the use of MStim and provided an historical overview of the therapeutic application possibilities of this treatment modality for UI [202, 241, 245].

These reviews were used to provide some background information regarding MStim, but did not otherwise contribute to the review.

Seven trials were found [225, 240, 246-250]. One report was an abstract; the trial has not yet been fully published [249]. Since the 3rd ICI two new trials have been published [246, 247].
a) Is MStim better than no treatment, placebo, or control treatment?

Six RCTs comparing MStim with sham for women with UI were found [240, 246-250].

But (2003) compared MStim from a home device (Pulsegen) with sham (identical but inactive device) in women with SUI, UUI and MUI [240], and subsequently in a sample with MUI [246]. In active and sham groups in both trials women were asked to wear the Pulsegen device day and night for two months; in the active group the device produced a pulsating magnetic field of B=10 μT intensity and a pulse frequency of 10Hz [240] or 18.5Hz [246].

Fujishiro (2000) compared a single session of MStim with sham in women with SUI [248], and subsequently women with urinary frequency and UUI [248]. In both trials the active group received 15Hz repetitive MStim of the sacral roots with 50% intensity output for five seconds per minute for 30 minutes. MStim was performed with the patient prone using a rapid rate stimulator with a Rapid circular coil. The coil was fixed over the sacrum to cover the bilateral third sacral foramina. The sham group received exactly the same treatment except the sham stimulating coil did not induce any electromagnetic field.

Gilling (2001) recruited SUI women, and compared MStim of the pelvic floor to sham, using a chair with an inbuilt magnetic coil (Neocontrol device) for 20 minutes [249]. A total of 16 treatments (three per week) were performed over six weeks. Both groups were also asked to do home PFMT.

Morris (2007) compared active MStim (Neocontrol device) with sham (an identical looking/sounding device containing a deflector plate to degrade the magnetic field). Treatment comprised 20 treatment sessions over six weeks, with at least 36 to 72 hours between sessions. Each session comprised two 10 minute periods of stimulation, at individual maximum tolerance, separated by two minutes rest. Frequency was 10Hz. The sham stimulation, with deflector in place, was run at a fixed intensity of 25% in order to provide the same noise as with the active device and to stay below the level required for patient perception.

1. Quality of data

Random allocation concealment was adequate in three of the trials [240]. Patients were blind in five of the trials [240, 248, 250], and blind outcome assessors were used by But (2003, 2005) and Morris (2007).

Only Morris (2007) based the size of the study population on an a priori power calculation, but due to a high dropout rate the analysis included only 29 of the 40 women needed. Fujishiro (2000) included 62 women (31 in each group) whilst Gilling (2001) randomised 70 women (35 in each group). In the studies by But, group sizes were 30 [240] and 23 [246] in the active and 22 [240] and 16 [246] in the sham group.

The proportion of dropouts was less than 10% in two trials [240], 34% in Morris (2007), and in the remainder this was not reported adequately. Two trials followed women up beyond the post treatment evaluation; Morris (2007) followed women up for six weeks, and Gilling (2001) reported six and 12 month follow up in their conference abstract but did not report these data in the full publication.

2. Results

i) Women with SUI: Fujishiro (2000) compared one session of sacral root MStim with sham in 62 women with SUI [248]. Active treatment was statistically significantly better than sham for leakage episodes (p=0.0023), leakage on pad test (p=0.037), and quality of life (p=0.0126). Based on these three measures 3% and 32% of the sham group were considered cured and improved respectively, versus 13% and 74% in the active MStim group, with more cured or improved in the active group (p=0.0009).

Gilling (2001) compared MStim with sham in 70 women with SUI and found no statistically significant difference between the active and sham groups at eight weeks for any outcome, nor between baseline and eight weeks in either group. A posthoc subgroup analysis suggested the women with poor PFM tone at baseline did better with active treatment than sham. The authors reported that follow-up was ongoing, but no data have been published.

ii) Women with UUI: Fujishiro (2002) compared a single session of sacral root MStim with sham in 48 women with urinary frequency and UUI. Active treatment was statistically significantly better than sham for voided volume/day (p=0.04), number of leakage episodes in three days (p=0.04), and quality of life score (p=0.01). No adverse effects were noted.

Morris (2007) found no between group differences for mean number of daytime voids, maximum interval, volume of leakage on pad test, number of leakage episodes, or quality of life. The only statistically significant difference was in the mean number of urge episodes per day (p=0.003); this difference favoured the MStim group.

iii) Women with MUI: But (2005) compared home-based MStim with sham in 39 women with MUI. Within group comparison suggested greater improvement in daytime frequency, nocturia, and pad use in favour of active MStim. Between group comparison showed statistically significant differences in favour of active MStim for time to first sensation of bladder filling (p=0.003), maximum cystometric capacity (p=0.0004), and self reported treatment success (p=0.021). There were no adverse effects in either group.
iv) Women with SUI, UUI, or MUI: But (2003) included 52 women of whom 21 had MUI, 22 UUI, and nine SUI, and compared MStim with sham. There were statistically significant differences in favour of MStim for pad use ($p=0.0017$), pad weight ($p=0.038$), power and duration of PFM contractions ($p=0.0071$ and $p=0.038$ respectively), self reported improvement in symptoms ($p=0.00012$).

**SUMMARY**

There was little duplication of MStim interventions, or sample populations, in the six small trials so it was not thought appropriate to combine study findings. For women with SUI one session of sacral root MStim might be better than sham (Level of Evidence: 2), but 16 sessions using a chair based MStim might not be better than sham (Level of Evidence: 2). Similarly in women with UUI, one session of sacral root MStim might be better than sham (Level of Evidence: 2), but chair based MStim might not be better than sham (Level of Evidence: 2). Home-based MStim might be better than sham in women with MUI (Level of Evidence: 2), and women with SUI, UUI or MUI (Level of Evidence: 2). No adverse events were reported.

**RECOMMENDATIONS**

Of the MStim protocols investigated to date, it seems that both sacral root MStim and home-based MStim, are worthy of further investigation in women with UI.

b) Is one approach to MStim better than another?

No studies were found addressing this question.

c) Is MStim better than other treatments?

A single trial was found that addressed this comparison; intravaginal EStim was compared with MStim in 17 women and 15 men with DO; stimulation was applied continuously at 10 Hz in both groups [225]. This trial was described and discussed in section B.4.2c. With only one small trial or poor methodological quality, in men and women with UI, it is not clear whether there is any difference in effect of MStim compared to EStim.

3. OTHER LUTS

No studies were found that reported the effects of MStim of other LUTS.

4. FACTORS AFFECTING OUTCOME

None of the included trials addressed the effect of age, or any other factor, on outcome of MStim. Sand (1999), in a prospective multi-centre study investigated factors predicting success of MStim [251]. Treatment success was associated with no prior hysterectomy, no prior anti-incontinence operations, UI symptoms for less than 10 years, and no use of medications known to cause UI. Brodak (1993) has suggested that detrusor response to stimulation might be better in 'thin' patients (presumably due to a shorter distance between the stimulating coil and the sacral nerve roots) and at low bladder volumes [252]. Overall, little is known about the factors affecting outcome of MStim.

VI. SCHEDULED VOIDING REGIMENS

This section examines the evidence on use of scheduled voiding regimens in cognitively intact, non-institutionalised women with UUI, SUI, and MUI and provides recommendations for their use in clinical practice. A summary of the search strategy and inclusion/exclusion criteria for selecting studies for review is provided (See appendix). See the chapter on the Frail Elderly for a detailed discussion of scheduled voiding regimens that are used in the management of UI in cognitively impaired, institutionalised, or homebound older adults, and the chapter on Neurogenic Incontinence for those voiding regimens appropriate for individuals with UI secondary to central nervous system or spinal cord disease.

- **Scheduled Voiding Regimens**

Bladder training is a term that has been broadly and sometimes inaccurately applied to any type of a scheduled toileting intervention. This has created conceptual confusion in interpreting research reports where few details are provided other than the statement that bladder training was used. The types of scheduled voiding regimens can be categorised as: bladder training, timed voiding, habit training, and prompted voiding [253]. Although these regimens share a common feature of a toileting schedule, they differ on the basis of adjustments to the voiding schedule; the active or passive involvement of the patient; the nature of patient education including the teaching of strategies to control urgency and prevent stress leakage, the use of reinforcement techniques, and the nature of the interactions between clinicians and patients. In practice, however, scheduled voiding regimens may share aspects of one or more of these features.

- **Bladder training**

Bladder training (also referred to as bladder drill, bladder discipline, bladder re-education, and bladder retraining) involves a programme of patient education along with a scheduled voiding regimen with gradually progressive voiding intervals. Specific goals of bladder training are to correct faulty habit patterns of frequent urination (if present), improve control over bladder urgency, prolong voiding intervals, increase bladder capacity, reduce incontinent episodes, and restore
patient confidence in controlling bladder function. The underlying mechanism of how bladder training achieves its effect is poorly understood. Several hypotheses have been proposed including improved cortical inhibition over detrusor contractions; improved cortical facilitation over urethral closure during bladder filling; improved central modulation of afferent sensory impulses; altered behaviour resulting from better individual awareness of the lower urinary tract function and circumstances that cause UI, and increasing the “reserve capacity” of the lower urinary tract system [188, 254, 255].

• Timed voiding
Timed voiding is a fixed voiding schedule that remains unchanged over the course of treatment [253]. The goal of timed voiding is to prevent UI by providing regular opportunities for bladder emptying prior to exceeding bladder capacity. Timed voiding has been recommended for patients who cannot participate in independent toileting [256]. It has been primarily used in institutional settings as a passive toileting assistance programme where a caregiver takes the patient to void every two to four hours including at night, and for patients with neurogenic bladders associated with spinal cord injuries (see Neurogenic chapter) [257]. However, it has applicability for use in outpatient settings with incontinent women who have infrequent or irregular voiding patterns [258] (and men who are independent in their voiding function [259]).

• Habit training
Habit training is a toileting schedule that is matched to the patient’s voiding pattern. Using the patient’s voiding chart, a toileting schedule is assigned to fit a time interval that is shorter than the patient’s normal voiding pattern and precedes the time period when incontinent episodes are expected. Thus, the voiding interval may be lengthened or shortened throughout the day depending on the patient’s voiding pattern with the goal to pre-empt UI. Habit training is usually implemented by caregivers, but patients may also be encouraged to suppress the urge to void until the assigned time. Habit training has been used primarily in institutional settings with cognitively and/or physically impaired adults, but it has also been tested in homebound older adults [260]. It is potentially useful for adults without cognitive or physical impairment, who have a consistent pattern of UI [258].

A Cochrane review on habit training was published in 2004 [261]. Prior to this, the last literature review was published in 1986 [253]. The Cochrane review identified three trials that described the effects of habit training combined with other treatment components compared to usual care on the frequency and severity of UI [260, 262, 263]. Participants were primarily care-dependent women with cognitive and/or mobility impairment, and thus, did not meet the criteria for this chapter. No studies were located that investigated habit retraining in independent-living women.

• Prompted voiding
Prompted voiding refers to a caregiver education programme in combination with a scheduled voiding regimen, typically every two hours. It is used to teach people with or without cognitive impairment to initiate their own toileting through requests for help and positive reinforcement from caregivers when they do so [264]. Although it has been used primarily in institutionalized settings with cognitively and physically impaired older adults, prompted voiding has applicability for use with homebound older adults (see the chapter on the Frail Elderly for a full review).

This section will examine the evidence for the use of timed voiding and bladder training for the prevention and treatment of UI in non-institutionalised women of all ages without cognitive or mobility impairments. However, the majority of evidence available pertains to bladder training thus the effects of bladder training are the focus of this section.

Questions addressed are:
• Can scheduled voiding regimes prevent UI?
• What is the most appropriate bladder training protocol?
• Is bladder training better than no treatment, placebo or control treatments?
• Is bladder training better than other treatments?
• Can any other treatment be added to bladder training to add benefit?
• Does the addition of bladder training to other treatments add any benefit?
• What is the effect of bladder training on other LUTS?
• What factors might affect the outcome of bladder training?

This section is based on previously published systematic reviews, including Cochrane reviews, and additional searches of the literature. Studies that were excluded from prior systematic reviews, due to the inclusion criteria for the review or restriction to RCTs or quasi-RCTs, were also considered. Conference abstracts were considered where adequate information was available.

1. PREVENTION

No trials were identified that examined scheduled voiding regimens as a sole intervention in the prevention of UI.

2. TREATMENT

Four systematic reviews on bladder training were
located that provided descriptive synthesis with evidence grading [214, 256, 265, 266]. The Cochrane Collaboration published a review in 1998 that has been updated in 1999, 2004, and 2007 [265].

**a) What is the most appropriate bladder training (BT) protocol**

No trials were identified that compared two or more methods of bladder training (BT). In the absence of trials comparing two or more approaches, a content analysis of the protocols used in trials investigating the effects of BT was performed. Fifteen trials on BT involving a total of 1,774 women were identified. Six of the trials provided no or minimal details regarding the specific BT protocol used [151, 267-271]. In trials that did provide some description, BT protocols were implemented in several ways.

All protocols involved some type of patient education, namely:

- Brief verbal instruction [268, 269]
- Brief written instructions [272]
- Verbal, written, and audiovisual instruction [188, 255]
- Participants were introduced to an individual who successfully completed BT [270]
- If specified, the education was provided by nurses [151, 188, 255, 267, 273, 274], or general practitioners [275].

Scheduling of voids varied in the following ways:

- Assignment of the initial voiding interval varied from 30 minutes to two hours, with one hour being the most common interval based upon the participant’s voiding pattern or 30 minutes beyond the participant’s average voiding interval [276].
- Adjustments to the voiding interval varied from 15 to 30 minutes, with 30 minutes the most common interval. Increases were made daily for inpatient regimens [271], after 48 hours of dryness [277], every four to five days [276], or weekly if schedule was well-tolerated [188, 255].
- Goals for optimal voiding interval varied from three to four hours.
- Voiding was ‘mandatory’ with restriction of voiding in between assigned toileting times even if UI occurred [271], a scheduled voiding regimen that allowed interruptions in the schedule if urgency became unbearable [188, 255, 273], or self-scheduling of voiding with a target goal to reach [272].
- Voids were not scheduled (allowed) during sleeping hours [271]; none of the other protocols identified how voids were handled during sleeping hours.

In some protocols the scheduled voiding regimen was supplemented by specific strategies to control urgency and/or stress leakage, including distraction and relaxation [188, 255, 272, 273], and pelvic floor muscle contraction [188, 267]. In other studies there was encouragement to suppress urge but it was not clear what strategies were used [55, 269, 275]. Feedback techniques included self-monitoring [188, 255, 268, 270, 273], goal setting with feedback of progress [274], and positive reinforcement [188, 255, 276].

Several protocols included use of adjunctive treatments:

- Fluid and caffeine adjustments [55, 273]
- Fluids allowed up to a certain level (1,500 ml) [277]
- No fluid modifications [188, 255, 272, 275]
- Advice on constipation prevention [273]

Finally, both in and outpatient BT programmes have been used. Early inpatient BT programmes involved five to 13 days of hospitalisation to ensure strict protocol adherence [271]. Outpatient programmes are more commonly described and the amount of health professional contacted had ranged from weekly visits for six weeks with fortnightly telephone calls for six additional weeks [188], to weekly visits [151, 255], fortnightly visits [276], and monthly visits [277].

Overall, there is a lack of consistency in BT protocols. Based on the BT protocols described in the literature to date is seems that a reasonable outpatient BT protocol would include:

- an initial voiding interval typically beginning at one hour during waking hours, which is increased by 15 to 30 minutes per week depending on tolerance of the schedule (such as fewer incontinent episodes than the previous week, minimal interruptions to the schedule, and the woman’s feeling of control over urgency and confidence to expand the voiding interval), until a two to three hour voiding interval is achieved. A shorter initial voiding interval, e.g. 30 minutes or less, may be necessary for women whose baseline micturition patterns reveal an average daytime voiding interval of less than one hour.
- education about normal bladder control and methods to control urgency such as distraction and relaxation techniques and PFM contraction.
- self-monitoring of voiding behaviour using diaries or logs in order to determine adherence to the schedule, enhance self-awareness, evaluate progress, and determine whether the voiding interval should be changed (Figure 8).

a supervising clinician to monitor progress, suggest adjustments to the voiding interval, and provide positive reinforcement to women undergoing BT at least weekly during the training period.
If there is no improvement after three weeks of BT, re-evaluation is warranted and other treatment options would be considered. Inpatient BT programmes may follow a more rigid scheduling regimen with progression of the voiding interval on a daily basis.

**SUMMARY**

There is no trials evidence to suggest the most effective method or specific parameters of BT. For those undertaking BT it is likely that more health professional contact will be better than less, based on the developing evidence for PFMT, which like BT requires behavioural change. The literature suggests several variables that could be investigated in future trials including the instructional approach, supervisory intensity, strategies for controlling urgency, scheduling parameters, frequency of schedule adjustments, length of treatment, and use of adjunctive treatments.

**RECOMMENDATIONS**

It is not clear what the most effective BT parameters are. Clinicians and researchers are advised to refer to the operant conditioning and educational literature to provide a rationale for their choice of BT parameters or approach (Grade of Recommendation: D). Clinicians should provide the most intensive BT supervision that is possible within service constraints (Grade of Recommendation: D). More research is needed to investigate which BT parameters, supervisory intensity, and adjunctive treatments are most effective. Future trials should include outcomes that matter to patients including the length and frequency of supervisory contact.

**b) Is BT better than no treatment, placebo or control treatments?**

BT as the sole therapy has been used in the treatment of DO, urodynamic SUI, MUI, UUI, UUI with a stable bladder, and OAB syndrome (also called urgency-frequency syndrome). Individual RCTs that met inclusion criteria and the Cochrane review [265] were used to address the question of whether BT is better than no treatment, placebo, or control treatments for UI.

Five RCTs reporting on 515 women were identified that compared the effect of BT to no treatment or control [151, 255, 270, 273, 275]. In one trial, it was not possible to identify the effect of BT alone, because results of participants in the treatment group who received BT (those with UUI or MUI) were combined with those who also received PFMT (SUI participants) [275]. However, in the Cochrane review, additional data were provided by the lead author to describe the women with DO who were randomised to BT versus control. In another trial with three consecutive treatments (self-monitoring, BT, and PFMT; with the decision for which treatments were implemented being based on participants' goals), it was difficult to discern the effect of BT alone as compared to a control group, because some participants had already undergone lifestyle modifications (caffeine and fluid modifications and constipation advice) and diary keeping in a prior self-monitoring condition [273]. Thus, this trial is not discussed further in this section.

In the four trials with analysable data, Jarvis (1980) investigated the effect of an in-patient BT programme in 60 women aged 27 to 79 years with a diagnosis of DO or coexisting SUI, whereas three trials [151, 255, 275] examined the effect of an outpatient programme. Fantl (1991) studied the effect of a six week outpatient programme in 123 women aged 55 to 90 years with urodynamic SUI, DO, or both who reported at least one incontinent episode on a weekly voiding diary. Yoon (2003) examined the effect of an eight week outpatient programme in 50 women aged 35 to 55

---

Figure 8: Self-monitoring of voiding behaviour (Courtesy of Dr Jean Wyman, University of Minnesota, USA)
years with UI (type not identified) who had pad test weights at least 1g or more and 14 or more voids during a two day diary. Lagro-Jansen (1992) studied the effect of an outpatient programme in 18 women aged 20 to 65 years who reported UI twice or more per month and had uro-dynamically confirmed DO.

1. Quality of data

In one trial random allocation concealment was inadequate [275]; in the remainder it was not clear if concealed. One trial used stratification based on urodynamic diagnosis of urodynamic SUI and/or DO [255]. Blinding of outcome assessors was described in only one trial [151].

Sample sizes in the four analysable trials were 50 [151], 60 [270], 123 [255], and 18 [275]. Fantl (1991) reported a power calculation although details were not described. Losses to follow up were none in one trial, although it was not clear if this was due to having no dropouts or due to lack of reporting [270]. In the other two analysable RCTs, loss to follow up was 6% [255] and 14% [151]. Dropout rates at the immediate follow-up time point seemed similar between the BT and the control groups; they ranged from 8% versus. 5%, respectively [255] to 10% versus 14%, respectively [151]. No trials reported whether analyses were based on intent-to-treat principles. Follow-up periods ranged from six weeks [255] to eight [151] and 12 weeks [270, 275], with an additional evaluation six months [270] and nine months [255] after initiation of treatment. Two trials noted whether there were adverse events with BT [255, 270]. No trial reported on adherence.

All of these RCTs, with the exception of the one by Jarvis (1980), were considered in the Cochrane review [265]. The Cochrane reviewers based their conclusions on data available from 172 women in the other three trials.

2. Results

Three of the four RCTs reported statistically significant improvements in the BT group as compared to an untreated control group with respect to incontinent episodes [255, 270, 275]; the fourth did not report data on incontinent episodes [151].

Jarvis (1980) reported that 90% of the participants in the treatment group were continent and 83% were symptom free at six months (method for determination of continence and symptom status was not specified but probably self-report) as compared to 23% of the control group who were both continent and symptom free. All women who were symptom free after treatment reverted to a normal cystometrogram.

Fantl (1991) reported that 12% of participants in the treatment group were continent and 75% had reduced their incontinent episodes by at least 50% or more at six weeks, as measured by a seven day voiding diary, as compared to 3% of controls with no incontinent episodes and 24% with at least 50% reduction in their incontinent episodes. These results were maintained at six months. Women with DO and those with urodynamic SUI with and without DO had similar improvement rates. Participants in the treatment group also significantly decreased the grams of fluid lost on a retrograde pad filling test by 54% with results maintained six months later; this was more pronounced in those who had DO with or without urodynamic stress UI. While some women did revert back to normal bladder function following BT, no relationship was found between changes in urodynamic variables and the number of incontinent episodes [278].

Lagro-Jansen (1992) reported that eight or nine patients in BT perceived improvement of UI compared to none of nine in the control group. Yoon (2003) reported that there was no difference between the BT and control groups in the amount of leaked urine at an immediate follow-up; however, it was not clear if this referred to pad test weights solely or a UI severity score. Conclusions from this trial are uninterpretable because of insufficient power.

The Cochrane review [265] noted that the few data available tend to favour BT; however, the scarcity of data implies that they should be interpreted cautiously.

Summary

From the few trials available, there is scant Level 1 evidence that BT may be an effective treatment for women with UUI, SUI, and MUI (Level of Evidence: 1)

Recommendations

BT is an appropriate first line conservative therapy for UI in women (Grade of Recommendation: A). Additional high quality studies are needed that examine the effect of BT versus no treatment in treatment of women with UUI, SUI, and MUI.

c) Is BT better than other treatments?

To be included in this section, trials needed to compare BT alone versus another active therapy. For the comparison of BT versus PFMT see B.2.3d. The only other comparison for which trials were found was BT versus drug therapy. Individual trial reports that met inclusion criteria and the Cochrane review [265] were used as the basis of the review of BT versus drug therapy.

Three RCTs were located that compared BT to drug therapy in 322 women [267, 271, 276]. The study by Park and colleagues [267] compared a 12-week BT programme to 2mg tolterodine twice daily in women (ages unknown) with OAB (unclear if UI was present); because there were no findings reported on UI, this trial is discussed in the section on Other LUTS (B.6.3).
The two trials included in this section used a combination of flavoxate hydrochloride and imipramine [271], or used immediate-release oxybutynin chloride [276].

1. Quality of Data

One trial reported adequate random allocation concealment [276]. Sample sizes were 50 [271] and 79 [276]. Neither trial reported a power calculation;

Follow up periods varied from four weeks [271] to six [276] and 12 weeks [271], and six months [276]. Both RCTs evaluated drug tolerability and adverse events. Dropouts were none in one trial; however, it is not clear whether this was a reporting issue [271]. In the other trial loss to follow up was 7% [276]. Neither trial identified whether intent-to-treat principles were followed. The Cochrane review [265] based their conclusions on the same trials.

2. Results

One RCT suggested that BT may be superior to drug therapy in women with DO [271]. Jarvis (1981) compared inpatient BT to outpatient treatment of 200mg of flavoxate hydrochloride (three times a day) and 25mg of imipramine (three times per day) in 50 women aged 17 to 78 years with DO, and concluded that BT was more effective. In the BT group, significantly more patients (84%) became continent and symptom free (76%) assessed by self-report, as compared to the drug group where 56% became continent and 48% were symptom free at four weeks. Patients who were symptom free at four weeks were able to maintain their outcomes at 12 weeks. In the analysis by the Cochrane review group, more participants in the BT group perceived that they were cured at the end of the treatment phase and approximately two month after treatment ended (RR 1.13; CI 0.94 to1.35). Adverse events included dry mouth, dizziness, headache, nausea, vomiting, and drowsiness in participants who received drug therapy; there were none in those who received BT.

Columbo (1995) reported that a six week course of 5mg oxybutynin chloride (immediate release) (three times per day) had a similar clinical cure rate (i.e. self-reported total disappearance of UI) in patients who received BT. This is consistent with the findings of the Cochrane review [265], which concluded that BT was more effective. In the BT group, 63% of patients were self-reported total disappearance of UI at 12 weeks. In the drug group, 59% of patients were self-reported total disappearance of UI at 12 weeks. Patients who were symptom free at four weeks were able to maintain their outcomes at 12 weeks. In the analysis by the Cochrane review group, more participants in the BT group perceived that they were cured at the end of the treatment phase and approximately two month after treatment ended (RR 1.13; CI 0.94 to1.35). Adverse events included dry mouth, dizziness, headache, nausea, vomiting, and drowsiness in participants who received drug therapy; there were none in those who received BT.

Columbo (1995) reported that a six week course of 5mg oxybutynin chloride (immediate release) (three times per day) had a similar clinical cure rate (i.e. self-reported total disappearance of UI) in patients who received BT. This is consistent with the findings of the Cochrane review [265], which concluded that BT was more effective. In the BT group, 63% of patients were self-reported total disappearance of UI at 12 weeks. In the drug group, 59% of patients were self-reported total disappearance of UI at 12 weeks. Patients who were symptom free at four weeks were able to maintain their outcomes at 12 weeks. In the analysis by the Cochrane review group, more participants in the BT group perceived that they were cured at the end of the treatment phase and approximately two month after treatment ended (RR 1.13; CI 0.94 to1.35). Adverse events included dry mouth, dizziness, headache, nausea, vomiting, and drowsiness in participants who received drug therapy; there were none in those who received BT.

3. Summary

It is not clear whether BT is more effective than drug therapy for women with DO or UUI (Level of Evidence: 1). This is consistent with the findings of the Cochrane review [265], which concluded that there was not enough evidence to determine whether first line therapy should be BT or anticholinergic drugs.

4. Recommendations

In a choice between BT and anticholinergic drug therapy for women with DO or UUI, either may be effective (Grade of Recommendation: B). BT may be preferred by some clinicians and women because it does not produce the side effects and adverse events associated with drug therapy (Grade of Recommendation: D).

d) Can any other treatment be added to BT to add benefit?

To be included, trials needed to investigate the effects of BT versus BT plus therapy A to address the additive benefit of therapy A to BT. Trials addressing the additional benefit of three other treatments were found: caffeine reduction, PFMT, and drug therapy. The trial addressing the added benefit of caffeine reduction [55] is considered in the section on Lifestyle Interventions (B.1.2d), and the trial addressing the added benefit of PFMT [188] is considered in the section on PFMT (B.2.3e). The trials addressing the added benefit of drug therapy are considered below.

One RCT was found that compared BT alone versus BT with tolterodine (2mg, twice daily) in 99 women with OAB [267]. However, incontinence status of the participants was unknown, and details regarding the study methodology were limited (abstract only). Therefore this trial was not considered further in this section.

A further three RCTs compared BT with placebo drug versus BT with drug therapy in patients with DO. One of these used terodoline (a drug that was withdrawn from the market) [269]. Therefore, this trial was not considered further in this section. In the other two trials the drugs used were imipramine [277] and immediate release oxybutynin [268].

Castleden (1986) studied 34 patients with DO (28
women aged 30 to 91 years and six men). Szonyi (1995) recruited 60 patients aged 70 years and over (56 women, four men). While it is possible that the placebo drug could augment BT, and both these trials included a small number of men in addition to women (and data for women were not reported separately), a pragmatic decision was made to review these two trials in this section.

1. QUALITY OF DATA

Neither Castleden (1986) nor Szonyi (1995) reported adequate random allocation concealment, or blinding. In Szonyi (1995) study size was based on a power calculation. Post-treatment follow up periods were variable. One trial evaluated participants at six weeks [268]; 16 were lost to follow up. The other trial did not have a clear endpoint but followed participants for one to 11 months; one participant was lost to follow-up [277].

2. RESULTS

It was not possible to discern the treatment effects in women only in these two trials, and the findings were inconsistent. Castleden (1986) found that more patients became dry on BT plus imipramine 25mg or more per day (14 of 19) compared to those in the BT plus placebo group (six of 14), but the authors reported that there was no statistically significant difference in outcome between the two groups. One patient in the imipramine group became confused and another complained that the drug made him feel ill. Several patients taking imipramine reported dry mouth and constipation (data not reported), but none on placebo.

Szonyi (1995) found no difference between BT plus 2.5mg of immediate release oxybutynin (twice daily) compared to BT and placebo for reducing incontinent episodes. Szonyi (1995) concluded, however, that the combined therapy group was superior to the BT and placebo group, because it had greater subjective benefit (86% versus 55%), and adverse events were similar in the two groups at 50%.

SUMMARY

In two small trials comparing BT plus placebo drug versus BT plus drug in DO, there was a suggestion that the effect of BT might be enhanced by active drug (Level of Evidence: 2). However both trials were small, placebo controlled, conducted in gender mixed sample populations, and the outcomes were not common to both trials. Thus, there is insufficient evidence to derive a conclusion related to the effectiveness of augmenting BT with drug therapy.

e) Does the addition of BT to any other treatment add benefit?

To be included, trials needed to investigate the effects of Therapy A versus Therapy A plus BT to assess the added benefit of BT over Therapy A alone. Trials were located that investigated the effects of PFMT alone versus PFMT plus BT, and drug therapy alone versus BT plus drug therapy.

Wyman (1998) compared the efficacy of BT, PFMT, and combination therapy in 204 community dwelling women aged 45 years and older with SUI and/or DO [188].

Two RCTs were identified that compared BT plus tolterodine (2mg twice daily) [267, 272] to drug therapy alone. In a three arm trial, Park (2002) included 99 women with OAB but it was unclear if UI was present. Therefore this trial was not considered further.

1. QUALITY OF DATA

i) BT plus PFMT versus PFMT alone: In a three arm RCT (n=204) Wyman (1998) randomised 136 women to PFMT (n=69) or PFMT with BT (n=67). Outcomes were assessed after the 12 week intervention and three months later. It was not clear if random allocation was adequate or outcome assessors were blind. Study size was based on a power calculation. Losses to follow-up were six at 12 weeks, and 16 three months later.

ii) BT plus drug therapy versus drug therapy alone: Mattiasson (2003) evaluated “simplified” BT (consisting of a one page instruction sheet) in a single blind study of 501 participants (378 women and 123 men) aged 18 years and over with OAB with or without UUI. Allocation concealment, blinding of assessors, and a priori power calculation were not described. Post-treatment follow up was 12 weeks, and then 24 weeks. Seven participants were lost to follow-up; five in drug therapy and two in combination therapy. Analyses were based on intent-to-treat principles. However, because of reporting issues, it was not possible to discern the effect of treatment in women alone.

2. RESULTS

i) BT plus PFMT versus PFMT alone: Post-treatment the combination therapy group had significantly fewer incontinence episodes compared to PFMT alone. More women in the combination therapy group than PFMT group reported cure (31% versus 13% respectively), or 50% improvement or more (70% versus 50%).

The combination therapy group also reported greater perception of improvement and more satisfaction with treatment than PFMT alone. However, three months later between group differences were not statistically significantly different for cure (27% versus 20%), improvement (59% versus 56%), perception of improvement, or satisfaction with treatment.
**ii) BT plus drug therapy versus drug therapy alone:**
Mattiasson (2003) reported no difference between participants who received brief written BT instructions plus tolterodine versus tolterodine alone with respect to reducing incontinent episodes (median reduction 87% versus 81%, respectively). Data were combined for men and women and most data were not presented separately for those who had UI versus those who did not.

**SUMMARY**
A single trial found that combining BT with PFMT improves short-term outcomes compared to PFMT alone, but the added benefit did not persist three months later. There is no evidence for an added benefit of combining brief written BT instructions with tolterodine (2mg twice daily) compared to tolterodine alone for urge incontinence (Level of Evidence: 2), although this trial included men and women and it is not known if one gender did better than the other with respect to outcome.

**Recommendations**
For women taking an antimuscarinic drug there may be no clinical benefit in adding brief written instruction in BT (Grade of Recommendation: B). More research is needed using an appropriately supervised BT programme (see B.6.2a) combined with anticholinergic or antimuscarinic drug therapies versus drug alone.

**f) Timed voiding**
There are anecdotal reports that timed voiding involving a two or three hour schedule may be beneficial in clinical practice. A Cochrane review on timed voiding for management of UI in adults was published in 2007 [257]. A previous literature review was published in 1986 [253].

Ostaszkiewicz (2007) considered randomised and quasi-randomised trials only and identified two trials that compared timed voiding combined with additional interventions (including medications) to usual care. Both trials were conducted in nursing facilities and most participants were elderly women with cognitive impairment, therefore neither study recruited participants that met the criteria of interest for this chapter.

Two non-randomised studies that were not included in the Cochrane review reported findings related to the effects of timed voiding in women with UUI, stable bladders with UUI, and MUI [279, 280]. Klariskov (1986) reported a consecutive series of 20 women aged 27 to 75 years with a double-blind crossover to compare timed voiding plus anticholinergic drug therapy (terodoline) to timed voiding plus placebo. As terodoline has been withdrawn from the market, this study is not considered further.

**1. QUALITY OF DATA**
Godec (1984) reported a case series report involved 20 women aged 24 to 94 years in women with a mild degree of UI, irregular voiding patterns, and normal urodynamic parameters (UI type not clearly reported) [279]. The voiding schedule consisted of a two hour voiding interval. Follow-up periods ranged from six weeks to eight months after treatment [279].

**2. RESULTS**
Godec (1984), reported a 79% success rate (not objectively quantified). Fifteen patients became totally continent, one had less leakage, three (with neurogenic diseases) remained unchanged, and one patient was lost to follow-up.

**SUMMARY**
There are no RCTs, or high quality observational studies, providing evidence on the effects of timed voiding for UI in women. Based upon the data from one small uncontrolled study, it seems a two hour timed voiding schedule may be beneficial in treating women with mild UI, infrequent voiding patterns, and stable bladder function (Level of Evidence: 3).

**Recommendations**
Timed voiding with a two hour voiding interval may be beneficial as a sole intervention for women with mild UI infrequent voiding patterns (Grade of Recommendation: C). It may also be helpful as an adjunct to other treatment.

**3. OTHER LUTS**
One trial was excluded from sections above, because it recruited participants with OAB and the continence status of participants was not clear [267]. Park (2002) compared BT versus tolterodine (2mg, twice daily) versus the combination of BT and tolterodine in 99 women with OAB [267]; this study was reported as a conference abstract. Park (2002) found that the tolterodine/BT group had greater reductions in diurnal micturition (32.6%), nocturnal micturition (63.2%), urgency scores (63.2%), and bladder symptom improvement rates (69.3%) than those in BT alone (27.1%, 55.8%, 48.4%, 50%, respectively) or tolterodine alone (30.3%, 61.9%, 62.5%, 58.3%, respectively). However, only the bladder symptom improvement scores were statistically significantly better in the combination therapy group. Thus, it is not clear if BT alone, tolterodine alone, or the combination, is better for LUTS other than UI in women with OAB symptoms.

The most common LUTS, aside from UI, are urgency, daytime (or diurnal) frequency and nocturia. Some trials that contributed to the sections above reported data specifically for these symptoms.
a) Urgency: Jarvis (1981) compared BT and drug therapy (flavoxate and imipramine), and 16% versus 44% of participants reported they continued to experience urgency post-treatment. Mattiasson (2003) compared BT with tolterodine versus tolterodine alone and patient rating of urgency was somewhat less in the combination therapy group.

b) Daytime (diurnal) frequency: Data on frequency are more commonly collected that data on urgency. Three trials reported diurnal frequency in comparisons of BT with no treatment. Jarvis (1980) reported a small controlled trial of inpatient bladder drill for DO [270]. After BT 17% in the treatment group and 77% in the control group continued to have symptoms of diurnal frequency. Fantl (1991), in subgroup analyses, found a significant reduction in diurnal frequency in participants with urodynamic SUI who had a baseline diurnal micturition frequency of at least 61 per week, and also in participants with DO with or without urodynamic SUI who had at least 57 diurnal micturitions per week [255]. Finally, Yoon (2003) reported that the BT group significantly reduced diurnal micturitions, whereas the control group deteriorated slightly [151].

Two trials compared BT with drug therapy. Jarvis (1981) reported that 24% of the BT group continued to experience frequency as compared to 48% of the drug group (flavoxate and imipramine) [271]. Columbo (1995) found that diurnal frequency was resolved in 18 (56%) of 32 patients taking oxybutynin versus 20 (69%) of 29 BT patients [276].

Another trial compared BT plus placebo versus BT plus drug [268]. Szonyi (1995) found that there was a greater reduction in diurnal micturition frequencies in participants taking oxybutynin alongside BT compared to those on placebo and BT. Similarly, in a trial of BT plus drug versus drug alone Mattiasson (2003) found that “simplified” BT significantly augmented the effect of tolterodine compared to drug alone for voiding frequency (33% versus 25% improvement, respectively; p<0.001).

c) Nocturia: Three trials reported data on nocturia in comparisons of BT with no treatment. Jarvis (1980) reported a small controlled trial of inpatient bladder drill for DO. After bladder training, there were 11% in the treatment group and 80% in the control group who continued to have symptoms of nocturnal frequency [270]. Fantl (1991) also found significant reductions in nocturnal frequency [255].

In subgroup analyses, nocturnal micturitions were only significantly decreased in women with urodynamic SUI alone, who experienced at least five episodes of nocturia per week, and not in those who had DO. Yoon (2003) reported that the BT group significantly reduced nocturnal micturitions, whereas the control group deteriorated slightly [151].

Two trials compared BT with drug therapy. Jarvis (1981) reported that the 19% of the BT group continued to experience nocturia compared to 68% of the drug group (flavoxate and imipramine) [271]. Columbo (1995) found that nocturia disappeared in three (27%) of 11 patients taking oxybutynin and 11 (61%) of 18 BT patients [276]. Another trial compared BT plus placebo versus BT plus drug [268]. Szonyi (1995) found no difference in nocturnal micturition frequencies.

Summary

Scheduled voiding regimens have been implemented in many forms and with a variety of intensities, ranging from strict in-patient regimens to simple instruction sheets. Most research has examined BT, and most of these trials have recruited women with symptoms of UUI or OAB. It is therefore disappointing that there is so little data about LUTS other than UI. The indications so far are that BT is effective for reducing UI, as well as frequency of micturition. The scant research comparing BT to drug therapy is inconsistent with some evidence for the superiority of each. It is not yet clear whether drug therapy can enhance BT, or whether BT can enhance UI outcomes from drug therapy, although it appears that reductions in frequency of micturition may be greater with the addition of BT.

4. FACTORS AFFECTING OUTCOME

a) Age

All trials with the exception of two RCTs [151, 275] included older women in their study populations. Three trials specifically recruited elderly women aged 65 to 70 years and over [268, 269, 277]; and two trials recruited women aged 55 years and over [255, 273]. In conducting analyses of factors predicting outcomes of BT alone, two trials reported that age was not a factor in treatment outcome [188]. Similarly, age was also not a predictor of outcome in a trial incorporating an intervention in which three consecutive interventions could be implemented depending on participant goals (self-monitoring, BT, PFMT) [273].

b) Other

Few BT trials examined other predictors of treatment response. Several trials discussed the effect of diagnosis on treatment outcome. Two trials reported that urodynamic diagnosis did not have an effect on treatment outcome as measured by incontinent episodes and the Incontinence Impact Questionnaire [188, 255]. These RCTs included women with urodynamic SUI, DO, or both diagnoses. BT also led to more clinical cures in one small drug trial. BT in women with sensory urgency (81%) and low compliance bladders (75%) produced better outcomes than in those on oxybutynin immediate release (60%, 67%, respectively); however, oxybutynin led to greater cure rates in patients with DO (93% versus 62%).
VII. COMPLEMENTARY AND ALTERNATIVE MEDICINES

There is emerging evidence that complementary and alternative medicines (CAMs) may influence both physiologic function and health outcomes. CAMs include those therapies that are not part of the traditional biomedical model, such as meditation, imagery, hypnosis, acupuncture and naturopathic and herbal remedies. While some consider BF part of complementary therapy, we have included BF in this chapter as an adjunct to physical therapies.

A search of AMED (Allied and Complementary Medicine) using the key words randomized controlled trials, and urine or urinary, retrieved 18 records. None of these reported a randomised controlled trial investigating the effect of CAMs that had not already been considered in this chapter.

No trials were found in a similar search when the report for the 3rd Consultation was prepared. A decision was made not to update this section of the report based on further uncontrolled studies.

Given the high placebo response rate in many studies of conservative therapies for UI it is crucial that further studies of CAMs include a control group. When placebo treatment is not possible due to the nature of the intervention, a standard treatment control group should be used.

Interested readers are referred to the report from the 3rd Consultation for the previous summary of the few uncontrolled studies of CAMs found prior to 2005.

VIII. SUMMARY

Some aspects of the conservative management of UI in women have received the bulk of research attention to date, such as the effect of PFMT. There are other areas, such as the effect of lifestyle interventions, which have received little. Although a reasonable number of trials were found investigating the effects of conservative management of UI in women, the standards of trial conduct and reporting vary considerably and the size of the trials is often small. All these factors contribute to the lack of data that can meaningfully be compared.

1. RECOMMENDATIONS FOR PRACTICE

While there are some recommendations underpinned by good and consistent evidence of effect, there are also many recommendations that are essentially hypotheses that need further testing because there is insufficient Level 1 or 2 evidence to be sure about the effect of an intervention.

a) Lifestyle interventions

- For morbidly and moderately obese women weight loss is a useful treatment to reduce UI prevalence (Grade of Recommendation: A) (Changed).
- A reduction in caffeine intake may help those with incontinence symptoms (Grade of Recommendation: B) (Changed).
- Given the fact that decreasing fluids may lead to urinary tract infections, constipation, or dehydration, this intervention should be reserved for patients with abnormally high fluid intakes (Grade of Recommendation: C) (Unchanged).
- Crossing the legs and bending forward might be useful in reducing leakage during coughing or other provocation (Grade of Recommendation: C) (Unchanged).

b) Pelvic floor muscle training (PFMT): Principal recommendations

The principal recommendations of the committee are that:

- PFMT is offered as first line conservative therapy to women with stress, urge, or mixed urinary incontinence (Grade of Recommendation: A) (Unchanged).
- Clinicians should provide the most intensive PFMT programme possible (in terms of exercise dose and health professional supervision) within service constraints because health professional taught and supervised programmes are better than self-directed programmes, and more health professional contact is better than less (Grade of Recommendation: A) (Changed).
- There does not appear to any benefit of adding clinic BF (Grade of Recommendation: A), or home based BF (Grade of Recommendation: B) to the PFMT programme (Changed).

b) Pelvic floor muscle training (PFMT): Other recommendations

The recommendations that follow may help with decision making in specific groups. Most of these are essentially hypotheses that need further testing.

Pregnant women expecting their first baby:

- Should be offered an intensive strengthening antepartum PFMT, with regular health professional contact to supervise training, to prevent postpartum urinary incontinence (Grades of Recommendation: A (for women continent at 18 weeks) and B (for population approaches, that is intervention offered whether women are continent or not at 20 weeks gestation)) (Changed).
Postnatal women, immediately after delivery:
- Who had a vaginal delivery of a large baby (4000g or more) or a forceps delivery will benefit from an individually taught PFMT programme that incorporates adherence strategies (Grade of Recommendation: C) (Unchanged).

For postnatal women with persistent symptoms of UI three months after delivery:
- PFMT is offered as first line conservative therapy (Grade of Recommendation: A) (Changed).
- The ‘best’ PFMT programmes are ‘intensive’ with regard to supervision and exercise content (Grade of Recommendation: B) (Changed).

For women with SUI:
- PFMT is better than EStim as first line conservative therapy, particularly if PFMT is intensively supervised (Grade of Recommendation: B) (Unchanged).
- PFMT is better than BT as first line conservative therapy (Grade of Recommendation: B) (Changed).
- PFMT and duloxetine are both effective therapies, although clinicians and women may choose to try PFMT first because of the side effects experienced with the drug (Grade of Recommendation: C) (New).
- PFMT and surgery are both effective therapies, although many clinicians and women may prefer PFMT as a first choice therapy because it is less invasive (Grade of Recommendation: C) (Changed).

For women with SUI or MUI:
- PFMT and VC are both effective therapies, although it seems PFMT is better as a first choice because of better leakage outcomes and because some women cannot or do not like to use cones (Grade of Recommendation: B) (Changed).
- PFMT is better than clenbuterol or phenylpropanolamine hydrochloride as first line therapy because of the side effects experienced with the medications (Grade of Recommendation: B) (Unchanged).
- A combination of PFMT/BT may be better than PFMT alone in the short-term (Grade of Recommendation: C).

For women with UUI or MUI:
- PFMT and BT are both effective first line conservative therapy (Grade of Recommendation: B) (Unchanged).
- PFMT is better than oxybutynin as first line therapy (Grade of Recommendation: B) (Unchanged).

**d) Vaginal cones (VC)**

For women with SUI or MUI:
- VC can be offered as first line conservative therapy to those who can and are prepared to use them (Grade of Recommendation: B); VC may be inappropriate in some cases due to side effects and discomfort.
- VC and EStim seem equally effective in the treatment of SUI and MUI, but the usefulness of VC and EStim in practice might be limited because of side effects and discomfort (Grade of Recommendation: B).

**e) Electrical stimulation (EStim)**

While the usefulness of EStim in practice might be limited because some women cannot use it (due to contraindications), have difficulty using it, or dislike it:
- For women with SUI, (a) six months of 50Hz daily EStim at home might be better than no treatment (Grade of Recommendation: C) (New), and (b) low intensity home based EStim daily for six months might be better than 16 sessions of maximal clinic based EStim (Grade of Recommendation: C) (New).
- For women with DO nine weeks of 4 to 10Hz twice daily EStim at home might be better than no treatment (Grade of Recommendation: C) (New).
- The addition of EStim to a BF assisted PFMT programme does not appear to add benefit (Grade of Recommendation: C) (New).

**f) Magnetic stimulation (MStim)**

- Any clinical use of MStim should only be in the context of a randomised clinical trial as the benefit of this intervention has not been established (Grade of Recommendation: D) (New).

**g) Bladder training (BT)**

With regard to Grade A recommendations for BT:
- BT is an appropriate a first line treatment for UI in women (Unchanged).

Grade B recommendations are:
- Either BT or antimuscarinic drug may be effective (Unchanged), although BT may be preferred by some because it does not produce the side effects and adverse events associated with drug therapy.
- There may be no benefit in adding brief written instruction in BT to drug therapy (New).
- For women with symptoms of SUI or MUI a combination of PFMT/BT may be better than PFMT alone in the short-term (Unchanged).

There are two Grade D recommendations, drawn
from expert opinion and narrative review of the existing literature, being:

• Clinicians and researchers should refer to the operant conditioning and educational literature to provide a rationale for their choice of training parameters or approach (New).
• Clinicians should provide the most intensive BT supervision that is possible within service constraints (New).

h) Timed voiding

• Timed voiding with a two hour voiding interval may be beneficial as a sole intervention for women with mild UI infrequent voiding patterns (Grade of Recommendation: C) (Unchanged).

2. FUTURE RESEARCH DIRECTIONS

There continues to be much scope for research on the effects of conservative therapies for UI and LUTS in women. Research that is urgently needed, in the opinion of the committee members, is highlighted with the use of italics. There are a few recommendations that apply to all further studies in women, namely:

• All future trials must be designed, implemented and reported in ways that maximise their usefulness in practice; this includes evaluation of cost-effectiveness and planned secondary analysis of trial data to investigate factors affecting outcome. Readers are referred to the revised CONSORT statement for guidance.
• Studies need to be larger, with longer follow up.
• Future trials should use a validated and reliable quality life measure as the primary outcome.

a) Lifestyle interventions

• The dual issues of weight loss and prevention of weight gain (and the role of exercise in these) should receive high research priority in UI research given the prevalence of both UI and obesity in women.
• Given the large proportion of women employed in occupations that require heavy lifting the association of such exertions and UI should be investigate further. Specifically research must establish whether heavy exertion is an etiologic factor in the pathogenesis of UI and whether changing exertions can alleviate established UI.
• Further prospective studies are needed to determine whether smoking cessation prevents the onset, or promotes the resolution, of UI.
• Larger RCTs to assess the effect of dietary factors, in particular caffeine reduction, are feasible and important.
• Further research is needed to delineate the role of straining in the pathogenesis of UI.
• High quality studies evaluating the effect of all other lifestyle interventions on UI are warranted.
• Future work should separately evaluate the impact of lifestyle interventions on nocturia, diurnal frequency, urgency and UI to delineate whether certain interventions preferentially affect different areas of OAB.

b) Pelvic floor muscle training (PFMT)

In antenatal and postnatal women, trials are needed to investigate:

• The effect of antepartum PFMT on preventing postpartum UI in multiparous women.
• The effect of a postpartum PFMT programme (suitable exercise dose and supervision) in the long term (five plus years).
• The effect of periodic refresher sessions after an initial supervised postpartum PFMT programme, in the long term (five plus years).

In all women, trials are needed to investigate:

• The effects of PFMT in the long term (five plus years)
• The effects of different types of PFM exercise (strengthening, endurance, co-ordination, functional training) and supervisory styles (e.g. individual versus group).
• Whether any indirect method of PFMT (Paula method, transversus abdominus training, hip abductor or adductor exercise) might be as effective as direct PFMT, or add benefit to a direct PFMT programme.
• Whether BF may benefit certain women, such as those with a weak PFM or with difficulty contracting the PFM in isolation.
• Whether the addition of any of the following adds benefit to PFMT: intravaginal resistance, cues to exercise, or bladder training.
• Whether the addition of PFMT to either vaginal cones or duloxetine adds benefit.

c) Vaginal cones (VC)

• If the combination of VC with PFMT is an intervention of interest for women then this combination of therapies could be explored further. VC could be used as an overload progression to active PFM strengthening exercises.

Thus, a VC programme could be offered to women with a demonstrated minimum PFM strength level and could be aimed at either additional strength training by pulling on the cone for three series of eight to 12 contractions daily [181], or endurance training, using a low-load over a sustained period of time.
d) Electrical stimulation (EStim) and magnetic stimulation (MStim)

- There is a need for studies to elucidate the purpose and biological rationale for EStim in different diagnostic groups, so these can then be tested and compared in clinical trials.
- Comparisons of EStim with other treatments that seem to be effective such as PFMT, vaginal cones, and bladder training are more important than comparison of EStim with sham.
- There is also scope for trials of EStim as an adjunct to treatments that seem to be effective such as PFMT, vaginal cones, and bladder training.
- Of the MStim protocols investigated to date, it seems that both sacral root MStim and home-based MStim, are worthy of further investigation.

e) Scheduled voiding regimes, especially bladder training (BT)

- There are several BT variables that could be investigated in future trials including the instructional approach, supervisory intensity, strategies for controlling urgency, scheduling parameters, frequency of schedule adjustments, length of treatment, and use of adjunctive treatments.
- Although additional studies are needed that examine the effect of BT versus no treatment, more important clinically are trials of BT versus another active treatment such as PFMT or drug.
- The potential benefits of combining BT and anticholinergic/antimuscarinic drug need further investigation, including comparisons of BT plus drug versus drug alone, and BT plus drug versus BT alone.
- Research is needed on habit training in women with a consistent pattern of UI who are ambulatory and cognitively intact.

**B. URINARY INCONTINENCE IN MEN**

UI in men remains under-reported and under-studied in comparison to studies including women. The report from the 3rd ICI indicated that the prevalence of UI and LUTS in men ranged from eight to 23% depending on the method of data collection, population accessed, and location [281]. Despite the prevalence of UI and LUTS in older men, the only aspect which continues to receive systematic consideration with respect to conservative management is post-prostatectomy urinary symptoms. Thus, the focus of this section is the prevention and treatment of UI after prostatectomy for benign or malignant disease. All prostatectomy types and approaches were considered for inclusion including radical prostatectomy (open radical retropubic or perineal, laparoscopic, and robotic) or endoscopic procedures (such as transurethral prostatic resection, high intensity microwave therapy).

- **Aetiology of UI after prostatectomy**
  For purposes of the current review, the reader is directed to the report from the 3rd ICI [281] in which the aetiology of UI after prostatectomy is covered in detail (see report from Committee 13: Surgery for urinary incontinence in men). In brief, risk factors which have been repeatedly identified for UI after radical prostatectomy and transurethral resection of prostate (TURP) are abnormalities of detrusor contractility [282] and age [283]. Other related factors include neurovascular injury during surgery, previous TURP [284], preoperative radiotherapy, trauma, spinal cord lesion, new obstruction such as prostatic regrowth, bladder neck contracture, urethral stricture, Parkinson’s disease [285, 286], dementia, and medications [281].

- **Treatment**
  The primary conservative treatment for UI after prostatectomy remains physical therapies with or without some form of BF. PFMT, along with anal EStim, BF or transcutaneous electrical nerve stimulation (TENS), MStim, and even pharmaceuticals have all been utilised and reported as modestly successful in some trials and not in others.

A literature search of relevant systematic reviews and reports of RCTs and quasi-RCTs was performed (see appendix). No other types of study design were considered. The report of the 3rd ICI [281] identified 14 relevant RCTs on conservative management of UI post radical prostatectomy (n= 12) or TURP (n=2) [287-300]. Seven new published trials and two abstracts [301, 302] were found, all in men undergoing radical prostatectomy [301-309]. One was excluded as it was not published in English and no translation was available [306]; another trial [288] was not an RCT but assigned the first 25 to control and the next 25 to treatment. This trial had been included in the previous ICI report but has been excluded from the current review because of the potential for bias in a non-randomised trial. Thus, one trial was removed and eight trials added to the current evidence base for a total of 20 trials on some aspect of continence treatment after radical prostatectomy and two on treatment after TURP.

**I. LIFESTYLE INTERVENTIONS**

Typically, as part of standard practice in the treatment of people with UI, lifestyle recommendations are made to stop smoking, maintain a healthy body weight,
avoid or reduce caffeine containing drinks, avoid constipation, and to drink approximately eight glasses of liquid a day. Whether these factors have a direct impact on continence is suggested but not known. To date, no trials have addressed the topic of lifestyle interventions for men with UI. Nevertheless, in practice, it seems reasonable to offer advice on healthy lifestyle choices that may reduce or delay the onset of continence problems.

II. PELVIC FLOOR MUSCLE TRAINING (PFMT)

The quality of trials included in this update of PFMT has improved from earlier ICI reports although heterogeneity and varying outcome measures continue to affect the ability to compare trial findings.

1. PREVENTION

Trials in this section addressed the effect of PFMT initiated preoperatively or postoperatively but before continence/incontinence was established. Four new trials were found [301, 303, 305, 309] making a total of nine trials in this category [287, 294, 295, 297, 300, 301, 303, 305, 309].

Two trials utilised preoperative BF assisted instruction in PFMT followed by postoperative self-PFMT at home, and compared this with postoperative verbal instruction [287], or usual postoperative exercise advice [303]. In Bales (2000) (n=100; 93 completing) initial instruction on PFMT was provided using surface BF two to four weeks prior to radical retropubic prostatectomy. The control group received only postoperative verbal instruction; both groups had written information and were encouraged to practice PFMT four times daily once the catheter was removed two weeks after surgery. In Burgio (2006) (n=125; 102 completed), participants had one BF session (rectal probe with three small balloons) two to four weeks preoperatively, plus daily pre and postoperative home exercises. The control group had no therapist contact and practiced postoperative exercises as per standard care (starting and stopping stream). Primary outcome was continence, defined as use of zero or one pad per day [287] or no leaks recorded on bladder diary [303]. In Lilli (2006) (reported only in abstract), 90 participants (all completed) were assigned to PFMT plus BF (method/type not described) or PFMT alone. Both groups were encouraged to do home exercises. Primary outcome was pad use, assessed at one, three, and six months post surgery.

One trial compared active pre- and post-operative PFMT programme to no PFMT instruction [297] and another pre- and post-operative instruction versus post-operative instruction [295]. Participants in Parekh (2003) (n=38; 36 completing) had two pre-operative and four post-operative sessions of anal probe BF plus post-operative home PFMT using an exercise ball, or no intervention (similar to Burgio (2006) above). Continence was assessed by patient reported number of pads and continence questionnaires at six, 12, 16, 20, 28 and 52 weeks post surgery. Sveppel (2001) randomised 16 men (no dropouts) to two pre-operative and five post-operative sessions of anal probe BF or five post-operative sessions. Both groups were asked to do self directed home PFMT. Continence and quality of life were assessed by AUA symptom score and quality of life questionnaire, pad count, 45 minute standardised pad test, and a leakage questionnaire at six weeks and one year post surgery.

In the study by Mathewson-Chapman (1997) all 51 (50 completing) participants had one session of preoperative instruction using BF and verbal coaching and were then randomised to intervention or control groups. The intervention group (n=26) practised PFMT daily with a home BF unit (anal probe) from weeks three to 12 after surgery, whereas the control group (n=24) only followed written instructions. Both groups completed questionnaires, pad counts, and 24 hour pad tests at two, five and 12 weeks post-operatively.

Finally, three trials commenced post-operative PFMT immediately after catheter removal [300, 305, 309]. Filocamo (2005) randomised 300 men to a PFMT programme or no formal instruction. Outcomes were ICS Male Questionnaire (ICS MaleQ), pad count, and pad test (one and 24 hours). Overgård (in press 2008) assigned 85 men (80 completing) preoperatively to one of two groups: 42 received weekly 45 minute PFMT guided by a physiotherapist and 43 received one PFMT training session then practiced home exercises. Outcomes were proportion of continent men, defined as self-report of no pads, 24 hour pad test, subject report and PFM strength obtained at six, 12, 24 and 52 weeks post surgery. Immediately after catheter removal, Wille (2003) assigned 139 subjects (128 completing) to one of three active groups: PFMT (method unclear), encouragement to do home exercises, and a three week rehabilitation programme (not described); twice daily PFMT with ESTim taught with surface anal electrodes, or PFMT with ESTim and BF using anal probe. All subjects received three therapist guided sessions immediately after surgery and at three and six weeks plus performed PFMT at home; the two intervention groups also utilised an ESTim or BF device twice daily at home (see also C.3). Outcomes were pad count with continence defined as use of zero to one pad per day or 20 minute pad test (continence was less than 1g urine loss) collected at three and 12 months post surgery.

1. QUALITY OF DATA

Of the nine trials in this section, only Burgio (2006) reported adequate random allocation concealment. With regard to blinding of outcome assessment, Bales (2000) attempted to control for bias in outcome...
assistance by having a nurse not directly involved in the study interview the subjects. It is not clear whether he/she was blinded to allocation group. Overgärd (in press 2008) had surgeons blinded to group allocation. Wille (2003) had data analysed by a professional statistician. Burgio (2006) had outcomes assessors blinded to group assignment. Dropouts were described by Burgio (2006), Filocamo (2005), Overgärd (2008), and number of dropouts was provided by Wille (2003) but reasons were not described. Sueppel (2001) indicated incomplete data but did not describe dropouts. Burgio (2006), Filocamo (2005) and Wille (2003) described ITT analysis.

2. RESULTS

i) Preoperative PFMT instruction with postoperative home PFMT versus control [287, 301, 303]: Burgio (2006) reported a statistically significant difference in favour of PFMT in time to regain continence (p=0.03) and proportion of men with severe or continual leakage measured by voiding diary at six months, 32/54 PFMT (59%) versus 40/51 controls (78%) (p=0.04); additional data provided by the authors on the 24 hour pad test did not indicate a difference between groups. Bales (2000) found no significant group difference on participant report of number of pads used or time to return to continence. Lilli (2006) did not find a difference between participants who received BF in addition to PFMT at any of the time points; at six months, 32/45 (71%) and 30/45(67%) respectively were reported as dry and no use of pads. In the Lilli trial both groups received intervention and it is not clear how intensive the pre-operative PFMT instruction was.

ii) Pre-operative PFMT instruction followed by supervised post-operative PFMT versus postoperative PFMT [294, 295, 297]: Parekh (2003) found more men continent in the pre and post treatment group at 12 weeks but there was no statistically significant difference at any other time point to 12 months. Sueppel (2001) reported that at one year the pre and post treatment group had less leakage on a standardised 45 minute pad test compared to the postoperative group (mean 2.8g (range 0.0-13.0g) versus 33.3g (range 0 to 194g)); statistical significance was not reported. Mathewson-Chapman (1997) found no statistically significant differences between groups at any of the time points.

iii) Post-operative PFMT immediately after catheter removal (no pre-operative instruction) [300, 305, 309]: The Filocamo (2005) trial favoured treatment at three months with 39/50 (78%) versus 105/150 (70%) reporting one or fewer pads a day. At six months 115 in the treatment group and 48 in the control reported themselves as ‘completely dry’ and at 12 months 134 and 101 were dry respectively. Differences between treatment and control were 96% versus 65% (p=0.00001) at six months and at one year 99% and 88% (not significant). There were no significant differences between groups on 24 hour pad test (Filocamo, personal communication). Overgärd (in press 2008) reported no difference between groups for proportion dry (no pads) or 24 hour pad test at three months; however, at 12 months, the proportion of continent men was statistically significantly greater in the treatment group (33/36; 96%) versus the control (28/39; 72%) (p=0.028). PFM strength and 24 hour pad test results did not differ between groups at any of the time points. Of note is that 20 participants in the treatment group did not receive face to face instruction due to distance from facility but rather followed detailed instructions provided on a DVD. Wille (2003) did not find a difference between groups at three and 12 months but all three groups received some sort of intervention.

SUMMARY

Nine trials were found addressing prevention of UI in a total of 803 men and used a variety of pre-operative or post-operative PFMT based interventions, or a combination of both. Any differences between experimental and control groups were modest and short term; differences did not appear to be sustained up to 12 months post surgery. A particular challenge in evaluating the trials is that participant reported outcomes in three of the recent studies [303, 305, 309] all indicate some level of improvement in the treatment groups; however, there are no clear differences in pad test results in any of the nine trials. Because all the studies reviewed were generally small, varied in design, and measures differed, it is difficult to interpret them as a whole. Whilst the evidence that therapist delivered PFMT with or without BF before or after surgery improves continence recovery after radical prostatectomy remains inconsistent; a growing number of recent trials suggest that men who undergo some sort of conservative management including PFMT will achieve continence in a shorter time frame than non-treated men but this difference is not significant at 12 months post surgery (Level of Evidence: 2).

Further discussion is needed on the outcomes of most importance. It is possible that the emphasis on quantitative outcomes is not meaningful to participants; men appear to find therapy personally helpful and value the direction provided by a therapist.

RECOMMENDATIONS

Some preoperative or immediate post-operative instruction in PFMT for men undergoing radical prostatectomy may be helpful (Grade of Recommendation: B); whether this is in the form of ‘hands on’ therapy of verbal instruction and support
remains unclear. Studies comparing the effectiveness of pre- versus post-operative PFMT, and the number of sessions required, are needed so that practitioners may advise men about pre-operative preparation and budget conscious health boards can make informed decisions on programme funding. In designing such studies, the natural history of UI after radical prostatectomy must be taken into account because the spontaneous recovery rate means that sample sizes must be large to detect any differences between protocols.

2. TREATMENT

a) PFMT with digital rectal feedback after radical prostatectomy

Two additional trials were identified [304, 307] resulting in a total of four [292, 293, 304, 307] in which PFMT was taught using digital rectal feedback (DRE) in at least one arm.

Dubbleman (2004) randomised 70 (63 completed) men to physiotherapy (not described) or written material on PFMT. Subjects received nine or fewer therapist-guided PFMT sessions using DRE starting at one week postoperatively. Joseph (2000) randomised a mixed group of 10 men (four radical retropubic prostatectomy and six radical perineal prostatectomy) to weekly verbal teaching plus DRE or BF assisted PFMT over a four week period. Manassero (2007) randomised 107 (94 completed) men to urologist taught PFMT using DRE (unclear how often) plus daily home exercises for up to a year; the control group did not receive any instruction. Participants were assessed at one, three, six and 12 months with a home pad test, VAS and DRE. In Moore (1999) 63 men (58 completed) were randomised to one of three groups: control (written materials only and no therapist contact), PFMT using DRE and abdominal palpation, or PFMT augmented with EStim via anal probe. Both treatment groups met with the therapist twice a week for up to 12 weeks.

1. QUALITY OF DATA

Only one trial [293] reported adequate random allocation concealment. Data were collected by blinded assessors in one trial [307]. In another, data were collected and outcomes assessed by the primary investigator who had a direct involvement in the trial, although treatment was provided by a therapist blinded to the control group outcomes [293]. Three studies described reasons for dropout [293, 304, 307], but none indicated how withdrawals/dropouts were dealt with in the analysis.

There was considerable variation in the type and intensity of interventions, follow-up ranged from six and a half months to 12 months, and primary outcomes varied from pad test, pad count or subject report.

2. RESULTS

Between them, the four trials had a total of 225 participants with complete data. Three of the four studies did not find statistically significant differences between the groups. Dubbelman (2004) found no significant differences at 26 weeks post catheter removal between physiotherapy and written PFMT information groups in one and 24 hour pad tests. Similarly, in the small study by Joseph (2000) no differences were found in outcomes measured by 24 hour pad test, voiding diary or quality of life (IIQ-7) between PFMT and PFMT with BF groups. Moore (1999) found no differences in pad test between PFMT and PFMT with EStim groups but confidence intervals were wide and subjects began treatment anywhere between eight weeks and 12 months post surgery.

Manassero (2007) reported a statistically significant difference (p=0.01) in proportion of continent subjects (<2g on 24 hour pad test) in the PFMT group at three, six and 12 months (54%, 33%, 17% compared to 78%, 60%, and 53% for the controls), with 9/54 versus 21/40 incontinent at 12 months.

SUMMARY

In the most recent and largest trial [307], which compared PFMT taught by DRE or no instruction there was a statistically significant difference in the proportion of continent men (based on 24 hour pad test) in the treatment group at three, six and 12 months. In the three other smaller and earlier trials, in which the control groups had written or verbal instruction on PFMT, there were no statistically significant differences between groups on pad test. (Level of Evidence: 2). Clinical heterogeneity meant that it was difficult to consider the findings from the studies as a whole.

RECOMMENDATIONS

Some instruction in PFMT may be helpful; it is not clear whether PFMT taught by DRE offers any benefit over and above verbal or written instruction (Grade of Recommendation: B). Further well designed studies are needed to test this hypothesis.

b) PFMT with BF after radical prostatectomy

Two new trials were available [308][302] abstract only), to make a total of six evaluating PFMT with BF compared to a non active or alternate treatment commencing after radical prostatectomy [290, 291, 296, 299, 302, 308].

Three of these trials compared PFMT with BF versus no treatment, placebo treatment, or usual care. Franke (2000) randomised participants (n=30; 15 completing) to PFMT with BF versus no treatment. PFMT was delivered via BF from perineal patch electromyography
in weeks six, seven, nine, 11 and 16 postoperatively, supplemented with home exercises. The control group received no written or verbal instruction about PFMT. Outcomes were number of incontinent episodes and 48 hour pad test averaged over 24 hours. Van Kampen (2000) randomised 102 men (98 completing) to PFMT with BF or placebo EStim. Treatment group subjects received detailed instruction on PFMT, received active treatment once a week and practiced home exercises three times a day; the control did not receive any instruction and had weekly placebo EStim. Both groups did home 24 hour pad tests daily until continent and practiced home exercises. Continence was measured by 48 hour pad test.

Three trials compared PFMT with BF versus verbal instruction and home PFMT [290, 296, 308]. Floratos (2002) randomised 42 men (all completed) to PFMT with EMG BF, 15 sessions three times a week for five weeks or one session of DRE guidance and verbal instruction starting approximately one week after catheter removal. Both groups practiced daily PFMT at home. Primary outcome was one hour pad test at one, two, three and six months. Moore (in press 2008) compared verbal instruction and written materials on home exercises versus weekly therapist provided PFMT with BF via anal probe plus daily home exercises (n=205; 166 completing). Primary outcomes were 24 hour pad test at four, eight, 12, 16, 28, and 52 weeks post surgery. Opsomer (1994) randomised 43 (39 completing) men to two sessions a week of PFMT with BF plus EStim (method not described) or to one session of verbal instruction on PFMT plus home exercises. Continence was measured by 48 hour pad test.

1. Quality of data

Two trials appeared to have adequate random allocation and concealment [299, 308], although in the latter treatment was provided by the primary investigator who was aware of group assignment. In Moore (in press 2008), therapists were blinded to the results of the control group; pads were weighed by a person unaware of group assignment; data was entered by a data manager. Van Kampen (2000) had pad weights done directly by the patient at home. Dropouts were accounted for and described fully by Moore (in press 2008) and Van Kampen (2000), partially by Opsomer (1994). There was a high dropout rate in Franke (2000) and these data were not accounted for in the analysis. There were no reported dropouts in the Floratos (2002) or Ribeiro (2008) trials. Floratos (2002), Moore (in press 2008), Van Kampen (2000) all described ITT analysis.

Continence evaluation was different for each study as well as timing of recruitment and intervention, content of intervention and control treatments. Outcomes varied widely: percentage of participants pad free [291], one hour pad test [290], 24 hour pad test (<2g=continent, Ribeiro 2008; Van Kampen 2000; <8g=continent, Moore (in press 2008) and a pad test not described [296]. Follow up ranged from 12 weeks to one year.

2. Results

Three trials compared PFMT and BF to a control condition. At 12 weeks, Ribeiro (2008) reported statistically significant difference in 24 hour pad tests (51g, SD 119 versus 197g, SD 269, p=0.026), but there was no statistically significant difference at six months post surgery.

In the Van Kampen (2000) trial at eight weeks, there was a statistically significant difference in mean urine loss (30g treatment; 82g control) but by 12 weeks this difference was no longer statistically significant. Van Kampen (2000) also found a statistically significant difference in proportion of treatment group participants reporting continence at three months compared to control (43/50 (88%) versus 29/52 (56%)), but no differences beyond three months. Franke (2000) reported no difference between groups on 24 hour pad test or pad-free rates but sample was small and dropout rate nearly 50%.

None of the three trials that utilised PFMT and BF versus verbal or written instruction on home PFMT showed statistically significant differences between the groups. Outcomes were measured using one hour pad test or number of pads [290], 24 hour pad test, International Prostate Symptom Score (IPSS), or subjective report of continence at eight, 12, 16, 18, or 52 weeks [308], and pad test at 12 weeks [296].

Summary

Health professional instruction in PFMT with BF when compared with control conditions seemed to reduce the amount of leakage in the early weeks of recovery (up to three months). However, comparisons of PFMT with clinic BF versus PFMT at home did not find similar differences. Based on the current evidence the addition of EStim or BF does not appear to improve continence outcomes over and above PFMT. (Level of Evidence: 2). However, BF may be less difficult for the therapist than DRE.

It seems those who do PFMT compared to no active treatment, might have less leakage in the first three months postoperatively. To the patient, this early improvement may be important in activity, wellbeing, and socialising. Such concepts require further investigation.
RECOMMENDATIONS

The use of BF in clinic, over and above home PFMT, is currently a therapist/patient decision based on economics and preference. (Grade of Recommendation: B).

c) PFMT after TURP

Little study has been dedicated to UI after TURP. In fact, the issue has been largely ignored, perhaps because the incidence of UI after TURP is reported to be very low. Two trials were potentially eligible for inclusion [292, 298], but the latter trial was grouped with studies of PFMT after radical prostatectomy because the 11 participants comprised one following TURP and 10 following radical prostatectomy. No new trials were found on PFMT after TURP. There is one on-going large trial with results anticipated in 2010 [310].

Porru (2001) randomised 58 men booked for TURP. At the baseline preoperative visit, PFM strength, tone and grading were established with a DRE. There were weekly follow up sessions for four weeks post TURP. It was unclear what information, if any, the control group received.

1. QUALITY OF DATA

It was not clear if random allocation was concealed or outcome assessment blinded, and the proportion of dropouts was not stated.

2. RESULTS

While there were statistically significant differences in UI and post micturition dribble as measured by voiding diary and IPSS, there was no statistically significant difference at four weeks.

SUMMARY

In the absence of sufficient data from rigorous and well-reported trials it is not known if PFMT reduces UI following TURP. More systematic investigation of the the natural history of UI after TURP is probably needed, to establish the potential cost/benefit of intervention, before further trials are initiated.

3. OTHER LUTS

Post micturition dribble (PMD) is an annoying problem experienced by many men of all ages likely due to a failure of the bulbocavernous muscle to evacuate the bulbular portion of the urethra, causing pooling of urine in the bulbular urethra which then dribbles with movement.

The 3rd ICI identified two RCTs on conservative management of PMD [289, 311] and no further trials were found for the current update. No trials were found on prevention of PMD and it is unlikely that such studies would be undertaken because of the longitudinal nature of such an exploration.

a) PFMT for post micturition dribble (PMD)

Two RCTs totalling 85 participants who had not undergone prostatectomy have been reported in which PFMT and/or urethral milking were compared to verbal instruction and lifestyle changes [289, 311]. Paterson (1997) assessed men assigned to one of three groups: daily PFMT, urethral milking, or lifestyle changes (consisting of relaxation therapy and oedema management) using four hour pad test at five, nine, and 13 weeks. In a study on erectile dysfunction [289], over 65% (n=36) of participants also complained of PMD. Participants were randomised to PFMT using BF (five weekly treatments plus home exercises) or lifestyle advice addressing smoking, alcohol intake, general fitness, a healthy diet, weight reduction, and saddle pressure. Outcome was patient report using a standardised questionnaire administered by an interviewer unaware of group assignment.

1. QUALITY OF DATA

It was not clear if allocation was adequately concealed in either study. In both studies data collection was done by the researchers but data analysis was done by a separate party.

2. RESULTS

Paterson (1997) found both PFMT and urethral milking were equally effective and better than lifestyle changes. Dorey (2004) found that the PFMT group not only reported a significant improvement in erectile function measured by International Index of Erectile Function (p=0.001) but also a significant improvement in PMD measured by standardised questionnaire (67% improved in treatment group compared to 7% of controls; p<0.002).

SUMMARY

Based on two small studies, it seems that PFMT and urethral milking might both be effective in the control of the annoying symptom of PMD (Level of Evidence: 2).

RECOMMENDATIONS

Men can be offered instruction to do a strong PFM contraction immediately after voiding, or urethral massage to empty the urethra, to improve symptoms of PMD (Grade of Recommendation: C).

4. FACTORS AFFECTING OUTCOME

Based on the current evidence, it appears that time from surgery to implementation of exercises does affect outcome and that by three months after surgery less improvement is noted. Future trials could consider analysis to evaluate the effect of length of time from prostatectomy surgery, co-morbid conditions, prior pelvic surgery, and medications (including smoking and alcohol use) on treatment outcome.
Electrical stimulation (EStim) is reported to be effective in the treatment of both UUI and SUI in men [223, 235, 312].

For men with DO and UUI there is often no known cause (idiopathic DO), although in some men symptoms can be associated with neurogenic disorders and to bladder outlet obstruction such as benign prostatic hyperplasia. It is believed that EStim for UUI acts through reflex inhibition of pelvic efferents or activation of hypogastric efferents through stimulation of the afferent input in the sacral route [225, 312].

Male SUI is rare but radical prostatectomy and, rarely, TURP may cause sphincter injury leading to SUI [293, 313-315]. DO, poor compliance and decreased contractility may also be factors related to post-prostatectomy incontinence [293, 316]. For male SUI, EStim can be used to enhance contractility of the PFMs in the same way as female SUI [317, 318], and may be used as stand alone therapy, as a second-line treatment when other methods have failed, or in combination with PFMT [300, 319]. It has been postulated that continence is regained more rapidly [320] and the duration of the application of EStim is reduced when PFMT is augmented with EStim [320, 321]. EStim is also believed to be more effective in patients who are initially unable to identify and contract the correct PFMs [213]. Interestingly, it is generally agreed amongst those using EStim that it should be avoided for those with carcinoma of the bladder for fear that EStim may increase abnormal cell activity [322]. Although there are no data to confirm or refute this, many physiotherapists are unwilling to use EStim for patients with cancer and, therefore, post radical prostatectomy. Further research is needed to clarify this risk.

This section will examine evidence for the use of EStim for the prevention and treatment of UI in men. Questions addressed are:

- What is the most appropriate electrical stimulation protocol?
- Can electrical stimulation prevent UI?
- Is electrical stimulation better than no treatment, placebo or control treatments for UI?
- Is electrical stimulation better than other treatments?
- Does the addition of electrical stimulation to other treatments add any benefit?
- What is the effect of electrical stimulation on LUTS other than UI?
- What factors might affect the outcome of electrical stimulation?

A literature search for reports of relevant systematic reviews and reports of RCTs and quasi-RCTs was performed (see appendix). No other types of study design were considered. Since the 3rd ICI only one new RCT [323] was identified and included in this chapter. A previous relevant Cochrane systematic review [324] was updated, and the new review [319] contributed to this section.

1. PREVENTION

There have been no studies on the effect of EStim for prevention of UUI or SUI (including post prostatectomy UI) in men.

2. TREATMENT

One systematic review was identified [319], along with nine RCTs [223-226, 239, 293, 296, 300, 323] of which one was new since the previous report [323]. An abstract of a trial by Ceresoli [325] reported data for men, but the separate effects of EStim could not be assessed and the study was excluded.

a) Is EStim better than no treatment, placebo or control treatments?

No studies were identified that compared EStim with no treatment or a control. Two placebo controlled trials were identified, and both included men and women. One included 29 men and 39 women with UUI [224], and the other 30 women and five men with SUI [223]. In the latter trial, four men had post-prostatectomy incontinence and one had sphincter deficiency due to sacral cord tumour.

1. QUALITY OF DATA

Both trials blinded patients and doctors to treatment allocation [223, 224]. For EStim in UUI, three patients (8%) in the active group and one (3%) in the sham group dropped out, and two patients in each group discontinued the treatment due to adverse events (5.4% and 6.5% respectively).

For EStim in SUI, two of 35 patients (6%) dropped out and none of the patients had adverse events.

2. RESULTS

i) Men with UUI: The authors reported statistically significant differences in cure (22% active and 4% sham) and improvement rates (81% active and 35% sham) between the groups; data were not differentiated for men and women [224].

ii) Men with SUI: None of the participants in the sham group were cured or improved. One man in the active EStim group was cured and a second was improved; five men participated in the study but it was not clear how many were allocated to sham and how many to active EStim.
EStim protocols for men are similar to those for women and like protocols in women vary widely. Intermittent, short-term stimulation (or maximal electrical stimulation) using a portable stimulation device at home [323] or in clinic [239, 293, 300] has most often been used. Rectal or surface electrodes are most common; surface electrodes are positioned over the perineal region [323]. For the treatment of SUI (and post-prostatectomy incontinence) EStim is most often used in combination with PFMT, but also as a monotherapy [239]. Usually a rectal electrode is used, and the stimulation artificially stimulates the pudendal nerve and its branches to cause direct reflex responses of the urethral and periurethral striated muscles [293, 323].

Frequencies of 14Hz have been used for UUI [323], while 20Hz [239], 27Hz [300] and 50Hz [293] have been used for SUI. Pulse form is mostly biphasic; pulse width varies and includes 300 microseconds [239], 250 milliseconds [323], one [293] and five seconds [300]. Duration of the stimulation varies as well, from 15 minutes [300] to 30 minutes [293], and from twice daily [300] [239] to twice weekly [293]. Duration of treatment has ranged from one month [239], to three months [300].

**Summary**

So far, no studies comparing EStim protocols have been identified. The most appropriate EStim protocol for different types of symptoms is unknown. EStim protocols for men have been developed from studies in women. The variability in the findings of the trials included in the remainder of this section may in part be due to differences in the effectiveness of the wide range of protocols that have been tested. There are many differences in clinical application that have not yet been investigated. Some populations or subgroups of men may benefit from EStim more than others, but this observation has not yet been investigated.

**b) Is one approach to EStim better than another?**

EStim protocols for men are similar to those for women and like protocols in women vary widely. Intermittent, short-term stimulation (or maximal electrical stimulation) using a portable stimulation device at home [323] or in clinic [239, 293, 300] has most often been used. Rectal or surface electrodes are most common; surface electrodes are positioned over the perineal region [323].

For the treatment of SUI (and post-prostatectomy incontinence) EStim is most often used in combination with PFMT, but also as a monotherapy [239]. Usually a rectal electrode is used, and the stimulation artificially stimulates the pudendal nerve and its branches to cause direct reflex responses of the urethral and periurethral striated muscles [293, 323]. Frequencies of 14Hz have been used for UUI [323], while 20Hz [239], 27Hz [300] and 50Hz [293] have been used for SUI. Pulse form is mostly biphasic; pulse width varies and includes 300 microseconds [239], 250 milliseconds [323], one [293] and five seconds [300]. Duration of the stimulation varies as well, from 15 minutes [300] to 30 minutes [293], and from twice daily [300] [239] to twice weekly [293]. Duration of treatment has ranged from one month [239], to three months [300].

**c) Is EStim better than other treatments?**

Three RCTs have compared EStim with other treatments. In a three arm trial Yokoyama (2004) compared EStim, magnetic stimulation (MStim) and verbal/written instruction in PFMT in men with post-prostatectomy incontinence [239]. Two trials compared EStim with MStim [225] or medication [226] in men and women with UUI.

**1. Quality of data**

Yamanishi (2000b) compared EStim with MStim for inhibition of DO in a urodynamic study of 32 patients (15 males, 17 females; aged 62.3 years, SD 16.6) [225]. Random allocation concealment was adequate; results were not reported by gender.

Yokoyama (2004) compared EStim, MStim and verbal/written instruction on PFMT in men with post-prostatectomy incontinence [239]. This study did not report method of randomisation, whether or not allocation was adequately concealed, or blinding of patients, healthcare providers or assessors. The number of treatments, duration and intensity seemed to be different between groups. Home EStim comprised 15 minutes of twice daily stimulation for one month, at maximum tolerable level of intensity. For MStim, treatment sessions were 20 minutes, twice a week for two months, with stimulating intensity gradually increased up to the tolerable level. PFMT consisted of PFM exercises in supine position with instructions how to contract the anal muscles selectively. Verbal and written instructions for home practice were given to the patients. Patients were followed up for six months.

Soomro (2001) compared EStim (Transcutaneous Electrical Nerve Stimulation, TENS) with medication (oxybutynin) for UUI in 43 patients (13 men, 30 women) with DO using a crossover design [226]. Results were not reported by gender. No information about randomisation procedure, random allocation concealment, blinding of observers, or drop-outs (if any) was given. Oxybutynin was started at a dose of 2.5mg orally twice daily and titrated to 5mg orally three times daily by day seven. Dual channel TENS with two self-adhesive pads connected to the stimulator and applied bilaterally over the perianal region (S2 to S3 dermatome) was used. Stimulation parameters were set at a frequency of 20Hz and a pulse width of 0.2msecs on a continuous mode. TENS duration was up to six hours daily.

**2. Results**

**i) Men with DO**: In the urodynamic study of EStim versus MStim, bladder capacity at first desire to void and maximum cystometric capacity increased significantly in both groups compared to baseline; the increase in maximum cystometric capacity was statistically significantly greater in the MStim (106%, SD 130) than the EStim group (16%, SD 34) (p=0.0135).

Soomro (2001) reported that EStim and medication improved subjective parameters but only oxybutynin showed statistically significant improvements in objective urodynamic parameters such as bladder...
volume at first desire to void and at first overactive detrusor contraction.

**ii) Men with post-prostatectomy incontinence:**

Amount of leakage in the 24 hours after catheter removal was 684g, 698g and 664g for the EStim, MStim and PFMT groups respectively. At one month, it was 72g, 83g and 175g (EStim versus PFMT, p<0.05), and at two months was 54g, 18g and 92g respectively (MStim versus PFMT p<0.05). Finally, six months later, the average 24 hour leakage weight was less than 10g in all groups. Quality of life measures decreased after surgery, but gradually improved over time in all groups. No complications were noted in any of the groups. The authors concluded that both MStim and EStim offered earlier continence compared with PFMT after radical prostatectomy.

**Summary**

There were few men in either of the two trials comparing EStim and MStim, the single trial comparing EStim with verbal/written instruction in PFMT, or single crossover trial comparing EStim with oxybutynin. In the absence of sufficient data it is not known if EStim is better than MStim or written/verbal instruction in PFMT or oxybutynin for UI in men.

**d) Does the addition of EStim to other treatments add benefit?**

Four RCTs have been identified investigating the addition of EStim to other treatments for men with post-prostatectomy incontinence [293, 296, 300, 323]. Opsomer (1994) compared intensive PFMT plus EStim (once a week) plus BF versus simple PFMT in 43 men. As it was not possible to differentiate the effects of additive EStim from adjunctive BF this study was not further considered. No trials were found in men with UI.

**1. Quality of data**

Moore (1999) compared standard treatment (verbal and written instructions about PFMT) versus intensive PFMT, versus intensive PFMT plus rectal EStim in 63 men with UI ≥ 8 weeks after radical prostatectomy. Randomisation was adequately concealed, there was a power calculation, and adherence to protocol was monitored using patient-recorded diaries. Five patients dropped out, three in PFMT/EStim and two in the PFMT group. In one patient dropout was related to the use of EStim (rectal pain). Intensive PFMT, which focussed on strength, endurance, speed and control, comprised physiotherapy for 30 minutes twice a week for 12 weeks. Initial contractions were of 5-10 seconds with a 10-20 seconds rest, with 12-20 repetitions. Endurance exercises focused on maintaining contractions at 65-75% of maximal strength. In the PFMT/EStim group EStim and PFMT were alternated per session. EStim was provided by a surface anal electrode, with intensity to induce visual lifting of the levator ani. Stimulation parameters were 50Hz, biphasic pulse shape with one second burst, a one second pulse width and one second pulse trains. All therapy was performed by one experienced physiotherapist.

Wille (2003) compared PFMT alone (n=47) versus PFMT plus EStim (n=46) versus PFMT plus EStim plus BF (n=46) in 139 men who underwent radical prostatectomy. Because in the group with both EStim and BF the results of each treatment modality could not be differentiated, we considered only the data from the PFMT alone versus PFMT plus EStim comparison. Randomisation, blinding of observers, and withdrawal or dropout rates were not described. Patients in the PFMT group received verbal and written instructions about postoperative PFMT from a physiotherapist, intensive postoperative physiotherapy for 20 to 30 minutes for three days, a post-discharge rehabilitation programme for three weeks (not described), and a three month home PFMT programme. In the PFMT/EStim group EStim was provided by a bioimpulser surface anal electrode for 15 minutes. EStim parameters were 27Hz, biphasic pulse shape with one second bursts, a five second pulse width and two second pulse trains. Intensity of current was controlled by each patient from 10-100%.

Hoffmann (2005) compared percutaneous EStim plus PFMT versus anal EStim plus PFMT versus PFMT alone in men with post-prostatectomy incontinence; this trial allocated 60 men per group, the intervention was for four weeks, and each patient was followed up for three months. It was not clear if random allocation was concealed or if observers were blinded. Dropouts were 22/60 in the anal EStim/PFMT group, 4/60 in the percutaneous EStim/PFMT group and 0/60 in the PFMT group. PFMT consisted of a “specialized program” of “continence training”, lifestyle changes, osteopathy and “Feldenkrais Lehre” three times/week in the clinic and three times/day at home, with a daily maintenance home programme after finishing the therapy.

**2. Results**

Hoffmann (2005) found that 9/60 men in the anal EStim/PFMT group reported recovery, versus 11/60 in the percutaneous EStim/PFMT group; data were not reported for the PFMT only group. Wille (2003) found more men in the PFMT/EStim group reported recovery compared to PFMT alone, but the difference was not statistically significantly different (OR 0.48, 95% CI 0.21 to 1.09).

Pad test results were not consistent. Using a 24 hour pad test Moore (1999) found a statistically significant difference in decrease of urine loss favouring PFMT over EStim/PFMT (MD -182.00, 95% CI -276.56 to -87.44). Wille (2003) found that 37% in the EStim/PFMT group were continent on pad test versus 29% in the
PFMT alone group immediately after catheter removal. At three months 77% in EStim/PFMT group were continent versus 65% in the PFMT group, with 82% and 77% continent respectively after 12 months. None of these differences at any of the three time points were statistically significant.

EStim was associated with adverse events. In Moore (1999) three out of 19 men in the EStim group dropped out because of bladder neck contractures. Hoffman (2005) reported that the main reason for dropouts was discomfort with EStim (18 of 60).

**SUMMARY**

Three RCTs investigated the addition of EStim to PFMT for men with post-prostatectomy incontinence. Data suggested no further benefit of EStim when added to PFMT over PFMT alone; the numbers in each trial were relatively small. (Level of Evidence: 2)

**RECOMMENDATIONS**

For men with post-prostatectomy incontinence there does not appear to be any benefit of adding EStim to a PFMT programme (Grade of Recommendation: B).

**3. OTHER LUTS**

No studies were identified which addressed this comparison in men.

**4. FACTORS AFFECTING OUTCOME**

*a) Age*

There are no comparisons of the effects of EStim for UI between younger and older men. While many EStim studies include participants over 50 years most studies don’t include those over about 80 years [326]. In the studies of EStim for post-prostatectomy incontinence in this chapter the mean age of men is about 66 years. Although post-prostatectomy studies have included older men it may be unwise to extrapolate the effects of EStim in older men with SUI to older men with UUI, because in the former UI is usually as a result of sphincter incompetence whereas in the latter the symptoms are those of an OAB. Further, it is not known whether the efficacy of EStim for UUI in elderly men is similar to that for women [293].

*b) Other*

Many other factors, such as types of electrodes, intensity, frequency and duration of stimulation, electrode positioning, the number of treatment sessions, diagnosis and underlying cause, patient selection, and treatment adherence are plausible factors affecting outcome. Little is known about the effect of any of these and there are no trials investigating these factors in male patients.

**IV. MAGNETIC STIMULATION (MSTIM)**

Background information about extra corporeal magnetic innervation, more commonly called magnetic stimulation (MStim), has been given in the section on MStim for women (see B5). MStim has also been used in men; it is unclear whether the mode of action and effects of MStim are similar in men and women. In men, MStim is used to treat UI after radical prostatectomy [239, 327] and for the inhibition of DO [225].

The questions to be addressed are the same as those for women (see B5). A literature search for reports of relevant systematic reviews and reports of RCTs and quasi-randomised trials was performed (see appendix). No other types of study design were considered. Since the 3rd ICI one further RCT has been published. Suzuki (2007) compared the effect of MStim versus sham MStim for UUI in 39 patients (23 females and 16 males). The study was not included in the review below because both groups also received PFMT, and data were not reported separately for men and women [328].

**1. PREVENTION**

No trials investigating the primary or secondary prevention effects of MStim for men with UI were found.

**2. TREATMENT**

Three RCTs were identified; two full manuscripts [225, 239] and one abstract of an ongoing study without data [327]. The trial by Yamanishi (2000b) included both men and women with UI; because the effects of MStim might be different between sexes (due to differences in the underlying aetiology of symptoms) this study has only contributed to the analysis where the researchers’ differentiated the effects of treatment in men and women.

*a) Is MStim better than no treatment, placebo or control treatment?*

No studies were found addressing this question.

*b) Is one approach to MStim better than another?*

No studies were found addressing this question.

*c) Is MStim better than other treatments?*

Two studies were identified [225, 239]. Both compared MStim with EStim; the latter also compared MStim and PFMT. Readers are referred to section C.3.2c for a description of these studies, findings, and summary.

**3. OTHER LUTS**

No studies were found.
4. FACTORS AFFECTING OUTCOME

None of the included trials addressed the effect of age, or any other factor, on outcome of MSTim. The relationship between age (or any other factor, such as treatment parameters, treatment adherence, or diagnosis) and the outcome of MSTim has yet to be determined.

V. SCHEDULED VOIDING REGIMENS

Scheduled voiding regimens include bladder training (BT), timed voiding (TV), habit training and prompted voiding. They are frequently combined to achieve maximum benefits. Although there is evidence to indicate that scheduled voiding regimens, especially BT and TV, are commonly used in the treatment of men with UI and other LUTS, there has been substantially less research that addresses their use in men compared to the literature on their use in women.

1. PREVENTION

No trials investigating the preventive effects of scheduled voiding regimens for men with UI were found.

2. TREATMENT

Since the 3rd ICI, there have been no new reports of BT that have included men in the study population. Five RCTs have included men; however, most included only a small number of men in the sample [55, 268, 269, 272, 277]. Two observational studies, but no RCTs, were found regarding TV. No studies were located that addressed habit training or prompted voiding in men.

a) Bladder training

A total of five RCTs involving 142 men met the criteria for inclusion in this review. All trials (previously described in section B6) had predominantly female participants; one RCT compared BT to BT plus caffeine reduction (seven men, 86 women) [55]; and three RCTs compared BT plus placebo drug versus anticholinergic drug therapy available prior to 1995 (six men, 28 women [277]; four men, 30 women [269]; two men, 58 women [268]). The largest RCT compared drug therapy alone (tolterodine) to drug therapy plus BT (123 men, 378 women) [272]. A sixth study was located that compared BT supplemented with drug therapy after three months, but it was excluded from review because the full length report was in Japanese and an English translation was not available [329].

As none of the trials reported outcome data separately for men, and with the proportion of male participants being so small (3%, [268]; 8%, [55]; 12%, [269]; 8%, [277]; 25%, [272]), there is insufficient evidence available to comment on the effectiveness of BT in men.

b) Timed voiding

There have been two clinical series that investigated timed voiding in men only [259, 330]. In the first, Sogbein (1982) applied TV in incontinent men in a geriatric hospital [330]. In the second study, 20 men (ages 55 to 89 years) with persistent post-prostatectomy incontinence were advised to void every two hours and keep a daily bladder record for two weeks as a run-in to being treated with BF-assisted behavioural training [259]. Outcomes were measured by a two week voiding diary kept at baseline and during two weeks of timed voiding by patients diagnosed with SUI, UUI, and/or continual leakage.

1. QUALITY OF DATA

Both studies used a clinical series design and patients in both subsequently received other treatment if they were not adequately improved. In the Sogbein study, nurses checked the patients’ clothing for wetness at each two-hour voiding interval and recorded the results. Data in the Burgio study were based on bladder diaries completed by the patients. Reasons for dropout [330] and non-adherence [259] were provided.

2. RESULTS

Sogbein (1982) reported an 85% improvement rate in UI men in a geriatric hospital. Burgio (1989), in men with persistent post-prostatectomy incontinence, found the two hour TV schedule was used with only 12 out of 20 men, because they were either already on a voiding schedule, unwilling to go on a voiding schedule, or results were not presented because the patient was noncompliant. In five men with SUI, TV resulted in a 29% decrease of incontinent episodes; in three men with UUI, two improved and one dramatically regressed producing a 33% increase in incontinent episodes. In four patients with continual leakage, there was no reduction in percentage of wet intervals.

SUMMARY

With limited Level 3 evidence (and no higher order evidence), there is insufficient evidence available to comment on the effectiveness of TV in men.

3. OTHER LUTS

No studies were identified in men.

4. FACTORS AFFECTING OUTCOME

a) Age

The five RCTs involving BT included older men, as well as women, in their study populations. Three trials specifically recruited elderly adults aged 65 to 70 years and over [268, 269, 277]. The largest trial of men recruited adults aged 18 and over with a median age of 62 years. There was no subgroup analysis related
to age and gender effects, so it is not possible to draw conclusions regarding the effect of BT in older men [272]. Voiding regimens are of particular interest for the elderly, but some are effective in younger patients with UI [253].

b) Other

No studies were identified on other factors affecting outcome of TV or prompted voiding in men.

Patients who appear to benefit most from scheduled voiding regimens are highly motivated individuals without cognitive deficits. Men and women with SUI and UUI have benefited, whereas patients with severe sphincter damage (e.g. after radical prostatectomy) generally do not [253].

VI. COMPLEMENTARY AND ALTERNATIVE MEDICINES

Similar to women, complementary therapies are used for the treatment of male UI. Therapies include relaxation, meditation, imagery, hypnosis and naturopathic and herbal remedies, but only trials of acupuncture therapy have been found in men with UI. Therefore, only acupuncture will be considered in the remainder of this section.

Acupuncture is a traditional Chinese modality and has been used for the treatment of urinary disturbances. Acupuncture has been reported to relieve OAB symptoms including UI due to spinal cord injury [331], and idiopathic DO or MUI [332-334].

1. PREVENTION

No studies were identified on the preventative role of complementary therapies in men.

2. TREATMENT

Acupuncture has been shown to improve urodynamic parameters such as bladder capacity in men with UUI [331, 332]. Acupuncture is a form of somatic sensory stimulation [334]. The mechanism by which acupuncture inhibits DO remains unclear, but suppression of the spinal and supraspinal reflexes that lead to bladder contractions is considered one of the most important mechanisms of acupuncture stimulation. In an experimental study with anesthetised rats, an acupuncture-like stimulation of the perineal skin and muscles inhibited detrusor contraction [335, 336]. A release of neuropathies (e.g. endorphins) by acupuncture may be another possible mechanism of increasing bladder storage [334].

Acupuncture may also change sphincter activity, which may be useful for men with SUI. Urethral EMG in rats showed excitation when acupuncture-like stimulation was applied to the skin and underlying structures in the rostral half of the body, the hind paw, the perineal area, testis or urethra, while less excitation was seen when the bulbocavernousus, sacrococcygeus or pubococcygeus muscles were stimulated [337]. Kubista [338] showed a significant increase in the urethral closing pressure. However, there has been no report on the effects of acupuncture for male SUI or post-prostatectomy incontinence.

a) What is the most effective acupuncture protocol?

Acupuncture has been carried out with disposable stainless steel needles (0.3mm in diameter, 60mm in length) inserted into the bilateral BL-33 (Zhongliao) points on the skin of the third posterior sacral foramina [331-333] or several other points (BL-31,32, 21, 23, SP-6, KI-3, LI-11, CV-1, 2, 4, 5) [339], and usually performed once or twice weekly [331-334, 340]. Acupuncture protocols vary and there is no apparent consensus between investigators. It is not known if any acupuncture protocol is more effective than another.

b) Acupuncture versus no treatment, sham acupuncture or any other treatment

Only one RCT has been identified including both men and women [341], but there is no study exclusively for men. In a randomised, placebo-controlled, single-blind study among 20 elderly patients (three males, 17 females) Ellis (1990) showed that the frequency of voiding at night was reduced after acupuncture [341].

In an uncontrolled study, Kitakoji (1995) treated 11 patients (nine males, two females) with OAB including three participants with benign prostatic hyperplasia [332]. Improvement of symptoms was noted in nine, overactive detrusor contractions disappeared in six and significant improvements in both maximum cystometric capacity and bladder compliance were obtained after the treatment. Acupuncture was benefited all three patients with benign prostatic hyperplasia.

In a second uncontrolled study, Honjo (2000) reported an improvement in UI due to neurogenic DO in 13 patients (11 males, two females) with chronic spinal cord injury [331]. Treatment was repeated once a week for four weeks. UI disappeared in two and decreased to 50% or less compared to baseline in six. Maximum cystometric capacity increased significantly from 76ml (SD 62) to 148ml (SD 82) one week after the fourth acupuncture treatment.

The evidence of the effectiveness of acupuncture for men with UI is limited by the lack of controlled studies. To date, the studies are small, objective measures of UI are not included and long-term follow-up is lacking. Preliminary data from predominantly uncontrolled studies suggest that RCTs of acupuncture of UI in men are warranted.

3. OTHER LUTS

In a RCT in patients with sensory urgency after TURP, Ricci (2004) reported significant improvements by
acupuncture reflexotherapy (EStim of somatic and auricular points) in terms of IPSS, QOL scores, decrease of daytime frequency and nocturia, but no improvements with the use of placebo or oxybutynin [340].

Honjo (2000) reported the effects of acupuncture on mono-symptomatic nocturnal enuresis [331]. Fifteen participants (10 males, five females) with mono-symptomatic nocturnal enuresis were treated, and nocturnal enuresis was improved in six just after the treatment and two months later seven were improved. In the six ‘responders’ nocturnal bladder capacity increased significantly from 201 to 334ml (p<0.05).

4. FACTORS AFFECTING OUTCOME

Aside from Ellis (1990), reported above, who specifically recruited elderly participants there is a lack of evidence about the effect of any prognostic factor for the outcome of complementary therapies in men.

VII. SUMMARY

Despite the prevalence of UI and LUTS in older men, the only group that has received much attention in research is men following radical prostatectomy. Overall, the effect of conservative treatment (lifestyle interventions, physical therapies, schedule voiding regimes, complementary therapies) has received much less research attention in men compared to women.

1. RECOMMENDATIONS FOR PRACTICE

There is generally insufficient Level 1 or 2 evidence on which to base recommendations for practice, and most recommendations are in effect hypotheses that need further testing in research.

a) Lifestyle interventions

- It seems reasonable for health professionals to offer men advice on healthy lifestyle choices that may reduce or delay the onset of continence problems (Grade of Recommendation: D) (New).

b) Pelvic floor muscle training (PFMT)

- Some preoperative or immediate post-operative instruction in PFMT for men undergoing radical prostatectomy may be helpful (Grade of Recommendation: B) (Unchanged).

- It is not clear whether PFMT taught by digital rectal examination (DRE) offers any benefit over and above verbal or written instruction in PFMT (Grade of Recommendation: B) (New).

- The use of BF to assist PFMT is currently a therapist/patient decision based on economics and preference (Grade of Recommendation: B) (New).

- Use of a strong pelvic floor muscle contraction immediately after voiding, or urethral massage to empty the urethra, can improve symptoms of post micturition dribble (Grade of Recommendation: C) (Unchanged).

c) Electrical stimulation (EStim)

- For men with post-prostatectomy incontinence there does not appear to be any benefit of adding EStim to a PFMT programme (Grade of Recommendation: B) (Unchanged).

2. FUTURE RESEARCH DIRECTIONS

There is much scope for research on the effects of conservative therapies for UI and LUTS in men. Research that is urgently needed, in the opinion of committee members, is highlighted with the use of *italics*. There are a few recommendations that apply to all future studies in men, namely:

- All future intervention studies must be designed to allow standardised and comprehensive reporting of results based on the ICS and CONSORT recommendations.

- The natural history of UI after radical prostatectomy must be taken into account in study design as the spontaneous recovery rate means that sample sizes must be large to detect any differences between protocols.

- More research is needed to find out what are the most important outcomes for men with UI, so such measures can be incorporated as the primary outcome measures in further trials.

- Data are needed to establish to the cost, and cost effectiveness, of conservative therapies in men with UI.

- Surgical approaches with laparoscopy or robotics offer promising improvements in visualisation for nerve-sparing procedures; further research should address continence and erectile function after these newer surgical procedures.

a) Lifestyle interventions

- To date, no trials have addressed the topic of lifestyle interventions for men with UI.

- *The effects of interventions such as weight and caffeine reduction, both of which show some evidence of benefit in women, are priorities for future research.*
b) Pelvic floor muscle training (PFMT)

- A comparison of preoperative versus postoperative PFMT verbal and written feedback to reduce prevalence and severity of UI following radical prostatectomy is needed.

- Methods of PFMT instruction and supervision require further investigation. Two areas of research interest are:
  - Whether PFMT taught by DRE offers any benefit over and above verbal or written instruction.
  - The effect of group exercise. Because of the peer support that men may receive from participating in a group [342] this might be useful after radical prostatectomy; both Moore [293] and Opsomer [296] reported that support in the post operative period may be important to healthy recovery.

- More systematic investigation of the natural history of UI after TURP is needed, to establish the potential cost/benefit of intervention, before further trials are initiated.

- The relationship between age, or any other factor, and the outcome of PFMT for UI in men has yet to be determined.

c) Electrical stimulation (EStim) and magnetic stimulation (MStim)

- It is not known if pre or postoperative EStim or MStim has a role in reducing the prevalence of UI after radical prostatectomy.

- RCTs in larger samples, with long-term follow up, are needed to investigate all aspects of the effectiveness of EStim and MStim as a treatment for UI in men, including:
  - Either type of stimulation versus no treatment, sham stimulation or other control conditions.
  - Comparisons of both EStim and MStim protocols.
  - EStim versus MStim.
  - Either type of stimulation versus medication.
  - Whether the addition of either type of stimulation to other treatments adds benefit, in particular the addition of stimulation to PFMT.

- The effect of age, and other factors, on outcome of stimulation. Elderly men may have more co-morbid conditions than young men, such as dementia, changes in the secretion of vasopressin, venous insufficiency, renal disease, heart failure, drug intake, restricted mobility and constipation. A more pragmatic approach to inclusion in EStim studies is needed.

d) Scheduled voiding regimens

In the absence of trials exclusively in men, or trials that report data separately for men and women, there is a pressing need for high quality RCTs with an appropriate sample size and long-term follow up to address the effects of BT, TV, habit training and prompted voiding in men suffering from UI.

C. PELVIC ORGAN PROLAPSE

Pelvic organ prolapse (POP) is common and is seen in 50% of parous women [343]. Women with prolapse can experience a variety of pelvic floor symptoms.

Treatments include surgery and conservative management. Choice of treatment depends on the severity of the prolapse and its symptoms, and the woman’s general health. Conservative treatment is generally considered for women with a mild degree of prolapse, those who wish to have more children, the frail or those unwilling to undergo surgery. Conservative treatment is defined here as lifestyle interventions, physical therapies, pessaries and complementary therapies.

The aims of conservative treatment in the management of POP include:

- to prevent the prolapse becoming worse;
- to help decrease the frequency or severity of symptoms caused by prolapse (vaginal, backache, urinary, bowel and sexual symptoms);
- to avert or delay the need for surgery;
- to provide a therapeutic/diagnostic aid (e.g. to establish, when it is not clear, whether a patient’s symptoms are caused by prolapse; to determine whether urodynamics are indicated prior to prolapse surgery; or to confirm suspected UI).

This section will examine the evidence for the use of conservative treatments in the management of POP utilising information from two recent Cochrane systematic reviews [344, 345], and literature identified via a search strategy summarised in the appendix.

I. LIFESTYLE INTERVENTIONS

Lifestyle interventions include weight loss, reducing exacerbating activities (e.g. lifting, coughing) and treating constipation. These interventions seek to avoid exacerbation of the prolapse by decreasing intra-abdominal pressure. The extent to which any of these lifestyle interventions are effective in managing prolapse is thought to be unknown [346]. Studies that investigated lifestyle interventions for the prevention or treatment of prolapse were searched for.
1. Quality of data

No body of literature about the effects of lifestyle changes for the prevention of POP was found. However, several studies were identified that addressed the association between factors such as occupation (involving heavy lifting/strenuous physical activity), bodyweight and constipation, and POP. These studies are reported here.

i) Association between POP and occupation: Two case control studies addressed the association between occupation and surgery for POP [22, 347]. Jørgensen (1994) compared the incidence of surgery for a non-specified degree of prolapse among 28,619 Danish nursing assistants, whose occupation exposed them to repetitive heavy lifting, with 1,652,533 female population controls of similar age. No adjustment for parity was made. Chiaffarino (1999) compared 100 control women with 108 women admitted to undergo surgery for second or third degree uterovaginal prolapse and/or third degree cystocele. Adjustments were made in this study for potential confounding effects, although occupation was collected as a social class indicator and yielded no information about physical effort.

Two further case control studies, conducted in the 1980s, addressed the association between occupations and POP assessed by physical examination [348, 349]. Spernol (1983) and Bao (1989) assessed 200 and 364 women respectively to see whether occupations involving hard physical labour were associated with the risk of development of POP. In Bao (1989) women were classified according to weight carried, however in Spernol (1983) past work history was subjectively assessed as light, medium or heavy work. These parameters were not further quantified nor were the study outcome measures validated. Bodner-Adler (2007), in a case series of 96 women diagnosed and treated for second or third degree uterine prolapse over a three month period at one hospital in Nepal, reported on associated risk factors including heavy lifting/work. [350].

ii) Association between POP and bodyweight: Spernol (1983) also investigated the association between bodyweight and risk of POP. Hendrix (2002), in a more recent cross-sectional study of 27,342 postmenopausal women used questionnaires and a pelvic examination to investigate factors (including occupation as assessed in four broad categories, and bodyweight) associated with POP [351]. Although the large study population allowed examination of numerous associations the study was not designed specifically to determine risk factors for POP. Similarly, despite the examination for prolapse being standardised, no validated grading system (e.g. POP-Q examination) was used to measure prolapse. Four other epidemiological studies, designed to analyse risk factors for prolapse, explored the influence of bodyweight on risk of prolapse [352-355].

iii) Association between POP and bowel function: Rortveit (2007) reported risk factors for symptomatic prolapse from the “Reproductive Risks for Incontinence Study at Kaiser”, a population study of 2,001 randomly selected, community-dwelling women in California, aged 40 to 69 years [356]. Data were collected by a mix of self-report, interview, physical examination and medical record review. Risk factors assessed included irritable bowel syndrome and constipation. Kahn (2005) and Arya (2005) looked specifically at bowel symptoms and constipation and their relationship to prolapse in a cross-sectional study (n=1,004) and a case-control study (cases n=60, controls n=30) respectively [357, 358]. One limitation of Kahn (2005) was the use of a non-validated bowel symptom questionnaire. Arya (2005) collected data on constipation (Patient Assessment of Constipation Symptom Questionnaire) and dietary fibre intake (National Cancer Institute Dietary History Questionnaire). Jelovsek (2005) studied bowel function and constipation in 302 women presenting consecutively to a urogynaecology clinic with either prolapse or lower urinary tract symptoms [359].

iv) Association between POP and anaemia: Scherf (2002) examined and surveyed 1,348 women in rural Gambia, and presented data on the associations between severity of prolapse, and socio-demographic and morbidity variables, including presence of anaemia [360].

2. Results

i) Association between POP and occupation: All but one [351] of the studies reported above found a positive association between occupations associated with lifting and the presence of prolapse. Danish nursing assistants were 1.6 times (95% CI 1.3 to 1.9) more likely to undergo surgery for POP than general population control women but as noted this analysis did not adjust for parity [22]; Italian housewives were 3.1 times (95% CI 1.6 to 8.8) more likely to undergo surgery for POP than professional/managerial women [347]; 68% of women with uterine prolapse reported a history of medium/heavy work compared to 40% of control women without prolapse (p=0.0001) [348], the increased risk remaining after controlling for childbirth; and female workers that generally lifted more than 20kg were more likely to have uterine prolapse than other workers [349]. Heavy work in the early post-partum period was cited by Bodner-Adler (2007) [350] as a risk factor for uterine prolapse in Nepalese women; 88% with prolapse reported doing such work.

ii) Association between POP and bodyweight: Spernol (1983) reported that 77% of women with POP were overweight compared with 45% of women with...
no prolapse (p<0.001). Hendrix (2002) reported that being overweight was associated with a significantly higher prevalence of uterine prolapse by 31% (OR 95% CI 1.15 to 1.48); rectocele by 38% (OR 95% CI 1.25 to 1.53) and cystocele by 39% (OR 95% CI 1.28 to 1.51).

Also, obesity was associated with a significant 40% (OR 95% CI 1.24 to 1.59), 75% (OR 95% CI 1.54 to 1.99) and 57% (OR 95% CI 1.41 to 1.74) increase in each of these conditions respectively. Overweight women were also reported to be at increased risk of prolapse in both the British Oxford Family Planning Association Study [352] and the cross-sectional study in menopausal clinics in Italy [355]. This finding however was not confirmed by Rinne (1999) or Samuelsson (1999) who concluded that increased bodyweight/ obesity did not predispose women to genital prolapse [353, 354].

iii) Association between POP and bowel function:
In a cross-sectional study, Rortveit (2007) reported that current constipation, experienced monthly or more frequently, was associated with an odds ratio for symptomatic prolapse of 2.5 (95% CI 1.7 to 3.7), after controlling for age, race, education and number and type of delivery. Kahn (2005) found, in women attending for routine gynaecological care, weak relationships between prolapse severity (POP-Q measurements) and bowel symptoms, however straining at stool was found to be associated with anterior vaginal wall (measured by POP-Q point Ba) and perineal descent (POP-Q points Gh + Pb). Arya (2005) found women with prolapse had an increased risk of constipation compared to controls (after allowing for age, prior pelvic surgery and total fibre intake), and this was partially due to their lower intake of dietary insoluble fibre. Jelovsek (2005) found that neither overall POP-Q stage of prolapse nor stage of posterior vaginal wall prolapse was associated with constipation. There was no difference in the prevalence of constipation between those with UI and those with stage III or IV prolapse in this study.

iv) Association between POP and anaemia: Scherf (2002) found that 46% of women had prolapse on vaginal examination (most commonly cystocele: 57%), and in those not pregnant at the time, moderate/severe anaemia (Hb<10) was associated with a two-fold increased odds of having prolapse.

Constipation is a modifiable risk factor which perhaps has potential to impact on development of prolapse symptoms. However, evidence regarding the association between constipation or straining at stool and prolapse was conflicting. Existing studies, particularly older ones, are hampered by their cross-sectional nature, inconsistent definitions of POP and use of un validated outcome measures, and failure to adjust for potentially important variables (such as parity and socioeconomic status).

Anaemia is a treatable condition, either through diet or medication, which may be worth considering further in research on prevention of prolapse.

2. TREATMENT
No studies have been identified to date that evaluate the effectiveness of lifestyle interventions in the treatment of women with POP.

II. PHYSICAL THERAPIES

The primary physical therapy for POP is PFMT, with or without other adjuncts. PFMT may include PFM assessment and education, PFM exercise instruction, and PFM bracing against increased intra-abdominal pressure, for example when coughing and sneezing (termed “The Knack” [361]).

Adjuncts (such as BF) or other physical therapies (such as neuromuscular EStim) may be used. These therapies aim to improve PFM strength, endurance, coordination and function.

The promotion of PFMT for prolapse varies between treatment centres with some providing only a patient information leaflet and others giving individual instruction from a physiotherapist [362]. Research shows that verbal teaching of pelvic floor exercises alone is insufficient [363]. It is suggested that 15% of women are incorrectly ‘bearing down’ when trying to carry out these exercises [363]. In women with prolapse, this could further add to the strain on the area and worsen the condition.

A Cochrane systematic review has indicated that PFMT should be offered as first-line conservative management for urinary stress, urge and mixed incontinence [134]. However, its role in managing prolapse is not established [364]. Some authors have extrapolated the results of trials relating to UI, implying for example that PFMT would be effective for prolapse. The importance of clarifying the place of PFMT in the prevention and management of prolapse has been highlighted [365, 366].

No prospective studies of lifestyle interventions to prevent prolapse were found. There is some evidence that occupations involving heavy lifting/hard physical labour or being overweight may play a role in the development of POP (Level of Evidence: 3).
1. PREVENTION

1. QUALITY OF DATA

No studies have been identified to date that evaluate the role of PFMT in prevention of POP. This lack of evidence was noted by Harvey (2003) in a systematic review of PFMT during and after pregnancy [113]. A longitudinal 12-year follow-up of women originally enrolled in an RCT of post-natal PFMT is currently underway (http://www.wellbeingofwomen.org.uk/index.asp?PageID=279), examining the prevalence of prolapse in this cohort who were randomised to a PFMT intervention or control group. No data are yet available. Borello-France (2007) examined 317 women without SUI, prior to prolapse surgery, to determine PFM function (Brink scale score) and prolapse stage (POP-Q) [367]. The association between PFM strength and severity of prolapse was reported.

2. RESULTS

Borello-France (2007) found the Brink Vertical Displacement subscore was significantly higher in women with less severe prolapse. That is, women with stage II prolapse were better able to elevate their pelvic floor than those with stage III or IV. The authors hypothesise that poor PFMs may be a contributory factor in the development of prolapse. Interventions to improve PFM function might thus prevent prolapse. However, conversely, the prolapse itself might contribute to PFM weakness.

SUMMARY

Currently, there is no evidence from intervention studies regarding the role of PFMT or other physical therapies in the prevention of POP; improved PFM strength could prevent prolapse (Level of Evidence: 3).

2. TREATMENT

An evidence-base is now emerging regarding the role of PFMT in the treatment of prolapse, both as a treatment in itself and as an adjunct. Data from five completed trials are now available, two of which had been ongoing at the time of the 3rd ICI. In addition, three sizeable trials are currently ongoing. Feasibility work for a further trial is in progress.

Five completed RCTs were found that evaluated the effects of PFMT in women with prolapse [368-372]. Piya-Anant (2003), Hagen (2006) and Ghroubi (2008) assessed PFMT alone as a treatment for prolapse, whilst Jarvis (2005) and Frawley (2007) focused on PFMT as an adjunct to surgery.

i) PFMT alone: Piya-Anant (2003) assessed the effect of PFMT in elderly women (aged 60 years or more) with genital (anterior) prolapse. This cluster RCT compared 324 control group women with 330 intervention group women; each group included women classified as having no prolapse, mild prolapse or severe prolapse. The intervention group received unspecified PFMT to strengthen the levator and perineal muscles and were instructed to exercise after one meal every day for 24 months. They were also given dietary and fluid advice. Women were followed up every six months for 24 months allowing comparison with baseline measurements. The main outcome measure in the study, worsening of genital prolapse, does not appear to have been determined using a recognised measure. No allowance appears to have been made in the study for the presence of other types of prolapse i.e. posterior vaginal wall prolapse or prolapse of the apical segment of the vagina.

Hagen (2006) conducted a feasibility study for an RCT of a PFMT intervention in 47 women (23 PFMT, 24 controls) with stage I or II prolapse of any type in two UK centres. The intervention consisted of five physiotherapy appointments over a 16-week period, with an individually-prescribed daily PFMT exercise programme. Control women received a prolapse lifestyle advice leaflet by post only. Outcome measures included: blinded prolapse assessment (POP-Q); prolapse-related symptom severity and quality of life via postal questionnaires; PFM strength (modified Oxford grading scale) (intervention group only).

Ghroubi (2008) conducted a trial in 47 women with stage I or II cystocele. Women were randomised to a conservative treatment group (PFM exercises plus advice on healthy living) or a non-treated group. Outcomes included clinical examination, the “Measurement of Urinary Handicap” (MUH) scale, urodynamic tests, the Ditrovie quality of life scale, patient satisfaction.

ii) PFMT and surgery: Jarvis (2005) investigated the effect of PFMT, bladder and bowel training on continence, quality of life and general health symptoms of 30 women undergoing surgery for UI and/or prolapse compared with 30 control women who received no training alongside their surgery. The intervention group received pre-operative training in PFMT exercises, and correct voiding and defaecation techniques with reinforcement post-operatively. There were no prolapse outcomes measured in this study. Results presented relate to the combined group of study women i.e. those having prolapse surgery, those having UI surgery and those having both.

Frawley (2007) compared physiotherapist-led pre- and post-operative PFMT versus usual care in 48 women undergoing prolapse repair surgery, with or without hysterectomy. Intervention comprised one pre-operative instruction session, and eight post-operative appointments, and a final appointment at nine months post-operatively. PFM strength was measured (manometry and modified Oxford grading...
scale) by a blinded investigator at four time points: preoperatively prior to randomisation, and three, six and 12 months post-operatively.

iii) Ongoing trials: In addition, there are three RCTs (two for PFMT alone, one for PFMT as an adjunct to surgery) and one feasibility study for an RCT (PFMT as an adjunct to pessary) ongoing at the time of this review. Following on from the feasibility study by Hagen (2006) a multi-centre trial of the same intervention, in women with stage I, II and III prolapse, is now underway in 17 UK centres (the POPPY Trial, ClinicalTrials.gov Identifier: NCT00476892 ), with additional international centres in New Zealand and Australia. Results are expected in 2010.

Bø and colleagues in Norway are undertaking a single blind RCT involving 100 women with stage I, II or III prolapse evaluating the effects of a PFMT intervention. The intervention spans a six month period, with weekly physiotherapy appointments for three months, then fortnightly appointments for three months, and a structured home training programme (the POP Study, ClinicalTrials.gov Identifier: NCT00271297). A case-control study is taking place simultaneously, including 50 women without prolapse, to assess risk factors for the condition. The results of this study are expected in 2008.

A RCT has just begun enrolling under the direction of the NIH-sponsored Pelvic Floor Disorders Network. This trial will compare two methods of suspending the vaginal vault in women undergoing vaginal surgery for POP and additionally will randomise half of the participants to adjunct post-operative PFM exercises and behavioural therapy and half to routine care. The analysis will assess whether such adjunct therapy improves both anatomic and symptomatic outcomes two years after surgery. The study is expected to be complete by 2012 (the OPTIMAL trial, ClinicalTrials.gov Identifier: NCT00597935).

A feasibility study (the PEPPY study) looking at the possible effects of PFMT with a vaginal pessary in situ is now underway in 17 UK centres (the POPPY Trial, ClinicalTrials.gov Identifier: NCT00476892 ), with additional international centres in New Zealand and Australia. Results are expected in 2010.

Outcome assessment was predominantly by self-reported questionnaire, and women knew the group they had been allocated to. Prolapse severity at follow-up was assessed by a gynaecologist who was blind to the group allocation of the woman. Blinding was not always successful as some women disclosed their group allocation during their assessment. Sufficient information on drop-outs was given. Ghroubi (2008), which was published very recently, is written in French with an English abstract. A translation has been requested in order to allow detailed description of the trial methods and findings.

ii) PFMT and surgery: In Jarvis (2005) randomisation was generated by a computer in balanced blocks of 20, and randomisation outcomes were stored in opaque envelopes separate from the clinic. It was stated that the physiotherapist assessing the women at follow-up was blind to their status. Sufficient information on drop-outs was given. No information on the randomisation methods was available from the published abstract of Frawley (2007). The PFM strength measurements were taken by a physiotherapist who was blind to the women’s group allocation. Numbers of drop-outs were adequately described.

2. Results

i) PFMT alone: Piya-Anant (2003) reported that PFMT was effective in elderly women who had a severe degree of genital prolapse. After 24 months of PFMT, the rate of worsening of genital prolapse was 73% in the control group and 27% in the intervention group (p=0.005). In the subgroup with ‘mild’ genital prolapse, the rate of worsening at 12 months was statistically significantly less for PFMT women than controls (p=0.02), but there was no difference between the groups at 24 months (p=0.1).

Hagen (2006) found that women in the PFMT group were more likely than controls to have an improvement in prolapse stage (Fisher’s exact test p=0.038). Intervention group women had significantly greater improvement by 26 weeks than controls in their prolapse symptom score (mean score decrease 3.5 versus 0.1, p=0.021). There were significant differences between the groups at both follow-up time points in perceived improvement in prolapse (20 weeks, p=0.001; 26 weeks, p=0.012); PFMT women were more likely to report their prolapse was better now than at the start of the study. A significant improvement in PFM strength was detected in the intervention group; mean muscle strength increased by 0.5 on the modified Oxford scale (95% CI 0.2 to 0.8, p = 0.008). However, PFM strength measures were not taken blinded to women’s group allocation.

Ghroubi (2008) found that immediately post-treatment, pelvic heaviness persisted in five women (19%) from the treatment group compared with fourteen (70%) in
the control group (p < 0.001). There were also significant differences in other outcomes, including quality of life and urodynamic measures. It was reported that 20 women from the intervention group retained benefits two years after the treatment had ceased.

**ii) PFMT and surgery:** Jarvis (2005) reported a significant improvement in both quality of life (improvement in score for treatment group 215, 95% CI 124 to 305 versus control group 47, 95% CI -26 to 121; p=0.004) and urinary symptoms (difference between groups in symptom score reduction 3.8, 95% CI 0.7 to 6.9; p=0.017) when pre-operative physiotherapy was given to women undergoing surgery for UI and/or prolapse compared with women who received no physiotherapy. There was no difference between the groups in SUI measured by pad test. Mean maximum PFM squeeze increased in the physiotherapy group by 2.7 cmH2O, and decreased in the control group (-1.8 cmH2O) (p=0.022). Frawley (2007) reported that despite the tendency towards improvement in the PFMT group over time, there were no significant differences in PFM strength scores between the controls and those who received PFMT at any of the post-operative time points.

Comparing the results for the two surgical trials [369, 371] it is interesting that one found an effect of PFMT on post-operative pelvic floor contraction pressure [369] while the other did not [371]. The latter appeared to have a more intensive intervention protocol (with one pre-operative and eight post-operative physiotherapy appointments up to nine months); however the former included teaching of voiding and defaecation techniques as well as a PFMT programme. In addition the trial populations were not identical, with some women having combinations of prolapse, hysterectomy and UI surgery. The sample sizes in both trials were small (n=60 and n=48 respectively).

**Summary**

Given the prevalence of POP and the fact that physical therapies, in particular PFMT, may already be part of the treatment offered to women in many centres [362] the lack of evidence of effectiveness is disconcerting. The results of further trials regarding the effectiveness of PFMT, which is costly in terms of therapist time, are awaited. These ongoing trials are large, have a control group, are randomised and use recognised objective measurements of prolapse severity, and thus will provide a high level of research evidence to inform practice. The effectiveness of PFMT used in conjunction with other treatments is another area where evidence is lacking [344] but trials to address this are also emerging.

Based on the evidence from one large trial, PFMT may prevent deterioration of anterior prolapse. However this trial had several weaknesses including its failure to utilise a recognised objective measurement of degree of prolapse and its restricted population (elderly women with anterior prolapse only). The results from two small trials provide some additional evidence of a positive effect of PFMT on prolapse symptoms and severity. In the next few years, the completion of two sizeable trials of PFMT for POP might provide a much stronger evidence base for clinical practice. (Level of Evidence: 2)

Pre- and post-operative PFMT may help to improve quality of life and urinary symptoms in women undergoing surgery for POP, but the findings regarding its effects on PFM strength are contradictory. The evidence available however is based on two small trials, one of which included women undergoing surgery for UI and/or prolapse. (Level of Evidence: 2)

**Reccomendations**

PFMT may help prevent deterioration in anterior prolapse, and may help improve prolapse symptoms and severity more generally (Grade of Recommendation: B). Further trials are needed to confirm these findings.

Preoperative PFMT may help improve quality of life and urinary symptoms in women undergoing surgery for prolapse (Grade of Recommendation: C). Larger trials are needed, and prolapse-specific measures should be primary outcomes in such trials.

Future studies of PFMT for POP should aim to reach a consensus on the optimal intervention programme prescribed in terms of the number of repetitions, type and duration of exercises and should also consider comparisons of individualised training with group training. There is also a need for studies of the effectiveness of physical therapies in comparison with surgery and vaginal pessaries.

**III. RINGS AND PESSARIES**

Pessaries aim to manage POP by supporting the pelvic area. These shaped devices are inserted into the vagina and rest against the cervix. They hold the prolapse inside the vagina, provide support to related pelvic structures and can relieve pressure on the bladder and bowel. Various shapes and sizes (Figure 9) and types (Figure 10) of pessary exist for use in the treatment of prolapse, a range of which is illustrated by Poma (2000) and Zeitlin (1992) [364, 373]. Modern pessaries are made from a variety of materials...
Figure 9: Range of pessaries (Courtesy of Mediplus Ltd, UK)

Figure 10: Types of pessaries
including rubber, clear plastic, soft plastic with metal reinforcements and silicone [373]. Until recently only a limited range of these has been available in some countries (e.g. the UK where often the choice is a ring or shelf).

Pessaries have been used for many years in the management of POP but their efficacy in treating this condition is unknown [374]. Surveys of pessary use have shown that 86% to 98% of gynaecologists/urogynaecologists prescribe pessaries [374, 375]. In the Cundiff (2000) survey of members of the American Urogynecologic Society 77% of physicians reported using pessaries as a first line therapy. Ninety percent of physicians believed that pessaries relieve symptoms associated with POP, while 48% felt that pessaries also had therapeutic benefit in addition to relieving symptoms.

Whilst there are identifiable trends in pessary use there are clear practice differences with respect to choosing a pessary for a specific patient. Similarly there are no clear prevailing removal regimes [375]. Many physicians receive little or no training in the use of pessaries [374] and have limited experience with pessary selection and fitting.

1. TREATMENT

Clinical experience suggests a substantial proportion of women with prolapse may be managed safely and effectively with a pessary [373, 376, 377]. Much of the evidence relating to pessaries originates from case reports describing complications arising from pessary use [378-381] and review articles that provide advice, primarily based on clinical experience, on the indications for pessary use, pessary selection, fitting, care and replacement [365, 373, 376, 377, 382-387].

A large number of observational studies relating to pessary use have been published. In addition, two completed intervention studies evaluating pessaries (one a before and after design [388], and one a RCT [389]) have recently been published, bringing some advances to research in this area.

1. QUALITY OF DATA

i) RCT: Cundiff (2007) reported a multi-centre crossover RCT, comparing a ring with support and a Gelhorn pessary for the treatment of symptomatic POP. One hundred and thirty four women were randomised; 71 to ring pessary with support and 63 to Gelhorn, followed by crossover to the second type of pessary, ring with support (n=54) or Gelhorn (n=54). Women had stage II or greater symptomatic prolapse and had no prior experience of a pessary. Forty eight percent had stage II, 42% stage III and 10% stage IV prolapse. The largest group (51%) had anterior prolapse. Mean age was 61 years, and most were parous and post-menopausal. There were no significant differences between groups in baseline characteristics. Participants were randomised to be fitted with one of the pessaries for three months, and then were fitted with the second pessary for a further three months. During each three-month period data were collected at one, six and 12 weeks from women who had a successful fit. At one year women had a final appointment to discuss pessary continuation and other treatment needs. Outcomes were measured at enrolment and three-months, including POP-Q, PFDI, PFIQ and a sexual function questionnaire.

Random allocation was by computer-generated random numbers using permuted blocks of variable size. Opaque, sealed envelopes were used to store the random allocation. Participants and clinicians were not blind to the allocation, but data were coded such that analysis was conducted blind.

ii) Non-randomised intervention studies: Lukban (2006) described a study of the effectiveness and safety of the Colpexin Sphere device in women (n=39) with prolapse beyond the hymenal ring [388]; all women had grade three or greater prolapse of at least one vaginal compartment (69% cystocele, 44% rectocele, 31% enterocele, 8% vault prolapse, 21% uterine prolapse). This is a spherical intravaginal device, similar to a pessary, which is placed above the levator musculature and requires active PFM contractions to keep it in place. The device has a string attached for easy removal and is available in six sizes. Its purpose is to reduce the prolapse while facilitating PFM strengthening which may treat co-existing bladder symptoms. Women were instructed to use the Colpexin Sphere only whilst in bed for the first week, and to use continuously thereafter, and were taught PFM exercises to be performed twice daily (Kegels and knee squeezes). The intervention period was 16 weeks. Outcome measures included prolapse stage (modified Baden and Walker classification system), PFM assessment (Brink Scale score), and a Pull Test to measure PFM tone and strength (a tensiometer is used to measure the force required to remove a 35mm sphere from above the levator plate). The small sample size, lack of control group and short follow-up were limitations of the study.

Kapoor (2004) reported on a cohort of 104 women attending a gynaecology service with symptomatic prolapse who completed the Sheffield POP symptom questionnaire [390]. Of these women 65 chose to have surgery and 39 chose to be fitted with a pessary. The baseline symptoms of these women were compared. Fernando (2006), using the same questionnaire, compared symptoms at one year follow-up between women (n=104) who chose surgery (n=48) and pessary (n=56) [391]. It is possible that these studies overlap as they take place at the same hospital.

iii) Observational studies: Several retrospective and prospective observational studies were identified that evaluated factors contributing to successful pessary fitting and usage, and/or the therapeutic impact of pessary use [390, 392-403].
Sulak (1993) evaluated the therapeutic usefulness of pessaries in a retrospective study of 101 women with pelvic relaxation. Wu (1997) performed a prospective study of 110 women with symptomatic POP to evaluate a protocol for pessary treatment. Handa (2002) described prospectively the course of POP amongst 56 women who used a supportive vaginal pessary for at least one year.

Both Hanson (2003) and Clemons (2004) conducted observational studies of 1043 and 100 women with prolapse respectively, to analyse the factors that contributed to successful pessary use. Hanson subsequently conducted further statistical modelling of their data and updated the study findings [397]. Clemons also published separately on the symptoms and patient satisfaction at two months of 73 out of the original 100 study women who had a successful pessary fit [398], and on continuation with pessary at one year of the sub-group who were satisfied users [399]. Mutone (2005) retrospectively reviewed the records of 407 women with symptomatic prolapse who had been fitted with a pessary in order to determine the factors influencing success at three weeks follow-up. Within the group of women 37% had previously undergone prolapse repair surgery. Bai (2005) reviewed the notes of 104 women who had been fitted with a pessary at one urogynaecology department and who were available for follow-up by questionnaire. Data on indications for pessary use, complications, satisfaction and frequency of removal were collected. Maito (2006) carried out a retrospective review of the notes of women who had been referred to a midwifery pessary clinic. Data on 120 women in whom pessary fitting was attempted were presented, including predictors of successful fitting and pessary continuation.

Fernando (2006) addressed the effectiveness of pessaries in alleviating symptoms associated with POP in a prospective study of 203 consecutive women attending a specialist urogynaecology unit.

Follow-up periods for observational studies varied from one week [396] to three years [393]. Only in some studies [394, 396, 398, 399] was a recognised measure of prolapse used i.e. POP-Q examination, to objectively assess and evaluate the prolapse. No consistent measure of pessary fitting “success” was used throughout studies. Commonly used questionnaires were the Sheffield POP symptom questionnaire, and the Pelvic Floor Distress Inventory (PFDI) and Pelvic Floor Impact Questionnaire (PFIQ).

2. Results

i) RCT: Combining the two trial periods in a crossover trial by Cundiff (2007), there were complete data on the ring pessary from 94 women, on the Gellhorn from 99, and on both pessaries from 85. Results were presented graphically with no mean values reported. There were statistically significant improvements in the majority of PFDI and PFIQ scale scores for both pessaries, including the prolapse specific sub-scores (POPD1 for symptoms and POPIQ for impact). However there were no differences between pessaries in improvement in these two sub-scores (POPD1, p=0.99; POPIQ, p=0.29). Considering clinically significant differences in scores (improvement of greater than half the baseline standard deviation), all POPDI sub-scores showed clinically significant improvements for both pessaries. However only for the Gellhorn were there clinically significant improvements in impact of prolapse symptoms (POPIQ), and only then for the physical sub-score and the total POPIQ score. Women who were highly satisfied with the Gellhorn also had improvement in a range of symptoms including the POPDI score; no similar significant association was found for the ring pessary with support.

ii) Non-randomised intervention studies: Lukban (2006) evaluated use of the Colpexin Sphere in 39 women, of whom 27 completed the 16-week assessment and were included in data analysis. Twenty two women (82%) had an improvement in their prolapse of at least one vaginal compartment. No detail of the magnitude of this improvement was given. Seventeen women (63%) exhibited increased PFM function as measured by the Brink Scale total score; however the statistical significance of this improvement was not reported. The Pull Test force during contraction increased significantly (p=0.029) between baseline (mean 1.84lb, SD 1.04) and 16 weeks (2.14lb, SD 1.26). Displacement of the sphere with defaecation was a problem for 72% of women. Only two women (5%) experienced vaginal ulceration, and the problem was mild. Twenty five out of 27 women said they would recommend the device to others for the treatment of prolapse.

Two studies compared symptoms in women having surgery and women having a pessary. Kapoor (2004) found that generally the symptoms present before treatment did not differ between the groups, with the exception of low backache which was significantly more common in the group who then opted for surgery. The surgery group were also significantly younger and more likely to be sexually active. One year post-treatment Fernando (2006) found no significant differences in prolapse, bladder, bowel and sexual symptoms between women who had undergone surgery and those fitted with a pessary. The surgery group had been significantly younger at the outset but parity, ethnicity and menopausal status had been comparable.

iii) Observational studies: Study results show that pessary fitting ‘success’ rates ranged from 56% [393] to 75% [403] of women with POP. Higher success rates for specific types of prolapse (83% for uterine prolapse and 82% for cystocele) were recorded by
Hanson (2003). Comparison of fitting success rates by pessary type was difficult due to use of differing protocols for pessary selection within studies. Wu (1997) used ring pessaries in 96% of women who were successfully fitted. Similarly, ring pessaries were the primary choice of treatment in the studies by Handa (2002), Clemons (2004), Bai (2005) and Fernando (2006), whereas the Gelhorn pessary was primarily used in the study by Sulak (1993). The fitting protocol used by Mutone (2005) specified the ring pessary with support diaphragm in the first instance. Of women who had a successful pessary fitting, ring pessaries were used more often in women with stage II (100%) and stage III (71%) prolapse whereas Gelhorn pessaries were used more often with stage IV (64%) prolapse [396]. Hanson (2006) found significantly greater success with the ring, ring with support and Gelhorn pessaries than other type of pessaries (p<0.05), however only 54% of women in this study had prolapse (the remainder had UI).

Parameters reported as associated with a successful pessary fitting were often contradictory. Hanson (2003), Clemons (2004) and Mutone (2005) reported that patient age was not significantly related to the success of pessary fitting whereas Wu (1997) reported that women who were fitted successfully tended to be older (p<0.05). Mutone (2005) found that women classed as obese were significantly less likely to have a successful fi, whereas Maito (2006) found weight was not a predictor of successful pessary fit. Clemons (2004) reported no effect on fitting success of previous surgical intervention. Whereas Wu (1997) reported that a history of pelvic surgery reduced the probability of a successful pessary fitting from 79% to 67%, although this result was not significant (p=0.2). Mutone (2005) also showed a significant relationship between previous hysterectomy (p<0.001) or prolapse repair (p=0.010) and unsuccessful pessary fit. Similarly Maito (2006) reported that having a prior prolapse procedure or hysterectomy predicted unsuccessful fitting (p<0.001). Hanson (2006) found a higher fitting success rate in women with previous abdominal gynecotuary surgery (71%) compared to those with a history of gynecotuary surgery via the vaginal route (60%) (p=0.027). Fernando (2006) found 75% retained the pessary at two weeks, and that failure to retain was associated both with increasing parity and hysterectomy in a multivariate logistic regression analysis; site and type of prolapse did not affect success.

Current hormone use did not predict greater likelihood of fitting success [393, 396], whereas use of local oestrogen (with or without systemic HRT) was felt to play an important role in successful pessary fitting [395, 397]. Wu (1997) reported that women with SUI before pessary fitting had a significantly lower success rate (p=0.03), whereas Clemons (2004) did not find SUI to be a risk factor for unsuccessful fitting (p=0.60). Maito (2006) found no significant difference (p=0.50) in success rates between women with SUI (94%), POP (89%), or both (81%).

Increasing severity of prolapse was not associated with an unsuccessful pessary fit [393, 396, 400]. Neither was large genital hiatus [396, 400] nor severe vaginal atrophy [396]. Clemons (2004) however did find shorter vaginal length and wider vaginal introitus were associated with an unsuccessful fitting. Women with foreshortened vagina were not less likely to have successful fitting than those without in the study by Mutone (2005). Mutone (2005) also found that the location of prolapse was not associated with pessary success. Maito (2006) however found mild posterior prolapse to be a significant predictor of successful fit (p=0.002).

Comparison of long term pessary usage rates was difficult due to differing follow-up periods used in the studies reported. In Sulak (1993) the average length of use was 16 months. Maito (2006) reported continued pessary use of on average six months (range one to 17 months); discontinuation of pessary use was associated with severe posterior prolapse (p<0.04) after adjustment for age. Fifty percent of women continued to use the pessary at an unspecified follow-up period and 21% discontinued pessary use despite having no surgery [392]. In Wu (1997) 66% of those who used a pessary for more than one month were still users after 12 months and 53% were still users after 36 months. Thirty four percent of women in Handa (2002) continued pessary use for at least one year. Women with greater degrees of pelvic support loss were more likely to continue using the pessary than those with less support loss [392]. The main complaint of patients who discontinued using the pessary was dissatisfaction because symptoms were not adequately relieved or pessary use was inconvenient [392].

With regard to the effect of pessaries on POP symptoms and prognosis, 21.1% (95% CI -0.2% to 43.7%) of women had an improvement in stage of prolapse (measured via POP-Q with pessary removed) and none had worsening after using a pessary at least one year, although improvement was limited to women with anterior vaginal prolapse [394]. Four months after pessary insertion Fernando (2006) found, in the 97 women with successful fit who completed the four month questionnaire, significant improvements in all prolapse symptoms and in many urinary, bowel and sexual variables (change in Sheffield POP questionnaire responses from before pessary fitted to four month follow-up with pessary still in situ). In Sulak (1993) 82% of women still using the pessary at an unspecified follow-up period described their degree of satisfaction with their symptomatic relief as excellent. Clemons (2004) reported 92% (67/73) of women successfully fitted with a pessary were satisfied with
it at two months. All prolapse symptoms were significantly improved, and half of the baseline urinary symptoms had improved or resolved. However 21% of women without urinary symptoms at baseline developed de novo SUI. The 67 women who were satisfied at two months were evaluated at one year [399]. Fifty nine of these women were available for follow-up, 73% had continued with the pessary for at least one year, and 27% had discontinued (after a mean of 5.9 months) and underwent pelvic reconstructive surgery. Logistic regression analysis revealed that age <65 years (p<0.001), stage III or IV posterior vaginal wall prolapse (p=0.007), and desire for surgery at first visit (p=0.04) were independent predictors for discontinued pessary use and surgery.

Despite Cundiff (2000) reporting that use of pessaries was associated with potential complications no major complications were observed in the studies conducted by Sulak (1993) or Wu (1997). Bai (2005) reported 73% of women had complications such as bleeding or erosion, but that these were not severe and 70% said they were satisfied or very satisfied. Nineteen percent removed the pessary most often because of pessary slippage or discomfort. Based on clinical experience many authors advocate the use of local oestrogen to prevent or treat sores [377, 383-387, 396]. Indeed physicians thought that oestrogen was a necessary adjunct “most times” to pessary usage [374]. Differing advice however was apparent with regard to the frequency and amount of oestrogen applied.

**SUMMARY**

In the only RCT of pessaries identified, there was no difference in symptom relief for women between the Gellhorn and the ring with support; however greater clinically significant improvement in prolapse-related quality of life may have been achieved with the former (Level of Evidence: 2). Therefore, despite the fact that pessaries are commonly used in current practice to treat symptomatic POP there is almost no RCT evidence to support recommendations for their use. Whilst pessaries are cheap and complications are rare there is no consensus regarding various aspects of pessary management including indications for different types of pessary, appropriate choice of pessary, pessary fitting procedures, replacement intervals, follow-up care and treatment of complications. Similarly, there is relative little research on the therapeutic benefits of long term use of pessaries for POP although data suggest that they provide symptomatic relief and may prevent worsening of prolapse or indeed promote improvement in prolapse stage.

Pessaries and surgery may equally improve prolapse symptoms, but the types of women who choose these treatment options are likely to be different.

**RECOMMENDATIONS**

In a choice between the Gellhorn and the ring with support, either may improve prolapse symptoms and decrease their impact (Grade of Recommendation: B).

There are a rapidly increasing number of studies in this area; however there remains a pressing need for well-designed RCTs to examine the effects of using the wide variety of different pessaries in the treatment of POP. Such trials need to address optimal pessary effectiveness, including the symptomatic and therapeutic benefits of pessaries as well as the indications for use, pessary fit, replacement and care.

These studies need to adopt consistent protocols regarding choice of pessary and allow sufficient follow-up periods. There is also a need for studies to compare the effectiveness of pessaries with surgery, which is a more expensive option that may have additional morbidity, and with physical therapies. PFMT in conjunction with a pessary is an intervention which may warrant evaluation. It is not clear whether women would consent to being randomised to surgery or pessary; women might consider this if surgery was offered after a period of pessary use. If non-randomised studies comparing surgery and pessary are done, then efforts should be made to match the characteristics of the treatment groups.

**IV. COMPLEMENTARY AND ALTERNATIVE MEDICINES**

No studies have been found that evaluate the role of complementary and alternative medicines in the prevention and treatment of POP in women. It is not known what scope there might be for such therapies.

**V. SUMMARY**

Despite the prevalence of POP in women, which is increasing with the growing elderly population, there has been little attention paid to the effectiveness of interventions for the condition. There are encouraging signs of more rigorous research in this area, with the publication of four RCTs [370-372, 389] in this field since the 3rd ICI.

**1. RECOMMENDATIONS FOR PRACTICE**

There is no Level 1 Evidence, and generally insufficient Level 2 evidence on which to base recommendations for practice, and most recommendations are in effect hypotheses that need further testing in RCTs.
2. FUTURE RESEARCH DIRECTIONS

There is much scope for research on the effects of conservative therapies for POP in women. Research that is urgently needed, in the opinion of the committee members, is highlighted with the use of italics. There are a few recommendations that apply to all future studies in POP in women, namely:

- The assessment and measurement of POP be made in a standardised fashion using a validated outcome measure (such as the POP-Q examination).

- The assessment of prolapse symptoms is made in a standardised fashion. The choice of a single validated tool is however problematic at present.

a) Pelvic floor muscle training (PFMT)

- PFMT may help prevent deterioration of anterior prolapse, and may help improve prolapse symptoms and severity more generally (Grade of Recommendation: B) (Unchanged).

- Preoperative PFMT may help improve quality of life and urinary symptoms in women undergoing surgery for prolapse (Grade of Recommendation: C) (New).

b) Rings and Pessaries

- In a choice between the Gellhorn pessary and a ring with support, either may improve prolapse symptoms and reduce their impact (Grade of Recommendation: B) (New).

c) Rings and pessaries

- There remains a pressing need for well-designed RCTs to examine the effects of using the wide variety of different pessaries in the treatment of POP. Such studies need to:
  - Address optimal pessary effectiveness, including the symptomatic and therapeutic benefits of pessaries as well as the indications for use, pessary fit, replacement and care.
  - Adopt consistent protocols regarding choice of pessary.
  - Allow sufficient follow-up periods.

- There are no trials that address the following. Randomisation may not be appropriate in such studies but efforts should be made to match the characteristics of the treatment groups being compared. Comparisons of interest are:
  - Rings and pessaries versus surgery; surgery is a more expensive option that may have additional morbidity.
  - Rings and pessaries versus physical therapies.
  - Ring or pessary in conjunction with PFMT. (Note: Feasibility work for a larger RCT is currently underway: [http://www.wellbeingofwomen.org.uk/index.asp?PageID=279]).

b) Pelvic floor muscle training (PFMT)

- Studies are needed to fully investigate the role of physical therapies in the prevention of POP. Such studies should:
  - Consider the exact nature and timing of any physical therapies.
  - Ensure that the effects of lifestyle factors and other potential confounding variables are taken into account.

- Further trials are needed to add to the evidence regarding:
  - PFMT alone to improve or prevent deterioration in prolapse severity.
  - The role of PFMT as an adjunct to prolapse surgery.

- There are no trials that address the following comparisons of interest:
  - Low versus high intensity supervision of PFMT
  - Individual versus group PFMT.
  - PFMT versus surgery.
  - PFMT versus rings and pessaries.

a) Lifestyle interventions

- Studies are needed to fully investigate the association between occupation/heavy lifting, bodyweight, constipation and POP. These studies should ensure that:
  - Occupation, physical activity, bowel function and diet are assessed rigorously, using instruments with sound psychometric properties.
  - Potential confounding variables are considered.
  - Attempts are made to overcome some of the obstacles in research in this area such as recall bias inherent in assessing lifetime occupational history, or healthy worker bias which is a problem when attempting to compare POP in women currently employed in heavy labour type jobs versus others.

- Only when the links between various lifestyle factors and POP have been more clearly established can good RCTs be set up to investigate the effects that changes in these lifestyle factors can have on preventing POP.

- Anaemia is a treatable condition, either through diet or medication, and further research on its role in prevention of prolapse is warranted.

c) Complementary and alternative therapies

- Any developments in this area should be studied in RCTs.
SEARCH STRATEGIES

A: Urinary incontinence in women:

Lifestyle interventions

We searched Medline (languages English, Scandinavian, German) and the Cochrane Register of Controlled Trials from 1966-January, 2008 using the following keywords which were linked to “urinary incontinence” or “urination disorders” or “overactive bladder” or “urinary urgency”: lifestyle interventions, weight, obesity, weight loss, exercise, work, physical activity, lifting, smoking, tobacco, coffee, caffeine, posture, constipation, bowel function, fluids, fluid restriction, pulmonary status, cough, and diet.

Pelvic floor muscle training and weighted vaginal cones

This review drew on the search strategy developed for the Cochrane Incontinence Group. Relevant trials were identified from the Cochrane Incontinence Group Specialised Trials Register, which is also described under the Incontinence Group’s details in The Cochrane Library. The register contains trials identified from the Cochrane Central Register of Controlled Trials (CENTRAL), MEDLINE, CINAHL, The Cochrane Controlled Trials Register and hand searching of journals and conference proceedings. The trials in the Cochrane Incontinence Group’s Specialised Register are also contained in The Cochrane Controlled Trials Register (CENTRAL). There was no restriction on language of publication or publication status (that is full publication, grey literature, etc). The date of the last search was 4-10-2007.

Electrical Stimulation

Relevant trials were identified from the Specialised Register of Controlled Trials of the Cochrane Incontinence Group. The register contains trials identified from MEDLINE, CINAHL, the Cochrane Controlled Trials Register (CENTRAL) and handsearching of journals. Additional trials were sought from the reference lists of included studies and a broader search of computerized bibliographic databases (EMBASE, EXCERPTA MEDICA, DUTCH NATIONAL INSTITUTE OF ALLIED HEALTH PROFESSIONS), from 1980 – October 2007, was undertaken. In addition, published abstracts presented at the International Continence Society, the European Association of Urology, the American Urogynaecology Society, and the American Urological Association were reviewed from 2003 to 2007, and cross-referenced to find if a full-length report had been published. Keywords were incontinence, urinary incontinence, detrusor instability, detrusor overactivity, bladder, overactive bladder, stress incontinence, urge incontinence, mixed incontinence, urgency, frequency, nocturia, physiotherapy, physical therapy, conservative management, conservative therapy, non-surgical stimulation, electrostimulation, neuromuscular stimulation, electrical stimulation, electrotherapy, RCT’s, controlled trials, evaluation, effectiveness, efficacy, and outcomes.

Magnetic Stimulation

Relevant trials were identified from the Specialised Register of Controlled Trials of the Cochrane Incontinence Group. The register contains trials identified from MEDLINE, CINAHL, the Cochrane Controlled Trials Register (CENTRAL) and handsearching of journals. Additional trials were sought from the reference lists of included studies and a broader search of computerized bibliographic databases (EMBASE, EXCERPTA MEDICA, DUTCH NATIONAL INSTITUTE OF ALLIED HEALTH PROFESSIONS), from 1980 – October 2007, was undertaken. In addition, published abstracts presented at the International Continence Society, the European Association of Urology, the American Urogynaecology Society, and the American Urological Association were reviewed from 2003 to 2007, and cross-referenced to find if a full-length report had been published. Keywords were incontinence, urinary incontinence, detrusor instability, detrusor overactivity, bladder, overactive bladder, stress incontinence, urge incontinence, mixed incontinence, urgency, frequency, nocturia, physiotherapy, physical therapy, conservative management, conservative therapy, non-surgical stimulation, electrostimulation, neuromuscular stimulation, electrical stimulation, electrotherapy, RCT’s, controlled trials, evaluation, effectiveness, efficacy, and outcomes.

Scheduled voiding regimens

This review began with reports identified in the previous edition [281], which were predominantly obtained from MEDLINE, CINAHL, BIOSIS, and the Cochrane Register of Controlled Trials from February 1966 to January 2004. Keywords linked to urinary incontinence or overactive bladder consisted of: bladder, bladder training, habit training, timed voiding, behaviour therapy, toileting, rehabilitation, and therapy. This literature was updated by adding reports obtained using the same keyword searches in Pubmed from January 2004 to January 2008. Reference lists were searched from protocols and systematic reviews.
published on timed voiding, habit training, and bladder training by the Cochrane Collaboration, the Agency for Healthcare Policy and Research (United States) [256], review articles, and retrieved manuscripts.

To be considered for inclusion, studies had to meet the following criteria:

Prospective research design: randomised controlled or non-randomised controlled trials. If there were non available, then non-randomised cohort studies, case control studies, and case series were reviewed.

Types of participants: cognitively intact, non-institutionalised women and men with stress, urge, and mixed incontinence. Studies involving participants with catheters, urinary tract infections, interstitial cystitis or other pelvic pain syndrome, neurological disorders, or who were pregnant or immediate postpartum were excluded.

Type of intervention: timed voiding, habit training, and bladder training used in the management of urinary incontinence or lower urinary tract symptoms. Studies were excluded where it was not possible to establish any direct effects due to a specific scheduled voiding regimen. For example, studies that compared an intervention that used both bladder training and pelvic floor muscle training to another type of intervention such as drug therapy were excluded because it was not possible to determine the effect of bladder training alone.

Publication type: full published reports in English

B : Urinary incontinence in men:

Lifestyle interventions, pelvic floor muscle training and complementary therapies

We searched the Cochrane Incontinence Group Specialised Trials Register, MEDLINE, EMBASE, CINAHL, ERIC, the reference lists of relevant articles and conference proceedings of Wound Ostomy and Continence Nurses Society, International Continence Society, American Urological Association, Canadian Urological Association and Society for Urologic Nurses and Associates from 2004 at the time of the last ICI to January 2008. Search terms included ‘incontinence’, ‘male incontinence’, ‘prostatectomy/post prostatectomy’, ‘continence’, ‘pelvic floor/muscle exercises/therapy’, ‘biofeedback’, ‘quality of life’, ‘prostate surgery’, ‘urge incontinence’. Manuscripts in languages other than English were retrieved and translation obtained. Randomised or quasi randomised trials were included; case series were excluded.

For Complementary Therapies, the same electronic sources and years were used, applying the search terms “acupuncture” or “hypnosis” or “complementary therapies” or “alternative therapies” AND “urinary incontinence” or “urination disorders” or “overactive bladder” or “urinary urgency” or “uterine prolapse”. Manuscripts that included only children in the study population were excluded.

C : Pelvic organ prolapse:

Lifestyle interventions, physical therapies, rings and pessaries

Reports of RCTs evaluating the effect of lifestyle interventions, physical therapies and the use of rings and devices were obtained from a search of the Cochrane Incontinence Group specialised register. This register contains trials identified from MEDLINE, CINAHL, the Cochrane Central Register of Controlled Trials (CENTRAL) and handsearching of journals and conference proceedings. The date of the last search was November 2007.

Reports of other studies evaluating the effectiveness of the above treatments in the management of pelvic organ prolapse were obtained by searching MEDLINE (January 1966 to November 2007), PREMEDLINE (9 November 2007), EMBASE (1996 to November 2007), CINAHL (1982 to November 2007) and PEDro (November 2007). Key search terms were: prolapse, pelvic organ prolapse, uterine/uterus prolapse, vault prolapse, urogenital prolapse, cervical prolapse, pelvic prolapse, vaginal prolapse, rectocele, cystocele, urethrocele, enterocoele, proctocele, sigmoidocoele, pelvic dysfunction, pelvic disorder, pelvic relaxation, vaginal defects.

The UK National Research Register (November 2007) and ZETOC database of conference abstracts (November 2007) were also searched.

I. INTRODUCTION

Surgery for male incontinence is an important aspect of treatment with the changing demographics of society and the continuing large numbers of men undergoing surgery and other treatments for prostate cancer.

Basic evaluation of the patient is similar to other areas of incontinence and includes primarily a clinical approach with history, frequency-volume chart or bladder diary, and physical examination. Since most of the surgeries apply to patients with incontinence after other operations or trauma, other investigations such as radiographic imaging of the lower urinary tract, cystoscopy, and urodynamic studies may provide important information for the treating clinician.

Although prostatectomy for benign disease has become less frequent in many countries, the complication of incontinence is a rare but unfortunate occurrence that merits treatment. After a period of conservative therapy has been tried, surgical treatment, with implantation of the artificial urinary sphincter, has cured or improved 75-80% of sufferers. Injection therapy with agents such as collagen has helped 40-50% of men in the short term but fewer in the long term. New sling techniques have shown promising results in studies.

Radical prostatectomy for prostate cancer is performed far more frequently now than 10-15 years ago. Approximately 5-25% of patients will experience incontinence and of those a significant minority will require surgical treatment. The artificial sphincter has provided a satisfactory result in most cases with a positive impact on quality of life. Sling procedures are increasingly being reported to have a good outcome. Injectable agents have not shown durable long-term results but newer technologies such as volume-adjustable balloons have shown reasonably favourable early results in a number of reports.

With new data emerging stratification of treatment based on the degree of stress incontinence may become feasible.

Incontinence following radiation therapy, cryosurgery, high-intensity focused ultrasound, other pelvic operations and trauma is a particularly challenging problem because of tissue damage outside the lower urinary tract. The artificial sphincter implant is the most widely used surgical procedure but complications may be more likely than in other areas and other surgical approaches may be necessary. Unresolved problems from pediatric age and patients with refractory incontinence from overactive bladders may demand a variety of complex reconstructive surgical procedures. Other unique problems encountered are fistulae between the urethra and skin and the prostate and rectum. Surgical reconstructions in experienced hands are usually successful.

With extensive worldwide use of the artificial sphincter in the surgical management of male incontinence, its complications and their management are well known. Durability of the device is an important aspect that impacts on outcome and cost of treatment.

Although the literature is replete with well done cohort studies, there is a continuing need for prospective randomized clinical trials.

1. MATERIALS AND METHODS

The committee was charged with the responsibility of assessing and reviewing the outcomes of surgical therapy that have been published since the Third Consultation [1] for non-neurogenic male incontinence. Articles from peer-reviewed journals, abstracts from scientific meetings, and literature searches by hand and electronically formed the basis of this review. The outcomes were analyzed, discussed among the members of the committee and included in the chapter.

The incontinence problems were classified according to their etiology, i.e. either primarily sphincter or bladder related, and are listed in Table 1. Treatment of fistulae is covered separately.

Specific recommendations are made on the basis of published results and determined by the levels of evidence. Consensus of the committee determined the recommendations, which are found at the end of the chapter. Recommendations for future research are also included.
Table 1. Classification of surgically correctable problems

- **SPHINCTER RELATED**
  - Postoperative
    - Post-prostatectomy for prostate cancer
    - Post-prostatectomy for benign disease
    - TURP and radiation for prostate cancer
    - Post-cystectomy and neobladder for bladder cancer
  - Post-traumatic
    - After prostatomeanobanous urethral reconstruction
    - Pelvic floor trauma
  - Unresolved pediatric urologic incontinence
    - Exstrophy and epispadias

- **BLADDER RELATED**
  - Refractory urgency incontinence due to detrusor overactivity
  - Small fibrotic bladder

- **FISTULAE**
  - Prostatouretral (urethrorectal)
  - Urethrocutaneous

II. EVALUATION PRIOR TO SURGICAL THERAPY

Recommendations for evaluation prior surgery have not changed substantially from the last edition in 2005[1]. Before surgical treatment of the incontinent male is undertaken, the following evaluations should be done [2]. Basic evaluation includes history, physical examination (including neuro-urological examination: perineal sensation, anal tone, voluntary contraction and relaxation of the anal sphincter, bulbocavernous reflex [3], urinalysis, and postvoid residual urine. A frequency-volume chart [4], or bladder diary (indicating daytime and nighttime frequency of micturition, incontinence episodes, voided volumes, 24-hour urinary output, etc.) is also helpful. No clear guidelines can be found in the literature indicating the minimum number of days necessary to furnish reliable data for a voiding diary. According to Wyman et al. [5] the 7-day diary can be considered as the gold standard for voiding diaries. Schick et al.[6] demonstrated that a 4 day frequency-volume chart is the shortest one which still gives reliable results, as compared to the 7 day diary. The pad test quantifies the severity of incontinence. The 24-hour home test is the most accurate pad test for quantification and diagnosis of urinary incontinence because it is the most reproducible [7]. The 1-hour pad test is widely used because it is more easily done and standardized. A pad test may be helpful in quantifying leak in AUS failures. Postvoid residual urine is a good estimation of voiding efficiency [8,9]. These basic investigations are recommended in incontinent males prior to surgical therapy.

Blood testing (BUN, creatinine, glucose) is recommended only if compromised renal function is suspected or if polyuria (in the absence of diuretics) is documented by the frequency-volume chart [10]. Further evaluation should be adapted to the particular patient.

Cystourethroscoopy is useful to verify integrity of the urethral wall (anterior aspect of the distal sphincteric mechanism in post-TURP incontinence [11], erosion by the cuff of the artificial sphincter, voluntary contraction of the pelvic floor, etc.) and the status of the bladder (trabeculation, stone, diverticula, etc).

Imaging techniques include plain film of the abdomen (KUB or Kidneys, Ureters, Bladder), in cases of incontinence following artificial sphincter implantation when during the original procedure the hydraulic system was filled with contrast medium. A KUB immediately following sphincter implantation serves as a reference point for subsequent comparisons [12]. Figure 1 illustrates the case of a young spina bifida patient in whom an artificial sphincter has been implanted with the cuff around the bladder neck. After more than 10 years, he became suddenly incontinent. Second KUB compared to previous one clearly demonstrated fluid loss from the system. Contrast studies include cystography which may demonstrate an open bladder neck when bladder denervation is suspected [13] (e.g.: following abdominoperineal resection of the rectum). Cystourethrography may be used to demonstrate a fistula, stricture or urethral diverticulum eg., following healing of the urethral wall erosion caused by the cuff of the artificial urinary sphincter (Figure 2). Ultrasound is widely used not only to evaluate the upper urinary tract, but also to evaluate postvoid residual urine. The sensitivity of 66.7% and specificity of 96.5% when post-void residual is 100 ml or more is adequate for routine clinical use [14]. It has been shown to be cost-effective when compared to catheterization [15]. Other modalities, for example transurethral ultrasound [16] and magnetic resonance imaging of the external sphincter are still under development.

1. URODYNAMIC TESTING

In the opinion of the Committee a thorough urodynamic evaluation to characterize the underlying pathophysiology is useful prior to invasive therapy. However, there are factors that must be considered. In patients with incontinence secondary to radical prostatectomy who developed bladder neck stenosis, the urethral catheter can create obstruction giving false values for Valsalva leak point pressure. Sphincter weakness can be documented by the Valsalva [17] or cough [18] abdominal leak point pressure. Peschers et al. suggested that Valsalva
leak point pressure is significantly lower than cough leak point pressure [19]. However, its reproducibility has been studied almost exclusively in women. Catheter size seems to have a significant influence, but the correlation is extremely high between the test-retest leak point pressure when the same size of catheter is used [20,21]. In male patients, abdominal leak point pressure should be evaluated via a rectal catheter because a urethral catheter is much more likely to invalidate Valsalva leak point pressure measurements than it does in female [22]. It has become evident that bladder volume influences Valsalva leak point pressure, i.e. it decreases with bladder filling [23-25]. However, this observation is not consistent [26]. Unfortunately, there is no agreed standardization of the technique at the present time which somewhat limits its usefulness [27]. Measurement of leak point volume may also provide information on the functional capacity of the bladder [28].

Retrograde leak point pressure has been used to study incontinence following placement of an artificial sphincter [29,30]. It correlates with the lowest abdominal leak point pressure [31]. The intraoperative use of this technique has been proposed and this allows early recognition of intraoperative urethral injury and mechanical malfunction[32]. Electrophysiologic studies, mainly sphincter electromyography, may be useful to document denervation of the pelvic floor when nerve injury or neuropathology is suspected [33].

Detrusor function is best evaluated by multichannel urodynamics. Its main purpose is to detect detrusor overactivity and/or decreased compliance during bladder filling. It can be coupled with fluoroscopic imaging, video-urodynamics. It has also been proposed by some that fluoroscopy be replaced by transrectal ultrasound [34, 35]. Ultrasound measurement of bladder wall thickness was proposed as a better predictor of bladder outlet obstruction than uroflowmetry [36] but at present is controversial [37].

Non-invasive pressure-flow urodynamic evaluation based on Doppler ultrasound seems to have potential for diagnosing bladder outlet obstruction [38]. However invasive pressure-flow studies are still the gold standard in the incontinent male to rule out bladder outlet obstruction accompanied by detrusor overactivity [39] which in turn can cause incontinence.

In most recently published studies, urodynamic testing has been done prior to surgery [40-44]. Cystoscopy is frequently done as well [43, 45-49]. However there are some reports that questioned the value of urodynamics studies in predicting outcomes after
surgery. Thiel et al [50] found no evidence that patients with detrusor overactivity, low first sensation filling, decreased compliance or low bladder capacity had worse outcomes after artificial sphincter placement in 86 men. Trigo Rocha et al [51] also found that preoperative urodynamic findings such as detrusor overactivity, impaired detrusor contraction, low valsalva leak pressure, bladder outlet obstruction, and mildly reduced compliance did not lead to a bad outcome after artificial sphincter implantation.

The proposed evaluation of the incontinent male is summarized in Table 2.

### Table 2. Evaluation prior to surgical therapy

- History
- Physical examination
- Urinalysis
- Urine culture
- Post-void residual (by ultrasound)
- Voiding diary (2-7 days)
  - polyuria without diuretics: BUN, Creatinine, Glucose

- Pad-test
- Cystourethroscopy
- Urodynamics:
  - Multichannel urodynamics:
    - to characterize the incontinence and to detect detrusor overactivity, decreased compliance, and/or outflow obstruction

### III. INCONTINENCE AFTER RADICAL PROSTATECTOMY FOR PROSTATE CANCER

#### 1. PREVALENCE

Urinary incontinence occurring after radical prostatectomy (RP) is a significant problem. Although its rate has lessened [52] in these last few years primarily due to a better understanding of the pathophysiology and improvements in surgical technique, its prevalence has probably increased due to the dramatic increase of RP in developed countries which has lead to an overall increase in the number of patients affected.

Data from large multicenter studies and prostate cancer databases suggest that following RP, 1% to 40% of patients complain of persistent urinary incontinence. The incidence of post prostatectomy incontinence (PPI) depends on the definition of urinary incontinence and the length of follow-up [53-55]. In addition to numerous definitions of incontinence, the tools used to evaluate incontinence vary from validated questionnaires, to interviews from a data manager, to response to the surgeon’s inquiry.

Recent reports of large cohorts use definitions that include “total control/perfect continence”, “occasional leakage but no pad”, and “less than one pad”. Because 1/3 to 1/2 of men who do not wear pads will have occasional leakage of urine, it is important to distinguish among those men who leak enough to require pad use and those who do not, as it has been demonstrated that health related quality of life is strongly correlated with the level of incontinence and wearing one pad more significantly affects the quality of life than wearing no pad [56]. In addition, not all men who leak will elect to have further treatment. Most large cohort studies indicate that between 6% and 9% of patients undergo subsequent surgical treatment for PPI following prostate cancer surgery [57-60]. Several large cohort studies are listed in Table 3 [55, 61-74].

#### 2. RISK FACTORS

Reported risk factors for incontinence following radical prostatectomy include patient age at surgery, stage of disease, surgical technique including nerve sparing, preoperative bladder function and urinary continence status, prior radiation therapy, preoperative length of the membranous urethra, prior transurethral resection of the prostate (TURP), and vascular comorbidities. However, various studies have come to conflicting conclusions on specific risk factors. Risk factors for incontinence after TURP have not been as clearly defined, probably because the incidence is so low, making the accumulation of large prospective series of this type of incontinence difficult. However, previous brachytherapy does predispose to post-TURP incontinence (Section VII in this chapter).

Pre-operative urinary incontinence has been reported as a risk factor for post-operative SUI. While pre-operative lower urinary tract symptoms, including urgency incontinence and “overflow incontinence” may improve with de-obstruction secondary to extirpative surgery [75], pre-operative SUI does not improve following RP. Several recent cohort studies have demonstrated that pre-operative sphincteric insufficiency (demonstrated either the pre-existing clinical sign of SUI or the urodynamic finding of lower maximal urethral closure pressure) predicts post-operative SUI [76, 77]. Pre-operative bladder dysfunction can also contribute to post-operative incontinence. Pre-existing abnormalities of detrusor function may predispose to leakage following surgery, especially in the setting of neurogenic detrusor overactivity due to Parkinson’s disease, dementia or spinal cord injury [78].

Advancing age as a risk factor is supported by several studies [60, 75, 79-83]. Steiner, et al found no
correlation between age and continence status, but only 21 of the 593 patients were 70 years or older [84]. Others have found advancing age and the number of co-morbidities to have a negative impact on the recovering time for continence during the first year after radical prostatectomy [85] although the rate at one and two years did not seem to be significantly affected [86] Mohamad and colleagues reviewed 16,524 patients who underwent RRP in public hospitals, covering 95% of all procedures in Austria between 1992 and 2003. They found that increasing age was associated with an increased risk of future AUS implantation. In those aged 45-49, 0.5% were bothered enough by PPI to merit AUS placement, while those age 70-74 were five times as likely to undergo AUS placement for PPI. [87] Similarly, Rogers, et al demonstrated that age affected post-operative continence status following laparoscopic RRP. In those < 50 years old, 100% achieved 0-1 pad per day continence at 1 year, which decreased to 91% and 81% for those age 50-59 and > 60 yrs, respectively (p<0.01) [88]. Strasser and colleagues hypothesized that age related sphincteric changes may be responsible for the age-related increase in post-operative SUI, and successfully demonstrated a progressive reduction in sphincter striated muscle cells with age [16].

Most large series have found no correlation between the stage of disease and incontinence rates [80, 81, 89-91] Loeb and colleagues specifically demonstrated excellent continence rates even in high risk (high local stage) patients [92]. However, in certain cases, the stage of disease may affect the surgical technique (i.e. nerve sparing) and incontinence rates may be higher, but this appears to be a reflection on surgical technique and not disease stage [82].

Regarding surgical technique, the many parameters involved in continence may explain difficulties in understanding the benefit of certain technical points. Bladder neck preservation has been reported to improve continence at 3 months [90] no difference was found at 6 and 12 months [93, 94]. Nerve sparing has no significant impact according to Steiner et al. [84] and Lepor and Kaci [66] recently confirmed this. Others did find benefit [76]. In particular, Nandipati and

Table 3. Continence rates after radical prostatectomy according definition of continence, Definition 1: total control without any pad or leakage, Definition 2: no pad use but loses a few drops of urine, Definition 3: use no or one pad per day.

</table>
colleagues reported that in a cohort of 152 patients followed prospectively, bilateral nerve sparing surgery was associated with a shorter time to regain continence as well as improved long-term continence rates compared to non-nerve sparing surgery. They additionally found that increased age was a risk factor for post-prostatectomy incontinence.[95] Burkhard, et al. similarly demonstrated a positive effect of nerve-sparing surgery on post-operative continence. In a prospective cohort study of 536 patients, PPI developed in 1/75 (1.3%), 11/322 (3.4%), and 19/139 (13.7%) with attempted bilateral, attempted unilateral and without attempted nerve sparing, respectively. Attempted nerve sparing was in fact the only statistically significant factor influencing urinary continence after RRP in this cohort. [96]

Within the last decade, laparoscopic and robotic-assisted laparoscopic radical prostatectomy have become standard treatments for men with prostate cancer. At this time the body of available data on post-operative continence is limited, but it would appear that continence rates are similar between open and laparoscopic/robotic approaches. Several studies have compared the techniques either prospectively in non-randomized fashion, [72, 73] retrospectively, [97] or via limited meta-analysis [71, 98] and similar continence rates were found. Further prospective comparative studies with open surgery are needed.

Perineal prostatectomy is done by only a limited number of urologists but is still advocated for obese patients and the continence rate was reported as similar to the retropubic route [66, 99, 100].

3. PATHOPHYSIOLOGY

Post-prostatectomy incontinence, like any urinary incontinence, may be caused by bladder dysfunction, sphincter dysfunction or a combination of both. Urodynamic investigations are helpful to rule out bladder outlet obstruction or significant bladder dysfunction. In addition to incontinence symptoms, storage and voiding symptoms may be associated [99, 101]. Urodynamics demonstrated that the sphincter incompetence occurs as the sole cause in more than two thirds of patients, while isolated bladder dysfunction (detrusor overactivity, poor compliance, detrusor underactivity during voiding) is uncommon, occurring in less than 10% [102, 103]. However, sphincter and bladder dysfunction can coexist in at least one third of incontinent patients. Bladder dysfunction may occur de novo after prostatectomy perhaps induced by bladder denervation; may be caused by outlet obstruction, or may be related to pre-existing factors such as the age. Impaired detrusor contractility and poor compliance resolved in the majority of patients within 8 months [104].

Decreased sphincter resistance may be due to tissue scarring in some cases and reflected by a low urethral compliance, however this parameter is difficult to measure [102]. Scarring may lead to an anastomotic stricture evidenced by endoscopy or urethrography, and is clinically suspected when both incontinence and decreased force of stream coexist.

The pre-operative length of the membranous urethra determined on MRI has been shown to be significantly related to time to post-operative continence. When urethral length was greater than 12 mm, 89% of the patients were continent at one year, versus 77% with or less than this length [105]. Urodynamic studies revealed that a reduced functional urethral length was a predictive parameter of incontinence [76, 106, 107], Different components of the urethra may also be involved. The urethral intrinsic component responsible for passive continence as well as the extrinsic component responsible for active continence may be involved as has been demonstrated in a urodynamic alpha blockade test [108]. This may explain passive incontinence despite a high voluntary urethral pressure or that measured during an active squeeze by the patient. Post-operative disruption of the innervation of the posterior urethra may also be involved and can affect both motor and sensory functions [109, 110]. In clinical practice, urodynamic evaluation of a urethral weakness may be assessed by resistance to antegrade leakage (ALPP or VLPP), retrograde leakage, or profilometric measurement (MUCP) [111]. However no such parameters have been correlated to outcomes of treatments for the correction of post prostatectomy incontinence.

The state of a patient’s pelvic floor may also influence continence or return to continence after RP. Physiotherapy and pelvic floor rehabilitation have been shown to improve or enhance continence (decreased time to final continence level) in the post-operative period in two randomized studies, but only if such measures are instituted before or immediately after catheter removal [112, 113]. Maximum difference between physiotherapy and no treatment is achieved at 3 months, with almost no difference at 12 months. Another study showed that providing patients with instructions for pelvic floor muscle exercise alone was equivalent to biofeedback or electrical stimulation [114]. A randomized study in which randomization occurred 6 weeks after surgery showed no difference in continence at 6 months [115]. On the same note, studies in which physiotherapy was used as a treatment modality for established incontinence have shown more variable results [116-119].

4. SURGICAL AND MINIMALLY INVASIVE TREATMENTS

a) Urethral bulking agents

Urethral bulking is a minimally invasive treatment proposed for post prostatectomy incontinence, and theoretically works by adding bulk and increasing
coaptation at the level of the bladder neck and distal sphincter. It can be done in an office or outpatient setting in a retrograde or antegrade fashion. Several different agents have been used for urethral bulking in men including bovine collagen (Contigen®), and silicone macroparticles (Macroplastique®). All agents share the similar problems including the need for multiple injections, deterioration of effect over time, and very low cure rates.

For collagen, “success rates” for post-prostatectomy incontinence range from 36-69%, with 4-20% of patients reporting being dry [120-127]. Unfortunately, the end points in most of these studies are subjectively based, making comparisons difficult; however, it is clear that cure rates (total dryness) are low, and multiple injections are required to achieve modest rates of subjective improvement. There is no advantage of delivery technique (retrograde vs. antegrade). Several authors have identified factors which negatively affect results include extensive scarring or stricture formation, previous radiation, and high grade stress incontinence and low ALPP [121, 123, 124, 127]. One study reported more favorable results for collagen in treating incontinence after transurethral prostatectomy as opposed to radical prostatectomy (35.2% “social continence” versus 62.5%) [124]. It appears that collagen injection does not adversely affect outcomes of artificial sphincter implantation and does not increase the complication rate [128]. Nor does collagen injection adversely affect outcomes of artificial sphincter implantation and does not increase the complication rate [128]. Nor does collagen injection adversely affect outcomes of artificial sphincter implantation and does not increase the complication rate [128]. Nor does collagen injection adversely affect outcomes of artificial sphincter implantation and does not increase the complication rate [128]. Nor does collagen injection adversely affect outcomes of artificial sphincter implantation and does not increase the complication rate [128]. Nor does collagen injection adversely affect outcomes of artificial sphincter implantation and does not increase the complication rate [128].

Other bulking agents such as polydimethylsiloxane (Macroplastique®) have shown some initial success, but results also deteriorate over time. Bugel and co-workers treated 15 patients. They noted rapid deterioration after initial improvements with success rates of 40%, 71%, 33%, and 26% at 1, 3, 6, and 12 months respectively [131]. They also noted that a urethral closure pressure of at least 30 cmH2O was essential for success. Kylmala et al. prospectively studied 50 patients with mild to moderate SUI (average 48 cc on 1 hour pad test), with 12% achieving short-term continence following 1 injection, and an additional 20%, 18%, and 10% achieving continence with 2, 3, and 4 injections respectively. Follow-up, however, was limited to 3 months [132]. In a randomized trial of AUS versus Macroplastique injection in patients with minimal SUI (the vast majority had SUI following BPH surgery, with greater than 1/3 of the cohort suffering from SUI following RRP), Imamoglu and colleagues demonstrated no difference in success with AUS versus Macroplastique. However, in patients with more severe incontinence, AUS was superior, with minimal improvement following transurethral Macroplastique [47].

Several other bulking agents are currently used or are under investigation for female stress urinary incontinence, although there is minimal data on the use of these agents in men with post RP incontinence, it is certainly hoped that their effect will be better than those of currently available agents. These agents include carbon coated zirconium oxide beads (Durasphere®), hyaluronic acid dextranomer (Zuidex®), dimethyl sulfoxide/ethylene vinyl alcohol copolymer (Tegress®, Uryx™), hydroxylapatite spheres in carboxymethylcellulose carrier (Coaptite), and autologous muscle cells, stem cells, and fibroblasts. In a single institution series of 18 patients followed for an average of 4.2 months, injection of ethylene vinyl alcohol copolymer, (Tegress, C.R. Bard, Inc., Covington, GA) 41.1% of patients achieved at least a 50% improvement, but the complication rate was 58.8%. Accordingly, this compound is no longer available as an injectable agent [133].

Transurethral injection of living muscle stem cells to reconstitute the deficient urethral sphincter has recently been introduced. Mitterberger and colleagues demonstrated a 67% continence rate at an average of 1 year follow-up in a cohort of men suffering from PPI who were treated with transurethral ultrasound guided injections of autologous fibroblasts and myoblasts obtained from skeletal muscle biopsies [134]. An earlier report from the same group demonstrated that men with PPI achieved a 52% dry rate with injection of adult autologous stem cells, which was superior to a similar cohort of men treated with collagen injection [135]. However, it must be pointed out that there was a retraction issued by the editors of The Lancet [136] for a previous article on the treatment of female SUI with autologous cells published by the same group [137]. The project was investigated by the AGES PharmMed, a department of the Austrian Government’s Agency for Health and Food Safety. The editors stated that in their view “the conclusions of the official investigation pinpoint so many irregularities in the conduct of their work that, taken together, the paper should be retracted from the published record.”

Conclusion: Bulking agents remain the most minimally invasive treatment for post RP incontinence after conservative measures. All agents for which there is peer-reviewed data available, show only modest success rates with very low cure rates. Effects tend to deteriorate over time. It remains to be seen if improvements in outcomes can be achieved with alternative agents, or if the concept of urethral bulking has achieved its maximal benefit with the agents available now. (Level of evidence 3; Grade of recommendation C)

b) Male sling

The male sling procedure is based upon the concept of passive external urethral compression, and has recently emerged as a treatment for PPI. The male
sling is actually based on the concept similar to that described by Kaufman and associates in the early 1970's [138-140]. At that time a high rate of failure, septic complications and pelvic pain as well as the advent of the mechanical artificial urinary sphincter (AUS) led to the abandonment of the Kaufman prosthesis. Now with the higher prevalence of PPI and patient desire for less invasive surgery and a non-mechanical device the concept has been revisited. Procedures have been developed based on principles used to treat female stress urinary incontinence using biological and synthetic graft materials. These procedures rely on compression from the ventral side of the urethra rather than the circular compression caused by a natural or artificial sphincter. Therefore, most successful sling surgeries rely on a device that is placed under tension, occluding the urethra at rest, and during stress manoeuvres [141-143].

Schaeffer and Stamey described the bulbourethral sling which uses Dacron bolsters placed under the urethra, which are suspended to the anterior rectus fascia by sutures [144]. Data on this procedure are limited to retrospective analyses from the two authors who described the procedure: it has never gained widespread popularity. In the initial report from 2 centers, 64 patients were included and 56% were “dry” and 8% “improved” at a mean follow up of 22.4 months [144]. Almost one-third needed secondary retightening procedures and patients with radiation fared poorly. Subsequently, Clemens, et al reported a questionnaire-based study of 66 men from a single institution and 41% were cured and 51% improved but mean follow up was only 9.6 months [145]. They also reported that the bulbourethral sling did not cause significant outlet obstruction [146].

The long-term efficacy of the bulbourethral sling was evaluated in 2005, where 95 patients were followed retrospectively at an average of 4 years postoperatively. With follow-up questionnaires returned by 71 patients, the authors found that in patients who had undergone radiation, had worse outcomes with 14% dry and 43% requiring 1 or 2 or fewer pads daily. Those patients who had not had radiation treatment had a cure rate of 42% and 72% used only 0-2 pads per day for mild leakage [147]. Others have described a bulbourethral sling using a polypropylene mesh graft with or without a porcine dermis backing (presumably to reduce the risk of erosion) [48]. In two small studies of 9 [148] and 16 [48] patients cure rates range from 56-69% and failure rates from 22-25% at a mean follow up of 14 months. Recently, John described the bulbourethral composite suspension where porcine dermis is secured to the bulbospongious muscle and a 1 cm wide polypropylene sling is placed over this and passed through the retropubic space to emerge from two suprapubic incisions (similar to the tension free vaginal tape procedure in women) [48]. He reported a 69% cure and additional 6% improvement in 19 patients, with a mean follow up of 14 months. Eight intraoperative bladder perforations healed without complication.

Xu and colleagues described a bulbourethral composite suspension utilizing a suburethral polyester patch plus a narrow polypropylene tape passed from a perineal incision to a suprapubic incision. At an average of 28 months, 22 (85%) of 26 patients were successfully treated [149].

The most common method of sling fixation involves use of bone anchors. The bone anchored male sling (BAMS) has increased in popularity, as bone anchor fixation obviates the need for any suprapubic incision for suture passage and fixation. Since 2001, reports of the BAMS have become more prevalent in the literature. In 2001, Madjar, et al reported on 14 patients with post RP incontinence that underwent the procedure with a synthetic or cadaveric fascial sling [150]. At a mean follow up of 12.2 months, 86% were “cured” wearing none or 1 pad. Comiter reported a 76% cure and 14% "substantially improved" rate in 21 men with post prostatectomy incontinence using polypropylene mesh with a mean follow up of 12 months [129]. In a 2005 update, the same author reported that with a median of 48 months follow-up, 65% of patients remained pad free and 15% required 1 pad per day [151]. Urodynamic follow up in 22 men, revealed that the sling had no significant effects on voiding function and no man was obstructed postoperatively [152]. Onur and colleagues reported on 46 men with a mean follow-up of 17 months (6-26) [153]. They used different materials for the sling (allograft dermis, allograft fascia lata, porcine small intestine submucosal (SIS) graft, synthetic mesh, and a composite of synthetic and dermis). Overall they reported 41% of patients dry and 35% improved (50% reduction in the number of pads). All patients in whom allograft or xenograft alone were used failed. A 24-month update from that group revealed a patient satisfaction rate of 70% and a 74% improvement in leakage at a median of 24 months [154].

Several new slings have been introduced, with a common objective of overcoming the potential problem of overcorrection or undercorrection of continence. Transobturator slings have been introduced, [44, 155, 156] which rely more on rotation of the dorsal surface of the proximal bulbous urethra and indirect support of the sphincteric urethra, rather than direct compression of the urethral lumen [157]. However, small numbers of patients, with limited follow-up do not allow for adequate assessment of this new technique enjoying early popularity.

In an effort to overcome the problem of undercorrection, two “adjustable” slings have been introduced — the readjustable sling procedure (REMEEX), [158], and the “Argus” [159] In 48 patients reported in a Phase III multicenter trial of the Argus
sling, a 73% continence rate and additional 10% improvement rate was realized at an average of 7.5 months. Erosion and infection necessitated sling removal in 10% of patients. Adjustments were indicated for persistent incontinence as well as for urinary retention. In a prospective multicenter Phase II trial of the Male Remex System (MRS) adjustable sling, 51 patients were followed for an average of 32 months (range: 16-50). With 90% of patients requiring at least 2 adjustments, a continence rate of 64.7% was achieved, with an additional 19.6% realizing improvement over baseline [160].

Sling results are shown in Table 4 [40, 41, 48, 144, 147-154, 158-165].

1. COMPLICATIONS

Due to the small size of most reported cohort series of male sling patients, and due to the limited body of literature on the subject, the precise complication rate is not known. However, reports from the largest cohorts of patients reveal an infection rate ranging from 0-6%, and a urethral erosion rate of 0-2% [41, 151, 163]. Bothersome scrotal pain or numbness affects 16%-72% of patients post-operatively, but has been reported to resolve in all patients by 3 months [151, 165]. Reported rates of recurrent incontinence following sling surgery, amenable to revision surgery, are low (<5%) [41, 151, 154]. But the small sizes of the cohorts, and the limited follow-up of < 5 years prevent meaningful comparisons to the AUS at this time. Urinary retention is uncommon with male sling surgery, and may be avoided by excluding those patients with detrusor underactivity on pre-operative urodynamics [165, 166].

2. PREDICTORS OF SUCCESS

Several cohort studies have demonstrated that prior radiation therapy is associated with diminished efficacy of the male sling, probably due to urethral fibrosis and inadequate urethral coaptation [147, 153, 165]. In addition, the use of organic (resorbable) material is less efficacious than synthetic (permanent) sling material [153, 163, 165]. The treatment of male ISD with a suburethral sling requires tension which can only be maintained with the use of synthetic material. Pre-treatment severity of incontinence measured by the degree of leakage also appears to influence sling results. Several reports indicate that those with more severe leakage do not achieve similar continence rates when compared to those with milder leakage [153, 163, 165]. Fischer and colleagues were able to quantify, in prospective fashion, that leakage greater than 423 gm on pre-operative pad weight predicted an inferior outcome, compared to those men with less leakage on pre-operative pad weight test [41]. In their report, 62 patients with SUI were followed prospectively. All patients were rigorously evaluated with 24-hour pad test, urodynamics and validated incontinence questionnaires. Success was determined by the Patient Global Impression of Improvement. Overall, 36/62 (58%) of surgeries were successful at a mean follow-up of 15 months. The only preoperative predictive factor was 24-hour pad weight. If pad weight was less than 423 gm, there was a 6-fold greater success rate compared to those with a pre-operative pad weight of greater than 423 gm.

Finally, previous AUS placement and explantation predict sling failure [152, 163]. However, it is not clear if this is directly due to the urethral fibrosis and poor urethral coaptability, and/or if those patients simply suffer from more severe incontinence, which interferes with successful sling surgery.

CONCLUSION

In the intermediate term, the male sling appears to perform reasonably well. In the UK as well, the National Institute for Health and Clinical Excellence (NICE) has stated that current evidence on the safety and efficacy of slings appears adequate to support their clinical use [167].

The best candidates appear to be those with lower and moderate degrees of incontinence, who have not had previous radiation. While reported revision rates due to recurrent incontinence are quite low, longer follow-up is obviously needed before definitive comparisons to the AUS can be made. Nevertheless, in men with adequate detrusor contractility and mild to moderate degrees of SUI, or for patients demanding a less invasive procedure or non-mechanical device, a sling procedure is a reasonable alternative to artificial sphincter, although longer term outcome is unknown. (Level of evidence 3; Grade of recommendation C)

3. ADJUSTABLE BALLOONS

The adjustable balloon procedure is based upon the concept of passive compression of the urethra utilizing two balloons located on either side of the urethra. Balloons may be progressively inflated until there is optimal coaptation, thereby achieving continence. The biomaterial name ACT™ (Adjustable Continence Therapy) was originally conceived and developed for female stress urinary incontinence, and subsequently was applied to male incontinence. The proACT™ device was developed and reported in 2000 [168].

The device consists of a silicone elastomer balloon attached to an injectable titanium port via a silicone tube. A balloon is implanted on either side of the urethra, either under the bladder neck for post-radical prostatectomy incontinence, or under the veru montanum for post-TURP-incontinence. The ports are located subcutaneously in the scrotum, allowing simple access for percutaneous adjustment of the balloon volume. The implantation is performed under general or spinal anesthesia through a short perineal

</table>
incision. A trocar covered with a U-shaped sheath is inserted up to the site of implantation, and then the balloon is pushed along inside the sheath. Fluoroscopic and urethroscopic guidance are used for the procedure. Transrectal ultrasound guided implantation [169] is a possible option. An isotonic medium with sterile water and contrast medium is prepared to fill the balloons with 2 ml during the initial procedure. Then, after a period of one month, the balloons are refilled with 1 ml of this solution at each period (maximum filling is 8 ml) until continence is achieved. The adjustment of the filling is volume limited and are carried out step by step in order to obtain a pseudo-capsule surrounding the balloons and therefore to minimize the risk of urethral erosion or migration. Results from 6 prospective studies [43, 46, 170-173] reported are shown in Table 5. Of 170 patients reported by Hubner [170] and Lebret [46], one-third became pad free. In other studies 70% of patients utilized 0-1 pads daily [46, 170-172]. Mean procedure time of 35 minutes was reported. Along with this improvement in pad use, there were parallel improvements in L-Qol quality of life score [46, 170, 171]. Based upon theses trials, the mean number of post-operative adjustments of the balloon was 3 to 5, with some patients requiring 6 to 8 refillings.

4. COMPLICATIONS

The most common peri-operative complications are urethral or bladder perforation, necessitating termination of the implant on the perforated side. However, contralateral implantation was not adversely affected, and repeat ipsilateral implantation was invariably achieved after healing of the urethral or bladder wall. Lebret et al. [46] reported a perforation rate of 10% and Hubner [43] reported a rate of 18% early in their series, but a lower urethral perforation rate in the most recent cases – illustrating a relatively short learning curve for optimal balloon placement near the urethral/bladder wall. Temporary urinary retention from presumed obstruction was reported at 5% [43]. Voiding was restored by removing fluid from the balloon.

Device explantation related to balloon failure, infection, erosion, or migration. The explantation rate ranged from 12 to 58% [43, 46, 170-173], but decreased with experience [43]. Device removal is straightforward, as a deflated balloon can be explanted transperineally. The only reported risk factor for failure and complications was prior external beam radiotherapy [46]. Kocjanic et al. [173] demonstrated a continence rate of 67% in non-radiated patients compared to 36% in radiated patients.

CONCLUSION

The proACT™ balloon technique appears to be a feasible procedure to improve the continence in short and median term, with better results occurring with more operator experience. Similar to the male sling procedure, appropriate candidates include those with mild to moderate leakage due to intrinsic sphincter deficiency, and no previous radiation. The benefit of an adjustable system should be weighed against the need for multiple sessions of refilling the balloon, and with reported rate of peri-operative and post-operative complications. Longer follow-up is needed before definitive comparison to male sling or artificial sphincter can be made. No recommendation is possible due to variable data on complication rates (12-58%). (Level 3, Grade D).

c) Artificial urinary sphincter

The artificial urinary sphincter remains the most effective long term surgical treatment for post RP incontinence due to sphincteric insufficiency. However, due to the cost of the device, patient reluctance to have or inability to use a mechanical implant, and fear of complications, it is not ideal for all patients. In addition the development of less invasive techniques (as described above) potentially gives patients new options for treatment. Ultimately the choice of AUS will be based upon patient dexterity, economics, degree of incontinence and patient expectations from surgery.

The AUS has the longest track record of success in the treatment of PPI. Two studies have reported that about half of the patients with severe incontinence will undergo AUS implantation [174, 175]. However, these studies were conducted before male slings and bulking agents became popular. The success rates for AUS as defined by a continence status of zero to one pad per day range from 59% to 90% [176, 177], as shown in Table 6 [51, 176, 178-187]. Just as with reported rates of incontinence following prostate cancer surgery depend on the definition of incontinence, continence rates with the AUS can vary with the definition of continence, the method of evaluation, and the length of follow-up. The lowest rates are from patient administered questionnaires when pad free rates range from 10-72% [179, 188-192]. Nevertheless, high satisfaction rates of 87% to 90% are consistently reported, even without total continence [180, 184, 188].

One potential downside of the AUS is the need for periodic revisions in a number of patients. Revision and explantation rates due to mechanical failure, urethral atrophy, infection and erosion vary considerably among studies with respectively reports of 8-45% and 7-17% [192]. In a large cohort reported by Lai and colleagues [187], non-mechanical failure has decreased from 17% to 9% and mechanical failure decreased from 21% to 8% following introduction of the narrow back cuff and mean time to reoperation was 26.2 months (mean 2-68 months). With a Kaplan-Meier analysis, the overall 5 year expected product survival was 75%. Only 6% of devices failed mechanically, at an average of 68.1 months, with 75% of patients requiring no revisions at 5 years. Actuarial freedom from revision at 5 years was estimated at 50%-75%.

The long term efficacy of the AUS was demonstrated by Fulford et al who reported that at 10-15 year followup, [193] 75% of patients with an implanted AUS either still had or died with a functioning device. Revisions include replacement of the malfunctioning part, cuff replacement, repositioning or downsizing due to urethral atrophy, a second or tandem cuff [194, 195] or transcorporal cuff placement [196]. Transcorporal cuff placement, which involves inserting the cuff through the corporal bodies to avoid perforating the dorsal aspect of the urethra, can be particularly useful for patients with prior radiation or urethral erosion; however potency if present may be compromised. Some have advocated tandem cuffs not only as a salvage procedure, but also as a primary procedure for men with severe incontinence [197, 198]. However, O’Connor et al. recently reported no difference in continence outcome and a higher revision rate in patients undergoing double-cuff implant versus single-cuff after longer follow up [199].

</table>
An increased revision rate has been reported for patients who received pelvic radiation [179, 200] but was not found in a recent series [177]. The results for continence for radiated patients are variable with some studies showing lower success rates [176, 200] while others do not [191]. It has been recommended that such patients have a lower pressure reservoir and/or longer period of deactivation time [179].

**CONCLUSION**

The AUS remains the gold standard for the treatment of PPI secondary to sphincteric insufficiency in patients with severe incontinence, and in those who have had external beam radiation treatment. It has the largest body of literature reporting long-term success. The long term success rates and high patient satisfaction seem to outweigh the need for periodic revisions in some patients. Intermediate term data with the male sling demonstrates that the sling is an alternative to the AUS in patients with mild-moderate SUI, provided that those patients have not failed previous AUS surgery, have not had radiation treatment, and have normal bladder contractility. Overall, the AUS remains the reference standard to which all other treatments must be compared. (Level of evidence 2; Grade of recommendation B)

**5. TIMING OF SURGICAL INTERVENTION**

There are no clear data on timing of a surgical intervention for the treatment of PPI, either with benign or malignant disease. Therefore, at present guidelines as to timing of the surgery cannot be formulated. A certain period of watchful waiting supplemented with conservative measures, particularly pelvic floor physiotherapy, seems to be a reasonable option. Thus, conservative management may be tried for periods of up to 6-12 months depending on whether there is any progress noted by the patient. In a prospective cohort study of men undergoing RRP, Lepor and Kaci63 demonstrated continued recovery of continence up to 24 months post-operatively, from 80.6% at 3 months to 95.2% at 12 months, plateauing at 98.5% at 24 months. Other cohort studies have demonstrated a plateau in continence rates at 12 months [201, 202]. Since continence may improve up to 12 months post-operatively, and possibly even until 24 months, it is generally recommended that behavioral/conservative management be utilized during the first year after prostate cancer surgery.

There have been some studies evaluating the effect of early interventional treatment for incontinence. Schneider and colleagues [203] demonstrated a beneficial effect on the earlier return to continence with early injection of periurethral bulking agent. Results were better in the subgroup of 34 patients that were injected early (mean 23 days post-operatively) compared to 10 patients treated at a mean of 26 months post-operatively. It could not be demonstrated, however, that long term continence is improved by early injection of bulking agent. Similarly, Jones and colleagues [204] demonstrated in a comparative cohort study of RRP patients treated either with or without a simultaneous suburethral sling, that sling placement at the time of RRP resulted in an earlier return to continence. There was no difference after 24 months. (Level of evidence 4; Grade of recommendation C)

**IV. INCONTINENCE AFTER PROSTATECTOMY FOR BENIGN DISEASE**

**1. INCIDENCE AND RISK FACTORS**

The incidence of urinary incontinence after prostatectomy for benign disease has been reviewed and described in the AHCPR “Benign Prostatic Hyperplasia” clinical Practice Guidelines [205]. The following percentages for stress incontinence and total incontinence, respectively, were reported:

- Open surgery (retropubic or transvesical prostatectomy): 1.9% and 0.5%.
- TUIP (transurethral incision of the prostate): 1.8% and 0.1%.
- TURP (transurethral resection of the prostate): 2.2% and 1.0%.

These figures were based on studies reported before 1990. Several other series were published after 1990. These series were reviewed for the 1st, 2nd, and 3rd International Consultations on Incontinence [1, 206, 207]. A clear description of the method of follow-up and assessment of the continence status was indicated in only about one third of these studies. The incidence of incontinence after open surgery, TURP, TUIP and HoLEP is low: the reported percentages ranged between 0 and 8.4%. Since the method of assessment of the continence status and the definition of incontinence is rarely stated it is actually not possible to make a distinction between simple stress incontinence and total incontinence. There is no clear indication that the incidence is affected by patient age or (resected) prostatic volume [206]. In a retrospective chart review from Wendt-Nordahl and colleagues [208], the incidence of incontinence following TURP was reported to have decrease over 17 years, from 3.3% in 399 patients operated on between 1987 and 1997, compared to 1.3% in 550 patients operated on from 1997-2004. Whether this statistically significant (p < 0.05) difference was due to improvement in surgical technique or patient characteristics is not clear, however both the earlier and later incontinence rates are consistent with those in the AHCPR and AUA guidelines reports.
In summary, the AUS is a successful surgical treatment option for post-prostatectomy incontinence. It is the most commonly performed surgery for post-prostatectomy incontinence, with the longest follow-up and therefore longest record of success. Level of evidence 2; Grade of recommendation B)

b) Injectable agents

Most series include post-prostatectomy incontinence after treatment for benign and malignant disease, with the majority after prostate cancer surgery. For collagen, “success rates” range from 36-69%, with 4-20% of patients reporting being dry [120-127]. Study results are inconsistent with both TURP [224] and radical prostatectomy [225] showing better outcomes. Other bulking agents such as polymethylsiloxane PDMS (Macroplastique®) have shown some initial success, but results also deteriorate over time. Bugel and co-workers treated 15 patients. They noted rapid deterioration of initial improvements with success rates of 40%, 71%, 33%, and 26% at 1, 3, 6, and 12 months respectively [131]. As mentioned previously in the section on post-radical prostatectomy incontinence Kylmala et al. prospectively studied 50 patients with mild to moderate SUI (average 48 cc on 1 hour pad test), with 12% achieving continence following 1 injection, and an additional 20%, 18%, and 10% achieving continence with 2, 3, and 4 injections respectively [132]. Follow-up, however, was only 3 months. In a randomized trial of AUS versus Macroplastique injection in patients with minimal SUI (the vast majority had SUI following BPO surgery, with less than 1/3 of the cohort suffering from SUI following RP), Imamoglu and colleagues demonstrated no difference in success with AUS versus Macroplastique. However, in patients with more severe incontinence, AUS was superior, with minimal improvement following transurethral Macroplastique [47]. There has also been some initial work with sphincteric injections of muscle stem cells [134, 135].

Bulking therapy fails in up to 75% of men. Of those who are improved only a minority actually becomes dry with short-term follow-up. Although bulking therapy may be slightly more efficacious in treating SUI following TURP compared to SUI following prostate cancer surgery, bulking is of limited value in those men with all but minimal SUI. (Level of evidence 3; Grade of recommendation C)

c) Male sling procedures

Since Frangenheim described his first successful urethral sling suspension for post-traumatic stress urinary incontinence in 1914, various sling materials and surgical methods have been reported [226]. Rectus fascia, as described by Frangenheim, has distinct advantages over alloplastic materials with respect to erosion and infection risks. Allograft off-the-shelf-materials like lyophilized fascia lata have a higher infection risk than does autologous fascia,
whereas the use of synthetic materials like polypropylene mesh or polytetrafluoroethylene slings are associated with a higher incidence of urethral erosion [227]. According to various published techniques, the sling can be placed either underneath the bladder neck, the urethral bulb or the membranous portion of the urethra. The principle of continence support is similar for all sling procedures and comprises passive compression of the urethra, which is dependent on the applied sling tension [161]. This mode of action favours sling procedures as a treatment option for intrinsic sphincter deficiency.

However, the sling tension needed for restoration of continence has not been standardized, with tensioning techniques ranging from perfusion sphincterometry, to a cough test, to visual approximation, [153, 228] and therefore the success of the procedure probably depends heavily to the surgeon’s experience and the degree of sphincteric incompetence. Overcorrection with consequent urinary retention (especially in the setting of detrusor underactivity) and undercorrection with persistent or recurrent incontinence are certainly possible, which may adversely affect continence, bladder emptying, and patient satisfaction. Published success rates are shown in Table 4 [40, 41, 48, 144, 147-154, 158-165].

Several new slings have been introduced, with a common objective of overcoming the potential problem of overcorrection or undercorrection of continence. Transobturator slings [44, 155, 156] rely more on rotation of the dorsal surface of the proximal bulbous urethra and indirect support of the sphincteric urethra, rather than direct compression on the urethral lumen [157]. However, small numbers of patients, with limited follow-up do not allow for adequate assessment of this new technique which is enjoying early popularity.

In an effort to overcome the problem of under-correction, two “adjustable” slings have been introduced — the readjustable sling procedure (REMEEX), [158], and the “Argus” [159]. In 48 patients reported in a Phase III multicenter trial of the Argus sling, a 73% continence rate and additional 10% improvement rate was realized at an average of 7.5 months. Erosion and infection necessitated sling removal in 10% of patients. Adjustments were indicated for persistent or recurrent incontinence as well as for urinary retention. In a prospective multicenter Phase II trial of the Male Remex System (MRS) adjustable sling [160], 51 patients were followed for an average of 32 months (range: 16-50). With 90% of patients requiring at least 2 adjustments, a continence rate of 64.7% was achieved, with an additional 19.6% realizing improvement over baseline.

---

**V. SURGERY FOR INCONTINENCE IN ELDERLY MEN**

With an increase in the aging population and improvements in anesthesia, availability of less invasive and shorter surgical procedures, reduced blood loss and reduced infection risk more aged patients are candidates for surgical treatment. Although every surgeon should be aware of those special risks in elderly patients which might require special peri-operative care, even in the very old well planned surgical procedures can be safe, and are justifiable, if it helps to improve continence and besides benefiting general health status leads to a better quality of life for the individual. Many studies have documented that the frequency of peri-operative complications increases with age [229]. This finding is not surprising given that the prevalence of significant co-morbid conditions is increased in the elderly [230]. It is however unclear whether the increased frequency of complications can be attributed to these co-morbid conditions or whether advanced age itself is an independent risk factor [231].

PubMed and Medline searches were conducted in May 2008 covering the time frame from 01.01.2004 to the present. The terms ‘surgery, male and urinary incontinence’ were used and the search was limited to English articles to update the previous comprehensive literature search done for the third edition of the ICI.

Data available are still sparse, since the search did not differentiate between fit and frail elderly. Since the latter are defined as patients with continuous severe impairment and/or co-morbidity, they are usually not candidates for surgical treatment.

Conflicting data are reported on age as an independent risk factor for incontinence after radical prostatectomy. In most reports, the patient’s age and preoperative urine leakage are predictive of postoperative urinary incontinence, whereas some came to the opposite conclusion [232]. Advancing age as a risk factor is supported by a number of studies [60, 79-83], Steiner, et al [84] found no correlation between age and continence status, but only 21 of the 593 patients were 70 years or older. However, Mohamad and colleagues reviewed 16,524 patients who underwent RP in public hospitals in Austria. They found that increasing age was associated with an increased risk of peri-operative complications [85] and with a higher incidence of peri-operative continence status following laparoscopic RP [88]. As mentioned above, Strasser and colleagues hypo-
thesized that age related sphincteric changes may be responsible for such age-related increase in post-operative SUI, and successfully demonstrated a progressive reduction in sphincter striated muscle cells with age [16].

Others have found that advancing age and number of co-morbidities have a negative impact on the speed of recovery of continence during the first year post radical prostatectomy [52, 85], but the rate at one or two years does not seem to be significantly affected [63]. Comparison of studies dealing with peri-operative risk of surgery in the elderly is complicated by the use of different definitions of diseases and outcomes, different modes of clinical care and diversity in the type of clinical procedure examined. Furthermore sub clinical diseases might not be detected and still may impose a risk factor. Although the overall frequency of peri-operative complications is increased in the elderly, it is still relatively low [233, 234].

Two frequently used options for incontinence in men after prostatectomy are injection therapy with bulking agents such as collagen and the placement of an artificial urinary sphincter. O’Connor et al. [235] concluded after having examined the outcome of primary artificial urinary sphincter in 29 men aged 75 years and older, that implantation of AMS Sphincter should not been denied to a patient simply on the basis of age. Thiel et al [50] found in their study of 86 men with artificial urinary sphincter surgery that older men conceived their improvement as less significant than younger men although the age difference between patients rated as ‘success’ and ‘failure’ was only two to three years and thus might not be clinically relevant. (Level of evidence 2 and 3; Recommendation Grade B)

Before implanting an artificial sphincter in a fit aged patient, mental status and dexterity have to be evaluated and discussed with the patient. No data could be found on how aging patients are able to manually operate and remember to use the artificial sphincter.

Most studies looking at these options for incontinence after treatment of localized prostate cancer did not look at age as an independent factor associated with certain complications [125, 128, 177, 236, 237]. Some investigators came to the conclusion that age does not predict treatment efficacy of bulking agents [126, 238]. (Level of evidence 3)

Recent series of slings with less than 2-year follow-up have shown satisfactory improvement rates, with results similar to those of the artificial urethral sphincter, although patient selection may be different. However, no stratification for age is available from the data.

TREATMENT OF DETRUSOR OVERACTIVITY

Therapy with intravesical neuromodulatory drugs such as capsaicin and resiniferatoxin as well as injection therapy with botulinum toxin has been extended to the treatment of non-neurological detrusor overactivity of the bladder after other treatment failed. These options are discussed in the section on Refractory Overactive Bladder (see below). No data were found on how these techniques work in aging bladders. Since detrusor contractility decreases with age [239] the incidence of bladder emptying problems might be expected to be higher in the elderly.

CONCLUSION

Age by itself should not preclude any patients from treatment. Although bulking agents are less invasive they have not yet been shown to be very effective. If co-morbidity, mental status and dexterity of the patient permit an invasive approach the implantation of an artificial sphincter, or a sling, should be offered to the patient. (Level of evidence 3; Grade of recommendation C)

VI. INCONTINENCE AFTER EXTERNAL BEAM RADIOTHERAPY ALONE AND IN COMBINATION WITH SURGERY FOR PROSTATE CANCER

The risk of incontinence after external beam radiotherapy (EBRT) for prostate cancer is variable and ranges from 0 to 18.8%. Lawton et al. [240] reported a risk of urinary complications of 7.7% in more than 100 patients, proportional to dose. Perez et al. [241] found incontinence in only 5 of 738 patients. Shipley et al. [242] reviewed more than 2500 cases with an incontinence rate of 0.5%. Similar incidences have been reported in more recent series. Madalinska et al. [64] reported an incidence of 6–7%. With three-dimensional conformal radiotherapy, Weil and colleagues [243] reported no incontinence in 168 consecutive patients and Hanlon et al. [244], in a series of 195 men, found that post treatment urinary symptoms were no different from a control group without cancer. With conformal radiotherapy, Sandhu et al. [245] reported a 9% incidence of stress incontinence in 110 patients. The impact of EBRT followed by prostatic boost, for a total of 66–70 Gy, was evaluated. Scalliet and co-workers [246] reported urinary incontinence in 16% of 230 patients, however, Fransson and colleagues [247] reported an increase in urinary incontinence on a patient-administered symptom bother scale 3 years after treatment in 153 men compared to pretreatment status. The increase was from a mean of 0, at the start to 2 out of 10 at 3 years. Poholzer et al. [248] reported incontinence in 18.8% of a group of 82 men who were surveyed 4.4 year after EBRT for prostate cancer. Furthermore urinary incontinence worsened from year 2 to year 6 in a cohort of 147 men treated with 3D conformal RT [249].
Pre-radiotherapy transurethral prostatectomy may be a risk factor for incontinence. Jonler et al. [250] reported an incontinence rate of 11% with pretreatment TURP. Green et al. [251] and Lee et al. [252] also reported a higher risk of incontinence with pretreatment TURP versus those without with 5.4% and 2% respectively. There are no series reported on the treatment of patients who only have incontinence after EBRT.

Salvage or adjuvant radiotherapy is frequently given after radical prostatectomy and the impact on continence is controversial. Petrovich et al. [253] reported no difference in incontinence in 2 cohorts of patients, one with and one without adjuvant radiation. In a follow-up study the same group reported no late toxicity [254]. Fontaine et al. also reported no change in continence status in 16 of 17 men after salvage radiation [255]. However, Petroski et al. reported that postoperative radiotherapy worsened continence in 26% of 129 patients followed for a median of 5 years [256]. On the other hand salvage radical prostatectomy following external beam radiotherapy has been has been generally reported to have a high incidence of urinary incontinence [257-259] possibly because of radiation induced fibrosis of the external sphincter [258].

**SURGICAL TREATMENT**

Results of surgical treatment of incontinence in this setting are based on retrospective clinical series. In the past the most commonly published treatment modality was the artificial urinary sphincter as therapy for sphincter damage. As discussed and referenced in the following paragraphs, the series published contain both patients who had and had not received radiotherapy and collagen injections have also been reported in case series.

There has been a higher reported revision rate for the artificial sphincter following radiotherapy (Table 7 [176, 177, 179, 187, 190, 200, 260, 261]) compared to low risk patients, 38% versus 22%. Although recent reports dispute the higher rate [177, 187]. However, generally this is due to a higher incidence of erosion and infection as well as urethral atrophy, possibly secondary to radiation induced vasculitic fibrosis of the urethra [179]. Radiation may also induce detrusor overactivity or poor compliance leading to urgency incontinence. Recurrence of bladder neck contracture may be more common [187]. Radiation was also identified as a co-morbidity associated with erosion [262]. However, good results are reported, and it is generally recommended that the cuff be inserted outside the radiated field [263].

Collagen injection has also been reported for incontinence after radical prostatectomy and adjuvant radiation [122, 126, 224, 264-266] or after salvage radical prostatectomy following radiotherapy [129,267]. Continence results are poorer compared to those without radiation [225]. Very few patients have been reported on with the use of Macro-plastique following radical prostatectomy and adjuvant radiotherapy.

The male perineal bone-anchored sling has been reported in patients following adjuvant RT. In Comiter’s group with the perineal compression sling 3/21 with radiation had no adverse sequelae [129]. Similarly in the series of Onur et al. radiation did not cause a worse outcome [153]. However, Schaeffer et al. reported that prior irradiation was the only identified factor that predisposed to failure. Their success rate following a single sling procedure was only 29% (2 of 7) for irradiated patients, and the corresponding rate for nonirradiated patients was 68% (39 of 57) [144]. They postulated that the sling acts by compressing and elevating the urethra, thereby increasing urethral resistance to abdominal pressures. Theoretically, radiation-induced fibrosis of the urethral and periurethral tissues would make compression and elevation more difficult by reducing tissue compliance and mobility.

</table>
In summary, despite the frequently reported higher incidence of complications of the artificial sphincter in post-prostatectomy patients after adjuvant radiation, it has provided acceptable treatment benefits. Collagen injections have yielded poor results. Although the data are limited, a perineal compression device may also be acceptable but suprapubic suspension bulbourethral slings may be less efficaceous. (Level of evidence 3; Grade of recommendation D)

**VII. INCONTINENCE AFTER OTHER TREATMENT FOR PROSTATE CANCER**

1. **BRACHYTHERAPY OF THE PROSTATE**

Brachytherapy is a form of radiation therapy in which radioactive materials are placed directly into the prostate gland. The incidence of incontinence following this modality is given in Table 8 [268-279] and was previously related to the treatment of post-brachytherapy retention of urine. Numerous series have reported retention to be associated with larger initial prostate volumes [280]. In a systematic review of brachytherapy series, Crook et al. [277] reported the incidence of retention to be 1-14%. Many patients require prolonged or permanent alpha blocker or TURP. The main risk factor for incontinence after brachytherapy is TURP. Hu and Wallner [274] reported on the incidence of urinary incontinence after TURP/TUIP following prostate brachytherapy for prostate cancer. Of the 10 patients who underwent the outlet relaxing procedures for refractory urinary obstruction, 7 developed some degree of permanent urinary incontinence. They surmised that the cause may be multifactorial and may include physical damage to the urinary sphincters and the radiation dose to the urethral region. Surgical therapy when required has included the artificial sphincter [275]. High dose brachytherapy that is administered over a short period of time may have reduced toxicity [281]. Urethrorectal fistula is another complication that has been reported in 1.8% of patients in a large U.S. medicare retrospective review [275]. Salvage brachytherapy leads to a higher rate of urinary tract complications [259].

2. **CRYOSURGICAL ABLATION OF THE PROSTATE**

Cryosurgical ablation of the prostate is used for clinically localized prostate cancer either as primary treatment or after unsuccessful external beam radiation therapy. The frequency of the main lower urinary tract complications are listed in Table 9 [282-294]. The artificial sphincter has been mentioned as one of the treatments for incontinence [293] Cryotherapy is an adverse factor for collagen injections. Urethrorectal fistulae can also occur in up to 5% of treated patients. Severe incontinence and fistulae that occasionally results may have to be treated with extirpative surgery and diversion [295].

3. **HIGH-INTENSITY FOCUSED ULTRASOUND (HIFU)**

Transrectal high-intensity focused ultrasound is emerging as another minimally invasive treatment for prostate cancer. HIFU destroys prostate cells by

* Implant plus external beam radiation
coagulative necrosis of the tissue without damaging the structures intervening between the transrectal probe and the target tissue [296]. Recent reports of efficacy also include morbidity. In a systematic review involving 37 articles/abstracts Rebillard et al. [297]. reported that stress incontinence occurs in 6-28%, urethra/bladder neck stenosis in 1-31%, and rectourethral fistula in 0-3% of treated patients. With improvements in techniques the risk of complications is decreasing [297].

4. INCONTINENCE AFTER NEOBLADDER CONSTRUCTION

The incidence of continence after neobladder construction following radical cystectomy for bladder cancer ranges from 85 to 100% during the day and 55 to 100% at night (Table 10 [298-310]). Most patients achieve daytime continence after one year and nighttime continence after 2 years. Most of the published reports do not comment on specific surgical management and imipramine is mentioned as treatment only occasionally. Martins and Boyd [179] reported on 8 patients treated with the AUS for persistent sphincter weakness incontinence. Six of these underwent revisions, 3 for infection and/or erosion and 3 for inadequate cuff compression. They cautioned against the use of the AUS and suggested alternatives such as intermittent catheterization at night. However, O’Connor and colleagues [311] reported a successful outcome, after AUS, with no complications in 5/5 men with incontinence after neobladder, with a mean follow-up of 22 months. The bone-anchored sling has been reported for one case [312]. Collagen has only been reported in women following neoblladder construction [313].

In summary there are not enough data upon which to recommend definitive surgical therapy, although the artificial sphincter looks reasonable. (Level of evidence 3; Grade of recommendation C-D)

VIII. TRAUMATIC INJURIES OF THE URETHRA AND PELVIC FLOOR

Incontinence following posterior urethral injuries occurs in 0-20% of patients [314, 315] and is thought to be due to the extent of injury rather than to the method of management.

The data on surgical treatment are all retrospective case series and the most commonly published surgical therapy is the AUS. The series published contain both patients with and without traumatic injuries. Perez and Webster [176] reported on 27 patients after urethral or bladder neck strictures. The revision rate was 41% and the continence rate was 85%. In a subsequent report from this centre on reoperations the patients with traumatic injuries were not discussed separately [316]. In Montague’s [178] series 22 out of 166 patients had incontinence after trauma. He did not separate the results of this group from those of the other patients. Martins and Boyd [179] reported on only one patient out of 81 with a traumatic urethral injury. This patient was dry and required no revisions. Venn
at el. [263] reported on 2 with pelvic trauma out of a total of 70. (Level of evidence 3; Grade of recommendation C)

Bladder neck reconstruction by excising the scar and narrowing the calibre was reported by Iselin and Webster [317] in 6 patients who had incontinence with an open bladder neck on cystourethrography, following urethroplasty for traumatic strictures. Bladder neck closure with a Mitrofanoff catheterizable abdominal stoma has also been reported as treatment following severe urethral or bladder trauma [318] (Level of evidence 3; Grade of recommendation C)

For patients with severe bladder neck strictures and incontinence after prostate surgery Meulen et al. [319] and the group from Baylor [187, 320] reported on the use of a Urolume stent with a bulbar artificial sphincter. Alternative management with perineal urethroplasty and subsequent artificial sphincter placement in 6 patients was reported by Simonato et al. [321] (Level of evidence 3; Grade of recommendation C)

In summary, the AUS provides a reasonable outcome in appropriate cases. Since there are so few reports of alternative therapies the C recommendations were based primarily on expert opinion as to what is reasonable surgical therapy in very difficult cases.

Achieving continence and protecting the upper urinary tract are important goals of reconstruction in patients with exstrophy-epispadias complex. However, these tasks remain formidable challenge for pediatric urologists. Urinary incontinence [322, 323] and other voiding problems [324, 325] due to these congenital anatomical abnormalities are continuing problems into adulthood. Although quite a few publications on the exstrophy-epispadias complex have appeared in the literature over the past 7 years, the long-term follow-up data into adulthood are still lacking [322, 326], and there have been no significant changes in the management of urinary incontinence. Furthermore, the definition of continence differs between studies. Despite the devastating nature of this disease, there have been few studies addressing quality of life issue and psychological assessment in patients with exstrophy-epispadias complex. Lee et al. surveyed 208 patients of which only 24 were 18 years or older. They found that of those older than 20 years all women and but only 60% of males had close friendships [327].

Published materials consist mainly of retrospective reviews of experience at various centers. Even major institutions struggle to gather large series of patients. Thus, we are still left with mainly level 3 evidence.

The management of the exstrophy-epispadias complex includes 2 principal aspects; initial management (primary treatment) and subsequent management of persisting incontinence. These 2 aspects are discussed separately. Based on the evaluation of the literature, recommendations are made at the end of this section.

I. INITIAL MANAGEMENT OF THE EXSTROPHY-EPISPADIAS COMPLEX

a) Staged repair versus one-stage primary repair

Staged surgical management of the exstrophy-epispadias complex (early closure with or without pelvic osteotomy, repair of epispadias and bladder neck reconstruction) has been the standard approach [323, 328-332] although the staged approach has undergone significant changes since first advocated by Jeffs et al [328]. Success rates for staged functional closure are high with continence rates reaching 75% to 90% [328-330]. However, these results were based on highly selected groups of patients and others failed to achieve such results. Continence rates of only 10% to 30% were reported with the staged approach [333, 334]. Complete primary repair described by Grady and Mitchell combined primary bladder closure with epispadias repair in one stage in neonates [335]. The idea was to optimize the chance for early bladder cycling and potentiate bladder development. It may also obviate the need for multistage repair of bladder extrophy including bladder neck reconstruction. Although acceptable short-term results were achieved, the procedure has been criticized in view of 50% incidence of antireflux surgery needed because of breakthrough urinary tract infections. A recent report from another institution has also shown that complete repair of exstrophy is feasible in neonates and older children after failed initial closure, with acceptable morbidity [336]. Urinary reflux was noted in 63% of renal units but did not require surgery in this series. There is short-term evidence of favorable outcome in newborns compared with older children [336]. However, we will have to wait for long-term results from those centers using this one-stage technique to know whether it is consistent in producing urinary continence and satisfactory sexual function.

The Mainz group has recommended primary urinary diversion (ureterosigmoidostomy, sigmoid rectal pouch, ileocecal pouch) with closure of the abdominal wall [337, 338]. The posterior urethra is closed as a seminal receptacle. While this approach is hardly used in North America, long-term reports have demonstrated excellent continence and upper tract preservation [337, 338]. Low pressure rectal reservoirs in children with bladder exstrophy have also provided excellent long-term outcome in continence (100%) and preservation of the upper tract (97%) [339]. However, prophylactic alkalinization does not prevent the long-term metabolic consequences. Subclinical metabolic acidosis and decreased linear growth are to be anticipated in more than 50% of patients, and moreover, significant bone demineralization is to be expected in all of these patients [339]. Thus, it is concluded that low pressure rectal reservoirs should be reserved for failed surgical reconstruction or patients presenting beyond the age suitable for reconstruction [339].

b) Bladder neck reconstruction

In a staged repair, bladder neck reconstruction is usually performed at age 4 to 5 years when the bladder gains enough capacity to provide for safe filling with good compliance and the child is ready to be dry and participate in a postoperative voiding program [328, 329]. The classic Young-Dees-Leadbetter technique has been modified in several ways [329, 332, 340]. The success of bladder neck reconstruction in both continence and emptying is highly dependent on the delicate balance between the bladder and outlet. Bladder capacity, contractility and outlet resistance are determinants of continence after bladder neck reconstruction [325]. A report from the Johns Hopkins group [329] describes that 77% of patients are completely dry by day and by night and voiding through the urethra without need for bladder augmentation or clean intermittent catheterization, and that another 14% have “social continence” (dry more than 3 hours during the day but still wet at night). Analysis of bladder capacity measurements under anesthesia, prior to bladder neck reconstruction, revealed that patients with a preoperative bladder capacity of greater than 85 cc had a better outcome [329]. However, subjective success with continence and emptying does not necessarily correlate with objective findings [325]. Despite near or total subjective continence (dry intervals of at least 2 to 3 hours) and “good voiding” in 18 patients, there were clinical (recurrent urinary tract infections, epididymitis and bladder stone) and urodynamic voiding problems in 72%, including flow rates of less than 10 ml/sec in 70%, postvoid residual more than 33% of capacity in 50% and acute urinary retention in 17% [325]. Another report from the Toronto group also highlights the extreme difficulty in achieving volitional voiding in an unselected extrophy population. Of 43 patients only 3 (7%) were voiding spontaneously through the native reconstructed urethra [341]. Similarly Burki et al. reported redo bladder neck reconstruction in 30 patients and all required intermittent catheterization [342]. Thus, perseverance in the pursuit of volitional voiding is more likely to result in repeatedly failed bladder neck
reconstruction and delay in the age at which continence is finally attained. Earlier recognition of the need for other storage improvement procedures such as bladder augmentation and/or appendicovesicostomy and bladder neck closure may facilitate the timing of achieving continence and self-esteem, and achieve a satisfactory result with fewer operative procedures [341].

c) Urodynamic evaluation

There are several reports on urodynamic evaluation in patients who underwent bladder neck reconstruction [343-345]. The majority of closed exstrophy bladders have normal filling dynamics before bladder neck reconstruction [344]. However, bladder abnormalities are very common after bladder neck reconstruction, with about 50% incidence of poor compliance and detrusor overactivity [343-345]. Detailed urodynamic investigation in patients with bladder exstrophy, after the first operation to create a functional bladder, is vital to guide the next step of management and to compare objectively the surgical outcome of reconstruction using different approaches.

d) The fate of the upper urinary tract

Preservation of the upper urinary tract is the most important goal in any form of lower urinary tract reconstruction. In several series of exstrophy patients, significant upper tract deterioration was noted in 22% to 26% of patients [323, 346, 347]. Because any type of outlet procedure that elevates the outlet resistance can be a potential cause of upper tract deterioration, upper and lower tracts should be monitored by ultrasound to measure the efficacy of bladder emptying and to look for subtle upper tract changes even in patients with a good bladder storage function who are undergoing any kind of outlet procedure.

2. MANAGEMENT OF PERSISTING INCONTINENCE

Regarding the management of persisting incontinence, there still remain considerable differences of opinion [337-339, 341, 347-352]. Various options are shown in Table 10. When planning the management of persisting incontinence, possible causes of incontinence should be thoroughly evaluated. Bladder and outlet storage function should be examined by detailed urodynamic investigation that allows for the individualization of treatment to optimize the chance of a successful outcome [345]. Multiple available reconstructive options may be considered to optimize continence outcome [353].

a) Augmentation cystoplasty

The late 1980s and early 1990s witnessed the more liberal use of bladder augmentation coupled with the option of a catheterizable appendicovesicostomy (Mitrofanoff procedure). The overall rate of bladder augmentation in patients with exstrophy-epispadias complex has been 22% to 40% [323, 325]. Preservation of the native bladder template has been emphasized by the Johns Hopkins group and others [330, 354]. This has two advantages, whether in the younger or older patients. First, using the template may decrease the amount of bowel needed for reconstruction. Second, if ureteral reimplantation is required, the bladder template is a better structure for reimplantation than a subtaenial tunnel of the bowel [330].

Stomach, ileum or colon can be used for bladder augmentation. Each type of augmentation has disadvantages that are inherent to the use of gastrointestinal segments, including metabolic derangement, urolithiasis [355], decreased linear growth [356], and hematuria-dysuria syndrome (in the case of stomach) [357]. A recent paper concludes that ileocystoplasty is safe and does not impact negatively on the linear growth or bone densities of patients with bladder exstrophy [358]. Gastrointestinal composite reservoirs, i.e. those made of a combination of stomach and other intestinal segments, may be considered to achieve electrolyte neutrality by contrasting electrolyte movements across the stomach and bowel [348].

b) Continent stoma

There are many surgical procedures, other than bladder neck reconstruction, to increase bladder outlet resistance, including injection of bulking agents and placement of bladder neck slings and artificial urinary sphincter [352]. Unfortunately, these outlet procedures have variable degrees of success with none being successful in all patients. It is not uncommon for some patients to undergo multiple procedures in an attempt to achieve continence. When these attempts fail, the creation of a catheterizable continent stoma with or without bladder neck closure is the preferred procedure to achieve continence [359]. Continence rate of 100% was achieved by bladder neck closure compared with continence rates of 56% by bladder neck reconstruction only and 67% by bladder neck reconstruction with augmentation and/or appendicovesicostomy [341]. However, the success of bladder neck closure is dependent in part upon patients’ compliance with intermittent catheterization [352]. In addition, those who have undergone bladder neck closure are at an increased risk for bladder stones [352].

c) Urinary diversion

Regardless of the type of continent urinary diversion used, most series demonstrate excellent success rates around 95% [359]. Based on the excellent continence rates achieved by urinary diversion
3. RECOMMENDATIONS

The published studies to date are retrospective case series with levels of evidence at best 3 with a grade of recommendation of C. The expert opinion of the Committee has resulted in the following recommendations regarding the evaluation and treatment of persisting incontinence in adulthood. (C)

- Patients with extrophy-epispadias complex should be evaluated and managed in specialized centers
- A universal definition of continence should be established
- Persisting incontinence should be evaluated with urodynamics and its treatment should be individualized based on urodynamic findings
- Life-long follow-up is mandatory in terms of continence, voiding efficiency, upper tract status and other urological complications
- Comparative studies, including quality of life and psychological assessment, should be undertaken if possible.

d) Outlet procedures

If the initial bladder neck reconstruction (original or modified Young-Dees-Leadbetter in many cases) fails and a low outlet resistance is the only cause of persisting incontinence, another outlet procedure is worth attempting. Option includes Kropp or Pippi Salle bladder neck reconstruction, injection of bulking agents, placement of bladder neck slings or an artificial urinary sphincter [352]. The presence of scarred tissue due to a previous surgery at the bladder neck may compromise the outcome. The value of the artificial urinary sphincter in dynamic control of outlet resistance in exstrophy patients is also questioned [323]. A vascularized gracilis muscle sling, to wrap around the compromised bladder neck of incontinent patients has been reported as salvage surgery [350]. Limited success has been reported with the use of bulking agents 361, 362.

3. RECOMMENDATIONS

X. DETRUSOR OVERACTIVITY AND REDUCED BLADDER CAPACITY

1. REFRACTORY URGENCY INCONTINENCE AND IDIOPATHIC DETRUSOR OVERACTIVITY

According to the Terminology Report of the International Continence Society the overactive bladder (OAB) syndrome refers to the symptoms of urgency, with or without urge incontinence, usually with frequency and nocturia [363]. Detrusor overactivity (DO) was redefined to indicate the urodynamic observation characterized by involuntary detrusor contractions during the filling phase that may be spontaneous or provoked. Idiopathic Detrusor Overactivity (IDO) exists when there is no defined cause and replaces the term “detrusor instability”. Neurogenic Detrusor Overactivity (NDO) is seen when there is a relevant neurological condition and replaced the term “detrusor hyperreflexia”. The criterion for considering detrusor overactivity as idiopathic is questioned, as Ahlberg et al found that 82% of patients initially considered idiopathic on careful searching actually had pathology potentially leading to the problem [364].

Idiopathic detrusor overactivity is a normal situation early in life. Children have urgency incontinence as a stage in acquiring bladder control. The incidence of detrusor overactivity during mid-life years (20 to 60) has been estimated as 10% [365]. In the asymptomatic elderly, detrusor overactivity once again becomes common, occurring in 50% of men over 70 [366]. In the symptomatic elderly, over 75 years old, it can reach 90% in men [367]. Detrusor overactivity may be a cause of severe storage symptoms such as frequency, nocturia, urgency and urgency incontinence. Conservative treatment of these symptoms such as bladder training and pharmacotherapy is discussed in other sections.

Magnetic stimulation may play a role in the non-invasive treatment of DO [368, 369]. Bradshaw et al. demonstrated an effect on cystometry of magnetic stimulation and found an improvement in urodynamic parameters but no consistent change in OAB symptoms [370]. Almeida et al. [371] in a prospective urodynamic controlled study of 91 women with UI, found an improvement on DO only in patients with initial bladder contractions <15 cm H2O. There are no other data available on the subject.

For symptoms that are refractory to conventional means, 4 interventional treatments have been reported: intravesical resiniferatoxin, botulinum-A toxin detrusor injections, neuromodulation, and bladder augmentation.
a) Resiniferatoxin

The use of intravesical neuromodulatory drugs such as capsaicin and resiniferatoxin was extended to DO of non-neurologic etiology after the suggestion that its etiology involved the enhancement of the C-fiber mediated spinal micturition reflex [372] and emerged as a minimally invasive procedure: the results are shown in Table 11 [373-380]. In spite of promising results, it is still considered experimental and more clinical studies are necessary for it to be licensed [381].

The mechanism of action is still under study. The mean bladder perception threshold is increased only in patients with clinical improvement [382]. The complexity of the mechanism is demonstrated by the presence of vanilloid receptors not only on sensory fibers but also in bladder urothelium and smooth muscle cells [379] and by ineffectiveness in treating an overactive bladder from idiopathic causes or suprapontine lesions with no vanilloid-sensitive fiber-mediated reflex [383]. It has been suggested that over expression of transient receptor potential vanilloid subfamily 1 in the bladder predicts the response [384]. A well designed double-blind placebo-controlled study revealed no difference between placebo ethanol 10% saline solution and 50 nM resiniferatoxin, nevertheless both treatments showed improvement in symptoms of women with IDO [380]. Some placebo-controlled studies either did a quasi randomization [385] or did not explain how it was done [379]. Patients with increased bladder sensation without DO presented some improvement in symptoms in a small non placebo controlled series [386]. (Levels of evidence 1 – 4; Grade of recommendation D, two level 1 studies have contradictory conclusions [379, 384]

b) Botulinum-A toxin injection in the bladder

The minimal invasiveness of this method makes it very attractive but long term results in IDO are lacking (Table 12 [387-403]). The effects of its use are still not fully recognized [404], with possible systemic consequences [405-407], such as generalized muscle weakness in two patients treated for neurogenic bladder overactivity, and the development of resistance to the drug [408, 409]. The FDA made a public notification of adverse reactions linked to Botox use in February 2008, in approved and nonapproved usages. The agency is currently reviewing safety data from clinical studies to further communicate to the public its conclusions [410]. Most of the initial experience come from its use in neurogenic bladders [411-414], with favorable results. Information about its use in children is scarce [415]. A randomized study comparing the results of botulinum-A toxin injections to intravesical resiniferatoxin in NDO showed superior clinical and urodynamic benefit with the use of botulinum-A toxin [414]. The need for reinjections seems to be overcome by the significant improvement in quality of life of these patients [416], and is likely to be cost-effective [417]. The use of botulinum toxin B is less efficient, with a duration of action of about 10 weeks [418].

The optimal site of injections, including or not including the trigone, is still under debate [419]. Kuo in 2007 [399], published a study comparing the injections into the detrusor, suburothelial area, and bladder base, with the last location improving urgency but not increasing capacity. Most studies on idiopathic overactive bladder have been done in women [393, 394]. Data are lacking on dose, concentration, site(s), numbers of injections and long-term efficacy and side effects. Attempts to determine whether poor responders could be predicted from preoperative urodynamic parameters showed only a very high maximal detrusor pressure over 110 cm H2O as an unfavorable predictor when using 200 units [401]. Studies in women suggest a longer duration of action than its mere motor-nerve blocking potency can explain [394]. Therefore, a dual mechanism of action has been proposed: in addition to binding to cholinergic terminals, it might also affect afferent nerve transmission, thereby decreasing urgency [420, 421].

There are two commonly marketed forms of botulinum toxin-A (Botox and Dysport) and they require different doses to achieve similar results, in a proportion around 1:3 [422]. The first report using Dysport in refractory IDO was only recently published with similar results to Botox [393]. In a study using type A neurotoxin, purified by a procedure using a lactose gel column, improvements were seen in 89% of patients treated for incontinence due to IDO and NDO [396].

Many studies with botulinum toxin detrusor injection use different outcome measures for results and are variable for the presence of residual urine and the need for intermittent catheterization, but 6-75% of cases may present high post void residual urine [394, 396, 398, 401]. Besides being an alternative for treatment of refractory DO, currently available data do not show superiority of any specific treatment plan, and therapy options should be tailored to the specific patient and physician preference [423]. Higher doses such as 200 units in IDO resulted in incomplete emptying, necessitating intermittent catheterization in 6 out of 16 patients (37.5%) in one study [401]. Sahai suggests a careful follow up of the patients after the injections, starting IC in symptomatic patients if postvoid residual urine is more than 100-150 ml [424].

Many reports do not separate genders and mix neurogenic and idiopathic etiologies. A large number of publications are reviews of the literature [425-435]. There is one randomized double blind placebo controlled trial showing favorable difference against saline injections for frequency and incontinence, but not for urgency [401]. (Most levels of evidence 3, with one level 2; Grade of recommendation C)

**c) Electrical stimulation and neuromodulation**

Electrical stimulation of the genital area was first used to control incontinence due to DO on an empirical basis for different etiologies [436]. Later, it was suggested that reflex sphincteric contraction induced by electrical stimulation can promote an inhibitory effect on detrusor activity, thus suppressing detrusor overactivity [437]. Many studies of external electrical stimulation for bladder inhibition of idiopathic urgency incontinence have been published, mainly in female patients [438-445]. The results vary from 45% to 85% success, with a mean of 38%, and 26% improved. Electrodes implanted in the pelvic floor, have not yielded good results [443].

Neuromodulation of sacral nerves has been reported as alternative therapy for urgency incontinence, urinary retention, and chronic pelvic pain. Good results have been published in treating neurogenic bladder dysfunction [446, 447]. The working mechanism of neuromodulation in the treatment of lower tract dysfunction is still unknown [448, 449]. A suggested mechanism is somatic afferent inhibition of sensory processing in the spinal cord [450, 451], therefore it may be a centrally acting treatment modality different from botulinum toxin, which is an end-organ therapy that specifically targets the bladder [452].

Long-term results suggest a sustained effect on restoring voiding in appropriately selected cases, but a revision rate of 42% at 5-year follow up remains a problem [453]. Its use in refractory idiopathic urgency incontinence has been limited to few patients, mostly women. Bosch and van Mastrigt reviewed 33 implanted women [454] presented results of chronic implantation in 15 women and 3 men, with an average age of 46 years. Significant improvements in voiding frequency, average voided volume, number of incontinence episodes and number of pads used were found, with no deterioration in response to stimulation with time. However, with subsequent experience in 14 men only 2 patients had a partial response and the rest ultimately failed [455]. Shaker and Hassouna [456] implanted 18 patients with refractory urinary urgency incontinence, but only 2 were in men. Groen, Bosch and van Mastrigt reviewed 33 implanted women and found no effect on urethral resistance and bladder contraction strength as consequence of the depressant effect of sacral (S3) nerve neuromodulation on detrusor overactivity [457]. Groenendijk et al. in a retrospective study for the Sacral Nerve Stimulation Study Group, reported urodynamic aspects of 111 patients implanted, but only 8 men were included [458]. They found a better result on urgency incontinence in patients without DO. The difference was not significant. This tendency was also found by South et al. in 67 women implanted [459]. Clinical or urodynamic values to predict the outcome of sacral nerve stimulation has been difficult do define. Evaluation of 19 women suggested that urethral instability seemed to be a good parameter to predict a favourable outcome [460].

Some studies do not specify the etiology of the DO and neurogenic and non-neurogenic causes are grouped together [456]. Some reports focus on technical or specific aspects of the procedure and the same patients may be included in different publications [458, 461, 462]. Implantation in children may be feasible in selected cases [463, 464] and poorer results are expected in older women [102]. The outcome in older men is unknown since there are no reports.

Table 13 [403, 453, 465-472] shows some recent studies.

Some reports are literature reviews [449, 473-475] or detail technical modifications [476, 477]. There is one systematic review on efficacy and safety of sacral nerve stimulation for urgency incontinence, but 13 of the articles analyzed are abstracts and it is also difficult to ascertain whether the same patients are included in different publications [478].

There are some publications with level 1[465, 466] or 2 [455, 468, 469] evidence and with a grade of recommendation D. However, due to relatively few men in the clinical trials, and poor results in one of the prospective trials, its general applicability to men with urgency incontinence may be limited. Level of evidence 3. Grade of recommendation D (due to lack of evidence)

**d) Surgical treatment by detrusor myectomy and augmentation**

Previously used treatments of surgical bladder denervation, open bladder transection, cystolysis, endoscopic phenol injections, hydrostatic bladder distention did not produce good results.

Bladder autoaugmentation or detrusor myectomy has been reported as an alternative to augmentation in neurogenic and non-neurogenic dysfunction. Table 14 [479-481] shows results of this treatment in patients with non-neurogenic detrusor overactivity. There are few long term results available [481]. Additional and longer term experience is still required to properly assess this procedure. (Level of evidence 3; grade of recommendation C-D)

Enterocystoplasty results are detailed in Table 15 [480, 482-488], which includes both male and female patients. Some publications are not clear about the type of surgery specifically done in IDO and about the gender [488]. Good results vary from 58% to 88%, with an average of 77%. Approximately 10 to 75% of patients require intermittent catheterization for bladder emptying. Ileum was the most frequently used bowel segment followed by sigmoid colon, although no scientific reason for the use of any particular segment was given. The surgery, as reported in other sections, has a significant complication rate and should be considered carefully when applying it to these patients. (Level of evidence 3; grade of recommendation C)

2. REDUCED BLADDER CAPACITY

Fibrosis of the wall produces a low-volume low-compliant bladder, leading to diminished functional capacity. Symptoms of frequency and nocturia occur as a result of progressive decrease in bladder volume, but urinary incontinence may also be the consequence of a very small capacity, especially if accompanied by urethral weakness. The diagnosis can be suggested by the micturition chart, and confirmed by urodynamics. The causes can be congenital or acquired. Acquired causes include multiple surgeries, inflammatory processes (chronic cystitis, interstitial cystitis, tuberculosis, schistosomiasis, and chemical cystitis) or following radiation.

Bilharzial contracted bladder is a problem that is primarily limited to endemic areas in Africa and the Middle East. Schistosoma haematobium migrates to the veins of the vesical and pelvic plexuses, where the female begins to lay eggs, promoting a initial inflammatory response. As a result, granulomatous lesions form in the lamina propria. Mucosal reactions vary from hyperplasia to polypoid cystitis. A contracted bladder occurs in 2 % of cases [489]. Bladder augmentation seems to offer reasonable results in these cases.

Similarly, small fibrotic bladders due to other etiologies can be treated successfully with enterocystoplasty. The results of this surgery are presented in Table 16 [488, 490-516]. The results are similar in all etiologies except for radiation. The poorer results after radiation may be due to other tissue damage in the surgical area. New conformal techniques for radiotherapy may improve results in the future, so that the need for augmentation cystoplasty decreases.

Almost all of these studies do not distinguish bowel segments or separate males from females in reporting results. Therefore, it is not possible to correlate any particular aspect with the chance of success or failure. However, overall the results seem reasonably good with the exception of patients who have undergone radiation. (Level of evidence 3; Grade of recommendation C)

XI. URETHROCUTANEOUS AND RECTOURETHRAL FISTULAE

Urethrocutaneous or rectourethral fistula may have congenital, inflammatory, neoplastic or traumatic origin. It is important to recognize the varying etiology because each type may require different surgical strategy. All reports except one are retrospective case series. The report by Shakespeare et al. [517] is from a prospectively collected data base of patients treated with radiotherapy for prostate cancer. (Level of evidence 3; grade of recommendation C).

1. URETHROCUTANEOUS FISTULA (UCF)

a) Acquired UCF

Hidden foreign bodies have been described as a rare cause of both strangulation of the glans penis and urethrocutaneous fistula. Tash and Eid [518] presented the case of a 30-year-old man who developed a urethrocutaneous fistula and penile shaft necrosis after a condom broke during intercourse. Neither the patient nor several physicians could identify the retained ring of condom, which had been buried under newly epithelialized skin. He underwent removal of the foreign body under general anaesthesia, followed 5 months later by a formal urethrocutaneous fistula repair.

</table>
Urethroperineal fistula, as a complication of open perineal prostate cryosurgery, occurs as an immediate perioperative complication in 10.7% [519]. Thomas et al. [520] retrospectively evaluated 250 patients after radical perineal prostatectomy and revealed only 1 (0.4%) urethroperineal fistula. Fahal et al. [521] published an unusual complication of *mycetoma*. The patient had an infection with *Actinomadura madurae* that involved abdominal wall, perineum and urethra. This resulted in urinary extravasation with a urethrocrotanous fistula.

c) Management of UCF

The diagnosis of UCF is made by physical examination, retrograde urethrography (Figure 3), urethroscopy, fistulography, urethral ultrasound or color Doppler imaging. Urethral sonography provides additional information about any involvement of the surrounding tissue, location of vessels and associated abnormalities such as a periurethral abscess [522].

Treatment of UCF usually requires urethroplasty techniques with modifications involving fistula excision and multiple layer closure [523]. *(Level of evidence 3; Grade of recommendation C)*

2. RECTOURETHRAL FISTULAS (RUF)

Culp and Calhoon described five basic groups of RUF according to the etiology [524]: congenital, iatrogenic, traumatic, neoplastic, and inflammatory.

a) Congenital RUF

Endo et al. [525] described the results of the Japanese Study Group of Anorectal Anomalies (JSGA) to determine the relative incidence of specific types of these anomalies in Japan. They included discussion of RUF regarding the relationship between the fistula levels and the blind end of the rectum, low type deformity, rare types, and associated anomalies. A total of 1,992 patients (1,183 boys and 809 girls) registered from 1976 to 1995 were analysed according to the pathogenesis of anorectal malformation in the field of molecular genetics. They reported that more than 20% of RUF should be categorized as intermediate or low deformity from the position of the rectal pouch. A significant preponderance of Down’s syndrome in the deformities without fistulae suggests that investigation of associated anomalies and congenital diseases may provide further insights.

The purpose of Rintala’s study was to compare the long-term outcome of sacroperineal-sacroabdominoperineal pull-through (SP-SAP) to that of posterior sagittal anorectoplasty (PSARP). In boys with high anorectal anomalies, PSARP was superior to SP-SAP pullthrough in terms of long-term bowel function and faecal continence [526].

b) Acquired RUF

Acquired RUF may occur after pelvic trauma, surgery of the prostate or rectum, pelvic cancer, radiation (either external beam or brachytherapy), cryosurgery, prostatic hyperthermia, prostatic high intensity focussed ultrasound (HIFU), inflammatory bowel disease affecting rectum, or rarely prostatitis inflammation.

Benchekroun and co-workers [527] report a series of 11 RUF observed over a 25-year period. The etiologies were surgical trauma (5 cases), fracture of the pelvis (2 cases), inflammatory lesions (3 cases), and one fistula was congenital. Colostomy was performed in 2 patients, surgical closure of the fistula was performed in 7 patients: abdominoperineal (3 cases), perineal (2 cases), transperitoneal (1 case) or by transanospinhincteric incision (1 case).

In 1972 Smith and Veenema [528] reported their 20-year experience with 160 patients undergoing radical retropubic prostatectomy (RRP) with an incidence of 15 rectal injuries. Only 4 fistulas developed in this group.

The most common single cause of RUF in the series of 23 male patients published by Tiptaft et al. [529] was a fracture of the pelvis and iatrogenic causes (two cases after transurethral prostatic surgery, two cases after open prostatectomy, and three cases after urethral instrumentation (Table 17). Noldus et al. [530] reported 23 (3.9%) rectal injuries during 589 RRP and cystoprostatectomy procedures. Eastham and Scardino [531] summarized the incidence of rectal injury during RRP in 3834 patients with an average of 0.7% (range 0.2-2.9%). The incidence of RUF, as an immediate perioperative complication of open perineal prostate surgery, is 1.4 %.
Nyam et al. [532] reviewed records of all patients who were diagnosed with RUF between January 1981 and December 1995 and 16 males were identified. All patients were interviewed by telephone for follow-up. The mean age was 68 years and the mean follow-up was 80 months. Adenocarcinoma of the prostate in 15 patients and recurrent transitional cell carcinoma of the bladder in one patient were the underlying malignant diseases. Nine patients had had a RRP with 2 fistulas after radiation, 2 after brachytherapy, and 3 after a combination of radiation and brachytherapy. One patient formed a fistula after cystectomy and dilation of a stricture. This heterogenous group of patients received multiple therapies including initial colostomy (7 patients), transanal repair (2 patients), parasacral repair (2 patients), transperineal repair (2 patients), coloanal anastomosis (3 patients), and muscle transposition (3 patients). Four of the patients required a permanent stoma.

Badalament et al. [533] managed one patient (0.4%) with a urethrorectal fistula after cryoablation therapy for prostate cancer. Zippe [534] reviewed preliminary results of prostate cryosurgery and reported a 2 to 5% incidence of RUF. Porter [519] found a 2.5% rate of RUF in 210 patients after TRUS-guided prostate cryosurgery and no urethroperineal fistulae. Ismail et al. [535] reported the experience of using salvage targeted cryoablation of the prostate (TCAP) in 100 patients for the recurrence after radiotherapy. The mean follow-up was 33.5 months and RUF occurred in 1%.

Montorsi et al. [536] reported a RUF after transrectal prostatic hyperthermia (43 degree C) in patients with advanced prostatic cancer after multiple treatment sessions. The fistula was cured after a urethral catheter was left in place for one month.

Kleinberg et al. [537] summarized results of 31 patients with stage T1 or T2 prostatic carcinoma following CT guided transperineal I125 implants and reported that only one patient developed a prostatorectal fistula that was managed with an ileal conduit.

Fengler and Abcarian [538] published their experience of eight patients with RUF in the course of treatment of prostate cancer (3 fistulae after radiation therapy alone, 3 after prostatectomy and 2 after both surgery and radiation therapy). Larson et al. [539] evaluated 5719 patients after radiation for prostate cancer. Ten had documented RUF. Lane et al. [540] treated 21 men with RUF following primary external beam radiotherapy and one after adjuvant external beam radiation therapy for prostate cancer. Time from the last radiation treatment to fistula presentation was 6 months to 20 years. Four patients underwent proctectomy with permanent fecal and urinary diversion. Successful fistula closure was achieved in the 9 patients who underwent urethral reconstruction. Chrouser et al. [541] identified a total of 51 patients with a history of external beam radiation for prostate cancer that subsequently had a urinary fistula. Of 20 patients meeting inclusion criteria, 30% received external beam RT alone, 30% received brachytherapy and 40% had received combined external beam RT/brachytherapy. Most fistulas (80%) were from the rectum to the urinary tract with an average diameter of 3.2 cm. Of patients with rectal fistulas 81% had a history of rectal stricture, urethral stricture, rectal biopsy, rectal argon beam therapy or transurethral prostate resection after radiation. All patients with rectourethral fistulas who achieved symptomatic resolution required urinary and fecal diversion.

Shakespeare et al. [517] reviewed the potential factors in fistula development and identified three cases (0.2%) of RUF among 1456 patients treated with prostate brachytherapy (BT), occurring at 19-27 months following BT. All these patients had BT monotherapy and had been investigated with endoscopy and low rectal biopsy. They concluded that gastrointestinal specialists should not perform biopsy of the anterior rectum in patients who have had BT unless there is a very high clinical suspicion of malignancy. Marguet et al. [542] described 6 cases of RUF in patients treated with brachytherapy plus external beam radiotherapy for localized prostate cancer and subsequent rectal biopsies or rectal surgery. Four patients underwent hyperbaric oxygen therapy, which failed. Three patients underwent fecal diversion with gracilis interposition flaps, and two underwent pelvic exenteration. They also concluded that biopsy of rectal ulcers in the clinical setting of combined radiotherapy should not be performed.
Badalament et al. [533] managed one patient (0.4%) with a urethrorectal fistula after cryoablation therapy for prostate cancer. Zippe [534] reviewed preliminary results of prostate cryosurgery and reported a 2 to 5% incidence of RUF. Porter [519] found a 2.5% rate of RUF in 210 patients after TRUS-guided prostate cryosurgery and no urethroperineal fistulae. Ismail et al. [535] reported the experience of using salvage targeted cryoablation of the prostate (TCAP) in 100 patients for the recurrence after radiotherapy. The mean follow-up was 33.5 months and RUF occurred in 1%.

Montorsi et al. [536] reported a RUF after transrectal prostatic hyperthermia (43 degree C) in patients with advanced prostatic cancer after multiple treatment sessions. The fistula was cured after a urethral catheter was left in place for one month.

Chang et al. [543] published a case of prostatic malakoplakia masquerading as a rectal tumor due to formation of a fistulous tract to the rectal muscular layers. Cools et al. [544] reported a very uncommon type of fistula between the large bowel and the prostatic urethra due to Crohn’s disease. Felipetto et al. [545] described a prostatocutaneous fistula as a complication of pseudomonas prostatitis.

Transrectal high-intensity focused ultrasound (HIFU) destroys prostate cells by coagulative necrosis of the tissue. Recent reports of efficacy also include morbidity. Rebillard et al. [297] reported RUF in 0-3% in a review involving 37 articles/abstracts.

c) Diagnosis of RUF

RUF may be strongly suspected from the patient’s history (fecaluria, abnormal urethral discharge, pneumaturia, leakage of urine from the rectum during micturition). Rectal examination, proctoscopy, careful urethroscopy, intraurethral injection of methylene blue dye, radiopaque contrast agent placed into the bladder and then voided usually appears in the rectum on X-ray, are the most important diagnostic steps [522, 546] (Figure 4).

d) Therapy of RUF

Small fistulae may resolve spontaneously with urinary and/or fecal diversion. Therefore, an initial trial of conservative therapy is reasonable. Selected patients with chronic fistulas who are poor surgical candidates may also be managed conservatively with antibiotics, pads and symptomatic care. Timing of repair is often individualized, mainly according to the etiology, delay in diagnosis, size of fistula, whether it is the first or subsequent repairs, and the general condition of patient.

Diversion of urine (suprapubic cystostomy) is generally recommended as well as correction of any urethral stricture distal to the fistula. Fecal diversion, with colostomy is used by some as a mandatory part of double diversion or selectively by others. Gibbons [547] stressed the need for a diverting colostomy for 3-4 months.

However, as surgeons obtained more experience, bowel preparations became standardized, and effective antibiotics were developed, and the enthusiasm for colostomy diminished. Currently, colostomy is recommended in circumstances where antibiotics alone cannot control the inflammation and infection associated with the fistula or when the fistula involves radiated tissue. Low residue diet is also useful for healing. Suitable drainage (perineal and urethral splinting) is stressed.

e) Surgical Approaches

Surgical management for rectourinary fistulas remains a reconstructive challenge. Two-layer closure of the urethra and rectum with suture lines at right angles and with interposition of soft tissue (eg. omentum [548], gracilis muscle [549], or scrotal flap [550]) has been described. Surgical approaches include transabdominal, transvesical, or direct exposure of the RUF.

There are only a few guidelines to direct the surgeon to the most successful and least morbid technique. Rivera et al. [551] staged RUF as stage I—low (less than 4 cm from anal verge and nonirradiated), stage II—high (more than 4 cm from anal verge and nonirradiated), stage III—small (less than 2 cm irradiated fistula), stage IV—large (more than 2 cm irradiated fistula) and stage V—large (ischial decubitus fistula). Diverting colostomy was performed for stages
III to V 6 weeks before definitive therapy. Some of the patients in addition to the RUF will also have urethral strictures that have to be managed. Reconstruction of both aspects to restore functional anatomy is possible with complex reconstructions [552].

The surgical approaches including the numbers of reported patients are listed in Table 18 [524, 527-530, 538, 546, 550, 553-569].

1. PERINEAL APPROACH

In 1926, Young [553] dissected the rectum away from the sphincters, divided the fistula, closed the urethra, and mobilized the rectum further cephalad in such a fashion as to pull the affected rectum caudally out of the anus where it was then transected and discarded, suturing the proximal rectum to the anal skin. Subsequently Lewis, in 1947 [554], described suturing the levator muscle fibers together in the anterior midline when possible.

Goodwin et al. [555] reported a series of 22 RUF approached perineally. They extensively mobilized the rectum posteriorly and the bladder anteriorly through wide perineal exposure allowing interposition of the levator ani muscles between the urinary tract and rectum. Singh et al. [570] described the management of a delayed post-traumatic RUF repaired via transperineal access without rectal or sphincteric transgression. An example of a preoperative and postoperative urethrogram is in Figure 5. Pratap et al. [571] described a simultaneous perineal and abdominal approach in a series of 8 patients with traumatic perineal injuries who had both complex urethral disruptions and RUF.

2. POSTERIOR SAGITTAL APPROACH

Kraske in 1885 [572] described a posterior midline incision extending to the left paramedian aspect of the coccyx and sacrum that involved partial removal of the sacrum in addition to coccyectomy. His method did not involve division of the sphincters, but rather sweeping the rectum laterally to ultimately facilitate resection and reanastomosis of a tumour-bearing rectal segment, thereby preserving fecal continence. In 1962, Kilpatrick and Thompson [558] used this approach when the rectum was completely mobilized circumferentially proximal and distal to the fistula. The RUF was then divided, sparing as much as possible on the urethral aspect. The rectal part of the fistula was excised and closed in two layers, and the urethra was repaired and stented with a catheter.

3. POSTERIOR (PARASACROCOCCYGEAL) TRANSPHINCTERIC APPROACH

In 1969 Kilpatrick and Mason [560] updated this method and advocated a more radical method of dividing the rectal sphincters to give direct access to the RUF. The procedure (the York-Mason approach) is simpler than some complicated transabdominal or transperineal approaches to RUF. It is still used because it allows direct visualization of the fistula via parasacrococcygeal (transsphincteric) incision especially to fistulae in the mid to lower rectum [538]. After the skin incision the mucocutaneous junction is marked with sutures and the internal sphincter is exposed. Division of the sphincter mechanism and posterior rectal wall allows exposure of the fistula. Each sphincter muscle is tagged with color-coded sutures. The next step of this procedure is the incision around fistula, followed by excision of the fistulous tract exposing the catheter in the prostatic urethra. The undermining of rectal wall allows sufficient mobilization. After closure of the prostatic urethra it is recommended that the full-thickness rectal wall flaps are close in a "vest over pants" technique (Figure 6). It is important to make sure that the suture lines do not overlie each other. The procedure is completed by suture of the rectal wall and approximation of the sphincter muscles (Figure 7). Fengler and Abcarian [538] reported healing of RUF in all of 8 patients with the York-Mason approach. Bukowski et al. [562] managed 7 acquired recurrent RUF (3 after prostatectomy, 3 after trauma and 1 after perineal abscess) using York-Mason technique and a similar experience was described by Fournier et al. [561] in the management of a case of the urethro-prostato-rectal fistula after a gunshot wound.

Stephenson and Middleton [559] modified the York-Mason repair and reported their experience with posterior sagittal, transanal, transrectal repair of RUF in 15 patients. The transsphincteric, transanal surgical approach provides many advantages, including easy access and identification of the fistula tract, good surgical exposure, adequate resection back to well vascularized tissue, and access to several vascularized flaps for interposition between the repaired urinary and gastrointestinal tracts.

Culkin [565] reported preliminary experience with the transsphincteric, transanal surgical approach to correct acquired urethrorectal fistula in five men. Mean patient age was 56.6 years (range 37 to 72). The etiology was surgical (radical prostatectomy) in 3 cases, traumatic in 1 and idiopathic in 1. The time from the diagnosis of urethrorectal fistula to surgery was 4 weeks to 4 years. Five men underwent excision and closure of a urethrorectal fistula with diverting colostomy. In 4 men (80%) urinary continence subsequently returned with adequate sphincter tone, while in 1 (20%) with perineal trauma and active proctitis the fistula recurred 6 weeks after surgery.

Dal Moro et al. [573] reviewed a 15-year experience using the York-Mason posterior sagittal transrectal approach to iatrogenic RUF in 7 patients. In one patient with Crohn’s disease the fistula recurred 11 years after the first surgery. The colostomy remained in place only in one patient with Crohn’s disease and in another with ulcerative rectocolitis.

Figure 5: A. Cystogram demonstrates RUF caused by a TURP. Negative shadow from Foley catheter is seen in the bladder. B. Retrograde urethrogram after transperineal closure of RUF
Erickson et al. [574] reported a novel surgical technique used to repair a rectourethral fistula associated with two short-segment urethral strictures located in the anterior and posterior segments of the urethra in a patient with prior unsuccessful repairs. The anterior urethral stricture was reconstructed with a ventral onlay of buccal mucosa in the exaggerated lithotomy position. In a modified prone position, the rectourethral fistula was repaired using the transrectal transsphincteric (York-Mason) technique and the posterior urethral stricture with a radial forearm fasciocutaneous free flap which was anastomosed to the inferior gluteal artery and vein. The coexistence of a rectourethral fistula and distal urethral stricture requires simultaneous repair, because the urethral pressure from the distal obstruction may compromise fistula closure.

4. TRANSANAL APPROACH

Parks and Motson [564] popularized the addition of a full thickness local flap of anterior rectal wall as an adjunct to fistula repair through the intact anal canal (Figures 8 [575] and 9). They modified the transanal technique by denuding the rectal mucosa lateral and distal to the fistula, and mobilized the rectal wall away from Denonvilliers’ fascia proximal to the fistula for four centimeters. Tiptaft et al. [529] also used a special anal retractor for this surgery.

With the Latzko procedure the RUF is closed in three layers with absorbable suture. A transurethral catheter is placed for 3 weeks. Noldus et al. [530] reported 23 patients (3.9%) with urethral injury during 589 RP and cystoprostatectomies. Of these 23 patients, 12 developed a RUF. Seven fistulas closed spontaneously with prolonged catheter drainage. The remaining 5 fistulas were all successfully closed with the transanal Latzko procedure.

Al-Ali et al. [546] treated 30 men with RUF caused by war wounds. He used the method of posterior transsphincteric anterior rectal wall advancement as the treatment of choice. Double diversion (end sigmoid colostomy and suprapubic cystostomy) for one month was performed in all patients. Double diversion alone resulted in ‘spontaneous’ RUF healing in 47% of patients but 53% required reconstruction. Early repair was recommended for large fibrous fistulas. Undiversion was done after two months when the urethra and anorectal canals were normal.

5. ANTERIOR TRANSPHINCTERIC, TRANSANAL SURGICAL APPROACH (ASTRA)

In 1973 Gecelter [566] performed a midline perineal incision to gain access to the urinary tract after placing the patient in exaggerated lithotomy position. The sphincter was incised anteriorly, tag sutures carefully placed, and the rectal incision was carried to the fistulous tract, which was excised and repaired in multiple layers with transposition of tissue as available. Castillo et al. [576] reviewed their first 110 consecutive laparoscopic extraperitoneal radical prostatectomies and reported 3 RUF. Only one was cured with conservative management. The other 2 patients were repaired by anterior transsphincteric, transanal surgical approach (ASTRA)

6. ENDOSCOPIC APPROACH

Wilbert et al. [568] reported two patients with RUF who were repaired endoscopically transanally. The

Figure 9. A. Retrograde urethrogram of a 55 year-old man who underwent a radical prostatectomy. He complained of fecaluria and urine per rectum. This shows urethral contrast in the rectum through a rectourethral fistula (Black arrow). B. Intraoperative photograph of transanal rectourethral fistula repair. The anus is held open by the ring retractor to permit direct access to the fistula. C. Intraoperative view of the rectal mucosal sutures in the rectourethral fistula repair. D. Retrograde urethrogram 3 months after transanal rectourethral fistula repair. There is no contrast entering the rectum from the urethra. The patient’s suprapubic tube was removed and his colostomy was reversed.
patients were positioned prone and the rectoscope mounted to the operating table was inserted into the rectum. The fistula was visualized and the opening excised to the level of the perirectal tissues with cautery. The rectal wall was mobilized full thickness with scissors and closed primarily in two layers with a microscope. The patient was then placed in lithotomy position and the urethral side of the fistula was coagulated and injected with fibrin.

Bardari et al. [569] used cyanoacrylic biological glue to close one prostato-perineal fistula complicating an abdominoperineal resection of rectum and one persistent neobladder-ileal fistula. The biologic sealant was administrated endoscopically through an open-end 6F ureteral catheter. Quinlan et al. [577] presented the case of an iatrogenic fistula in a 71-year-old man treated by a transanal endoscopic microsurgical (TEM) approach, without recourse to a stoma. Bochove-Overgaauw et al. [578] reported successful repair of 1 of 2 RUF with transanal endoscopic microsurgery (TEM). The RUF occurred after laparoscopic radical prostatectomy.

7. Other modifications

Youssef et al. [556] successfully treated 12 male patients who presented with RUF from 1990 to 1997 using the perineal subcutaneous darts flap procedure. The RUF resulted from crush pelvic injury in 6 cases, gunshot wounds in 2, and post prostatectomy in 4. The fistula was associated with a urethral stricture in 4 cases. A perineal approach was used and combined with a transsymphseal approach in the 4 patients with posterior urethral stricture. They interposed a subcutaneous darts flap as a tissue flap between the repaired rectum and urethra. No leakage or perineal collection developed and there was no fistula recurrence. Follow-up ranged from 9 to 42 months. This technique of a perineal subcutaneous darts flap may fulfill the principles for successful repair of RUF. Varma et al. [579] also concluded that darts muscle interposition is a straightforward technique that can result in successful fistula repair, but should not be used in immunocompromised patients or after radiation therapy.

Felipetto et al. [545] used human fibrin sealant (Tissucol) to close a prostato-cutaneous fistula (as a complication of pseudomonas prostatitis). Venkatesh and Ramanujam [580] prospectively studied the efficacy of autologous fibrin glue for closure of recurrent anorectal fistulas. Overall success rate was 60% however patients with acquired immunodeficiency syndrome who had fistulas associated with the urinary tract failed to respond.

Finally Chirica et al. [581] reported their experience with coloanal sleeve anastomosis (Soave procedure) as a salvage procedure for complex rectourinary fistulas after radical prostatectomy or followed anterior resection for rectal cancer after radiochemotherapy. All eight patients had a temporary ileostomy, which was successfully reversed in 7.

f) Summary

A review of recent literature shows an increasing number of papers describing treatment. All available studies are retrospective cases and case series (level 3 evidence). There are many causes of these fistulas described in the literature but there is a lack of valid epidemiologic data about the incidence of UCF and RUF. The diagnostic algorithm has not changed in many years.

The aim of the surgical approach is the closure of all types of fistulas. While spontaneous closure and success with a one-stage procedure has been reported, most cases to date involve 3 stages (double diversion, closure technique, and undiversion). An endoscopic approach using biological sealants is promising. Only a few urologists and general surgeons have gained wide experience in the management of UCF or RUF. No single procedure has yet proved to be best or universally applicable. Conservative treatment is generally ineffective in the management of large RUF. Surgical intervention offers symptomatic relief and improved quality of life in most patients. All reports are still only retrospective case series (Level of evidence 3; grade of recommendation C).

XII. THE ARTIFICIAL URINARY SPHINCTER (AUS)

Different devices designed to control urinary incontinence in the male go back to the middle of the 18th century [582]. Since then research eventually produced external and implantable devices. The gold standard today is considered to be the artificial urinary sphincter (AUS) designed by F.B. Scott, W.E. Bradley, and G.W. Timm in 1973 [583]. The original model underwent a number of modifications, but the basic principle remained the same. It consists of a fluid filled hydraulic system with a cuff around the urethra, a pressure regulating balloon and an activating device, the pump, placed in the scrotum.

1. Availability and cost

The results of an e-mail survey among urologists and gynecologists were previously published in the 3rd ICI, whereby members of the International Continence Society asking them if the AUS was available in their country; and if so, what was the price of the device (in US dollars). About 10% of the members responded by email from 31 countries. The price varied from $4000 to $10,000 USD. The high price in some countries at the time (Georgia, Hong-Kong, Romania and Saudi Arabia) precluded its use. Very few gynecologists implant the sphincter, probably since the majority of patients receiving the device are male.
2. INDICATIONS

The indication for AUS placement is for the treatment of SUI due to ISD that is persistently bothersome despite 6-12 months of active conservative management. As the most common cause of SUI in men is iatrogenic injury during prostate cancer surgery, it follows that the most common indication for AUS is post-prostatectomy incontinence (PPI). The use of the AUS for the treatment of PPI varies regionally. For example, within the United States, state-by-state use of the AUS ranges from 1% to 10% of all RRP patients, with an average of 6% of RRP patients ultimately undergoing AUS implantation. In 2005, 4,426 AUS units were sold in the United States, which represents approximately 1 unit per every 3 U.S. urologists [584]. Nearly half of all AUS implantations in the U.S. were indicated for SUI following prostate cancer surgery [184, 193, 263, 585, 586]. The remaining 50% of units are used for patients with neurogenic disorders (such as spina bifida or neurogenic ISD), for those with incontinence after transurethral resection of the prostate, and for females with ISD following failed sling surgery.

Previous radiotherapy to the pelvis is not a contraindication for AUS placement in males, [587] as the ultimate outcome seems to be similar in men whether or not they have received radiation therapy [236], although a higher incidence of urethral atrophy, erosion and infection requiring surgical revision has been reported in irradiated patients compared to those not irradiated (41% vs 11%). Despite this observation, long term continence and patient satisfaction appear not to be adversely affected in the irradiated male patient [236]. Unlike in men, previous external beam radiation is a relative contra-indication for implantation in females due to a considerably higher erosion rate [263].

The compressive effect of the AUS is temporarily relieved when the patient squeezes the scrotal/labial pump, transferring fluid from the urethral cuff to the pressure-regulating balloon. Subsequently, the bladder can then empty either by bladder contraction and/or by abdominal straining. Accordingly, patients voiding with the Valsalva manoeuvre because of an underactive or neurologically acontractile bladder, do not seem to be at an increased risk of complications [588]. It should also be noted that patients with previous anti-incontinence procedures show a significantly higher explantation rate [589].

Clinical experience suggests that enterocystoplasty or gastrocystoplasty can be done simultaneously with the implantation of the AUS [590, 591]. However, AUS placement at the time of cystoplasty is associated with earlier infections, especially during the first 3 years post-operatively [592]. In the long-term (> 3 years) the infection rate is the same whether the AUS is implanted after or at the time of cystoplasty, AUS can also be successfully implanted in patients after bladder substitution [311], and in those with locally recurrent prostate cancer with a relatively good prognosis [593], or those with severe post-radical prostatectomy Stricture in whom a stent has been placed previously [320].

Finally, advanced age is not a contra-indication to AUS placement. A retrospective analysis by O’Connor and colleagues of a cohort of men over age 75, revealed excellent success rates, with 21 of 29 men (72%) achieving successful continence. Revision rate was 14% at an average of 5 years follow-up, with 14% requiring explantation, and 21% requiring device deactivation due to deterioration in overall health precluding proper use of the AUS at an average of 47 months after placement [235].

3. SURGICAL TECHNIQUES

The original technique of implantation is illustrated in Figure 10. The cuff of the sphincter around the bulbous urethra is placed via a midline perineal incision, while the pressure regulating balloon and the scrotal pump are inserted via a separate inguinal incision. A relatively new surgical approach has been described using a single, upper transverse scrotal incision which allows the placement of all 3 components of the system, the cuff, the pump in a scrotal pouch, and the reservoir behind the fascia transversalis [223]. Alternatively, the pressure-regulating balloon may be placed through a separate inguinal incision, with the cuff and control pump placed via a single trans-scrotal incision, with the connections among scrotal pump, balloon reservoir, and urethral cuff tubing made in the usual inguinal incision. While the trans-scrotal approach potentially minimizes the invasiveness of the AUS surgery, by limiting the surgical approach to a single incision [223], a few reports have revealed that surgical success might be diminished compared with perineal cuff placement and abdominal balloon reservoir placement [594, 595]. Henry and colleagues [596] noted in their retrospective analysis of patients treated with a perineal versus trans-scrotal AUS over a 17-year period (mean follow-up not given), the former group had a completely dry rate of only 28%, versus 57% in the perineal group (p<0.03). Beyond the difference in “completely dry” rate, social continence was also better in the perineal versus scrotal surgery (73% versus 60%). Thus the perineal approach for initial artificial urinary sphincter implantation appears to control male stress incontinence better than the trans-scrotal approach.

The trans-scrotal approach appears particularly useful for simultaneous placement of an AUS and inflatable penile prosthesis through a single incision, with Kendirci and colleagues [596] reporting a urethral erosion rate of 9%, an overall revision rate of 14%, and a social continence rate of 100% in 22 patients at 17 months average follow-up. Sellers, et al. [597] recommend the simultaneous surgery for cost-efficacy.
Figure 10: A. With the patient in lithotomy position, a perineal incision is made behind the scrotum to expose the bulbar urethra. B. The urethra is mobilized circumferentially within the bulbospongiosus muscle and the measuring tape is used to obtain the cuff size. C. The belt-like cuff is positioned around the urethra. D. A right lower quadrant (RLQ) abdominal incision is made and the extraperitoneal space is entered lateral to the rectus muscle for insertion of the reservoir. E. After reservoir insertion the cuff is pressurized with fluid. F. A scrotal space is created under the dartos and the pump is inserted (held with a Babcock clamp).
They demonstrated a $7,000 cost savings when both devices were implanted simultaneously through a scrotal approach, compared to staged implantation with 2 separate surgeries.

The trans-scrotal approach is also useful for revision surgery. Van der Horst and colleagues [598] described AUS revision through a trans-scrotal approach, with addition of a second cuff distal to the primary cuff. In addition, Comiter [166] described the trans-scrotal approach for placement of an AUS following previous perineal sling surgery. In the case of suboptimal continence following sling surgery, placing the AUS cuff distal to the sling through a scrotal incision allows the surgeon to avoid the previous operative field, minimizing dissection through potentially scarred tissue; secondly, it leaves the proximally placed sling as a partially effective compressive device proximal to the AUS cuff.

4. COMPLICATIONS

Complications following implantation of the AUS can be divided into the broad categories of incontinence, erosion and/or infection, and unusual complications. While the number of AUS procedures performed varies geographically throughout the world, especially within the United States. Certain “centers of excellence” perform substantially more procedures than do community hospitals [584]. However, the total number of procedures done in a given center does not seem to be a determining risk factor for complications. Comparable erosion/infection rates have been reported from centers with fewer than 50 or more than 100 cases [206]. This suggests that erosion and infection may be more closely related to the physiologic state of the host rather than the experience of the surgical team, provided standard precautions are strictly applied.

a) Incontinence

Incontinence following implantation of an AUS can result from (1) alteration in bladder function, (2) atrophy of the urethra, or (3) mechanical failure of the device. These causes may co-exist.

1. ALTERATION IN BLADDER FUNCTION

This situation has been reported principally in patients with neurogenic bladder dysfunction, especially in children [599-604]. These changes include de novo involuntary detrusor contractions, decrease in bladder compliance, and the development of a high pressure system, causing incontinence, hydronephrosis and ultimately renal failure. Modifications in detrusor behavior (including its consequences on the upper urinary tract) occur in up to 57% of cases [599-610]. It should be pointed out, however, that there has never been a published report of hydronephrosis following implantation of an AUS for incontinence after prostatectomy [611]. The best candidates for sphincter implantation are those with a low pressure, relaxed, and compliant bladder but an incompetent urethral sphincter [608].

2. ATROPHY OF THE URETHRA

This may occur at the cuff site secondary to long-term mechanical compression of the periurethral and urethral tissues. It is not often reported and some
authors do not even mention it as a possible cause of AUS failure [237, 263, 611]. About 4 months following implantation, cuff efficiency diminishes, presumably because pressure atrophy occurs in every patient to some extent [612]. The incidence of urethral atrophy leading to revision varies from 3% to 9.3% [178, 184, 187, 586, 609, 613-615]. This atrophy can be lessened with nocturnal deactivation of the cuff [616].

3. MECHANICAL FAILURE

This includes perforation of one of the components with loss of fluid from the system, air bubbles or organic debris within the system causing inadequate function of the pump, disconnection of the tubes, or kinking of the tubes. Introduction of “kink-free” tubing has virtually eliminated this last complication.

The incidence of these complications varies widely with ranges from 0% [613] to 52.5% [193] with the longest follow-up. In this latter study, the cuff seemed to be the most vulnerable part of the system (22 cuff failures in 18 patients, most of them occurring during the first 2 to 3 years following implantation), followed by pump failure (6 times in 4 patients). Blockage is an exceptional event, occurring only once in 61 patients followed from 10 to 15 years [193]. In a recent publication from Baylor [187], chronicling a 13-year experience with the AUS, mechanical failure occurred at an average of 68.1 months postoperatively. An unusual mechanical complication has been reported recently. The locking tab became displaced distally into the cycling portion of the cuff preventing the fluid from flowing into the cuff surrounding the urethra [617].

4. EROSION AND/OR INFECTION

Erosion and infection are two major complications that almost invariably necessitate removal of the prosthesis. Their incidence may be reported separately, or more commonly as a single complication. The incidence of these complications varies from 0% to 24.6% [178, 263, 586, 602, 608, 609, 613-615, 618, 619]. Most recent large series report an incidence of infection and erosion generally less than 8% [51, 186, 187, 198, 237, 611, 620, 621]. As would be expected, the highest incidence has been reported with the longest follow-up (10-15 years) [178]. Lai and colleagues [187] from Baylor recently reported that erosion occurred at an average of 19.8 months postoperatively rather than in the peri-operative period. Previous surgery [622] at the site of cuff placement increases the risk of erosion. This, however, may be decreased by delayed cuff activation [623]. Some authors, however, did not find an increased incidence of complications when a new cuff was implanted at the site where several months before a cuff has been removed for infection or erosion [624]. Other risk factors include urethral catheterization and urethral endoscopic manipulations with an activated sphincter in place [625].

A likely etiology of early erosion is intra-operative laceration of the urethra when dissecting it from the corpora cavernosa, where a difficult anatomical plane exists. Intraoperative recognition of urethral injury can be facilitated by retrograde perfusion sphincterometry using a flexible cystoscope [32]. While recognition of a urethral injury may alert the surgeon to the necessary termination of the procedure, urethral erosion may still occur without a known urethral laceration [626].

As mentioned above, while the majority of authors consider previous radiotherapy a risk factor for increased infection and erosion, it is not a contraindication to implantation of an AUS in the male patient with PPI [177, 179, 200, 236, 237, 260, 627]. Overall patient satisfaction is similar in those who have been irradiated, compared to those who have not been [177, 188, 236]. Furthermore, the degree of satisfaction does not diminish with an increased number of surgical revisions [192, 628].

5. RARE COMPLICATIONS

Several unusual, although rare complications have been recently reported in the literature, such as the intravesical migration of the reservoir with secondary stone formation in the bladder [629], or a giant urethral diverticulum at the site of a previously removed cuff because of erosion and urinary extravasation [630].

5. DURABILITY OF AUS COMPONENTS

When defining durability of one of the components or the AUS as a whole, one should distinguish between explantation of the device due to device malfunction (e.g. leak in one of the components) or complications caused by an otherwise properly functioning sphincter unit (e.g. erosion by the cuff, infection at the site of implantation, etc.). This distinction is rarely made in the literature. Durability of a device is defined as the time elapsed during which no mechanical problem alters the normal function of the device. This should exclude the second group from further analysis.

There are very few references in the literature pertaining to the length of time a device functioned normally before its removal due to mechanical failure. In a multicenter trial, for neurogenic bladders, conducted in France [609], the authors mention that the “mean operational life” of the sphincter was 56 months (range 3-118 months). Haab et al [184] analyzed 68 patients and noted that the mechanical failure rate dropped from 44.4% to 12.4% since modifications were made to the device, mainly the cuff component. Survival time of these components was not provided. Similar conclusions can be drawn from a series from the Mayo Clinic [190] where the modification of the cuff design (narrower back) resulted in a significant drop of the reoperation rate at 5 years. In the “narrow back” group 17% (31/184) required reoperation. In that cohort, non-mechanical failure decreased from 17% to 9% and mechanical failure
decreased from 21% to 8% following introduction of the narrow back cuff [190]. Mean time to reoperation was 26.2 months (mean 2-68 months). Using Kaplan-Meier statistical analysis for this group of patients, the overall 5 year expected product survival was 75%. In Lai’s report regarding Baylor’s recent 13-year experience with the AUS, only 6% of devices failed mechanistically, at an average of 68.1 months, with 75% of patients requiring no revisions at 5 years [187]. In a review, Venn et al [263] analysed the outcome of 100 patients in whom an artificial urinary sphincter was implanted for more than 10 years. Thirty-six percent of them still had the original sphincter and were continent at a median follow-up of 11 years. The bulbocavernous function, as compared to the bladder neck cuff provided a slightly better continence rate at 10 years, 92% and 84%, respectively. The lowest erosion rate occurred with the bulbocavernous function. Device survival rate at 10 years was 66% in this series.

In a series of 30 boys with spina bifida Spiess et al [631] found that the mean lifetime of all AUS was 4.7 years, with no statistically significant difference in sphincter survival of those inserted at the bladder neck or the bulbous urethra (4.6 and 4.9 years, respectively). A sharp drop was observed at 100 months with only 8.3% of the original sphincters still functioning beyond this point. In a series of 35 adolescents with neurogenic voiding dysfunction implanted with a bladder neck cuff over an 11-year period, with an average follow-up of 5.5 years, Lopez Pereira and colleagues [632] reported a 20% mechanical failure rate, with an additional 8.6% erosion rate. Adverse bladder storage changes developed in 31.8% of patients, who thereby required augmentation cystoplasty. However, continence was achieved in 91.4% of individuals. Ruiz and colleagues [633] followed 19 adolescents for an average of 80 months who were implanted with bladder neck cuffs over a 14 year period for reasons other than spina bifida. They reported a mechanical failure rate of 26.3%, an infection/erosion rate of 15.8%, and a revision rate of 26.3%. However, even in this very high risk group, a continence rate of 87% was achieved despite this high complication rate. It might be useful to consider patients with ‘primary adequate function’ when no revision is necessary to achieve continence separately from those with ‘additional procedure-assisted adequate function’, where one or more revisions are necessary to obtain favourable outcome. Klijn et al. [183] showed in their series of 27 men who became incontinent after a radical prostatectomy that at a mean follow-up of 35 months, 81% of the patients achieved satisfactory continence. The 5-year ‘primary adequate function’ and ‘additional procedure-assisted adequate function’ rates, based on the Kaplan-Meier curves, were 49% and 71%, respectively. The median time to failure for the ‘primary adequate function’ group was 48 months, the median time to definitive failure of ‘additional procedure-assisted adequate function’ was more than 72 months.

In other recent series, the global long term (2 to 7.7 years) revision rate, for any of the above mentioned reasons varies between 16% and 50% [186, 187, 191, 192, 628, 632-635]. In Webster’s recent report [628] of 554 implantations over a 10 year period, (i.e. performed since the 1987 device modification), he noted a mechanical failure rate of only 31/554 (5.5%). Non-mechanical failure was 88/554 (15.9%), with 63/554 (11.3%) due to urethral atrophy and 21/554 (3.8%) due to cuff erosion. Of the total cohort, 21.4% required at least one revision surgery, while 78.6% did not. Of those 119 patients who required re-operation, 76.5% required no further treatment (similar to the non-reoperation rate of the initial cohort), while 23.5% required re-operation for either mechanical or non-mechanical failure. Five-year durability of the AUS following primary or secondary implantation was comparable, with 80% for the initial placement, and 88% following revision surgery. Similarly, continence status was comparable, with 90% of primary and 82% of revision patients achieving 0-1 pad per day urinary control. Patients with neurological deficit seem to have a higher risk of non-mechanical failure and the overall continence rate may be poorer compared to non-neurologic patients [29].

6. Diagnostic Procedures Related to Artificial Sphincter Failure

The diagnostic evaluation of urinary incontinence after the placement of the AUS is critical for the management of these patients and represents a challenging problem for the urologist. Several diagnostic and management algorithms have been proposed, some relatively simple, others more complex [29, 30, 200, 206, 610, 636-638]. Figure 11 shows an algorithm to investigate and treat the male patient with a previously functioning AUS who becomes incontinent.

Physical examination should exclude infection at the site of the cuff or the scrotal/labial pump. Difficulty compressing the pump suggests tube kinking, fluid loss or an obstructed system.

Plain X-rays of the abdomen or pelvis may show fluid loss, if the system is filled with radio-opaque solution [639, 640] (Figure 1). Alternatively, sonography of the pressure regulating balloon may show volume loss. It is necessary to obtain a baseline film at the discharge of the patient from the hospital for subsequent comparison because radiographic imaging of the balloon does not detect changes until at least 50% of its volume has been lost [12].

Cystometry or complete urodynamic study will demonstrate changes in bladder behavior following insertion of the AUS as described above. Cystourethrogram could eventually demonstrate a urethral diverticulum at the site of previous cuff erosion (Figure 2). Endoscopy will disclose any urethral erosion by the cuff (Figure 12).
Figure 11: Algorithm for managing incontinence after AUS placement
Retrograde perfusion sphincterometry has been reported to diagnose the loss of compressive pressure in the urethral cuff [29]. It is done by infusing fluid from the meatus in a retrograde fashion. If the AUS cuff is functional and the urethral is intact there should be no flow when the pressure equals the AUS balloon pressure. This technique can also be used intraoperatively to detect urethral perforation or to adjust the pressure in the cuff [32]. This seems to be more useful than urethral pressure profile (UPP) [606].

Intraoperative electrical testing, using an ohmmeter [619, 637] has been described to determine the site of fluid leakage from the system. This test can be helpful to avoid the need to change the whole system, and allow replacement of the leaking part only.

7. TREATMENT OF COMPLICATIONS

As outlined above, complications directly related to the presence of an artificial sphincter can be divided into categories: incontinence from alteration in bladder function, urethral atrophy, and/or mechanical failure, and infection/erosion. The treatment of each of these complications deserves comment, as no detailed reference can be found in the literature dealing with the treatment of these complications.

a) Alterations in bladder function

De novo (or pre-existing) detrusor overactivity can be treated with parasympatholytics. In a small proportion of patients systemic side effects will prevent the use of these drugs; there might also be some medical contraindications, or the drug may be ineffective. Other options such as bladder augmentation or enterocystoplasty may be considered. To date no report can be found where implantation of an artificial sphincter resulted in the deterioration of the upper urinary tract in a neurologically normal post-prostatectomy patient [188, 611]. It has been reported that enterocystoplasty performed together with the placement of an AUS in the same operative session does not increase the morbidity of the procedure and does not affect the success rate [590]. However, in a recent review of 286 patients Furness et al. [641] demonstrated an infection rate of 14.5% and 6.8% with simultaneous and staged procedures, respectively. Catto, et al. [592] however, showed that while infections may occur earlier with simultaneous procedures, the ultimate infection rate is no different when augmentation cystoplasty and AUS placement separately or simultaneously. No clear urodynamic guidelines exist to select patients who need bladder augmentation in combination with an AUS [612], although small voided volumes with reduced cystometric capacity, poor compliance, or severe detrusor overactivity after failed medical treatment would suggest the need.

b) Atrophy of the urethra

Several therapeutic options exist to increase cuff pressure around the atrophied urethral wall: changing the balloon reservoir for one generating a higher pressure, downsizing the cuff diameter [12, 179, 642], or increasing the amount of fluid in the system. Another approach consists of placing the cuff inside the corporal tunica albuginea on the dorsal aspect of the urethra (transcorporal). This allows a safer mobilization of the urethra and adds some supplementary bulk of tissue to the circumference of the urethra, possibly decreasing the risk of erosion [196]. It should be mentioned, however, that there is a risk of reduced erectile function with this technique. The vast majority of such patients, however, already suffer from erectile dysfunction secondary to the prostate cancer surgery. Guralnick reported a retrospective chart review of 31 patients with an average of 17 months follow-up after trans-corporal cuff placement for varied indications (previous erosion, urethral atrophy, radiation). The vast majority of patients (84%) realized 0-1 pad per day leakage post-operatively, with no device erosions or infections, while 3 patients (9.7%) required revision surgery for malfunction. Overall, 29 of 31 had erectile dysfunction prior to the procedure, and only 1 of 2 had deterioration of his erectile function post-operatively. Magera and Elliott [643] reported their results of 18 patients who underwent tandem cuff transcorporal salvage surgery. Ten patients had only the distal cuff placed transcorporally, while 18 had both cuffs placed transcorporally. Infection occurred in 1 patient (5.5%), and erosion occurred in 1 patient (5.5%), while 69% reported that they were very
improved or extremely improved with respect to continence at an average of 26 months follow-up. The implantation of a double-cuff AMS 800 has become more popular, as a primary procedure in the totally or severely incontinent patient [197, 644], or as a salvage procedure, by adding a second cuff, following a failed previous single cuff [194, 195, 644]. Dimarco’s group [195] and others have shown excellent results with the addition of a second urethral cuff, placed 1.5–2.0 cm distal to the primary cuff. Alternatively, a circumurethral wrap of an organic bulking agent can be fitted, with subsequent placement of the AUS cuff over the biologic external urethral bulking agent [645]. Early reports of primary double cuff placement did not demonstrate any significant increase in morbidity with the double-cuff as compared with the single cuff system [197], and patient satisfaction also seems to be higher [198] at an average of 21-41 months follow-up. However, with longer follow-up (58-74 months), the same group [199] reported that the complication rate was higher in men with primary double-cuff placement (55% versus 28%), and there were no significant differences in overall continence and QOL measures.

c) Mechanical failure
As with any device, mechanical failure can be expected with the AMS 800 AUS. The treatment involves surgical replacement of the failed component and reconnecting the system.

d) Infection
With overt infection the accepted treatment option is removal of the entire device and appropriate antibiotics. A second system can be subsequently implanted with equally good results [623]. It has been demonstrated, however, that immediate reimplantation of a new AUS after the removal of an infected, but not eroded, prosthesis can be a valid option with an overall success rate of 87% [646]. In 2007, AMS introduced the InhibiZone-coated artificial urinary sphincter (rifampin and minocycline hydrochloride coating) [643].

e) Erosion
In case of urethral erosion by the cuff, the “offending” cuff must be removed. No clear guidelines exist whether removal of the whole system is superior to removal of the cuff alone but it must be assessed for infection. If infection is present the whole device should be removed. Reservoir erosion into the bladder has been described following the removal of an eroded cuff [629]. Furthermore, it is not known whether it is necessary to allow the urethra to heal over a catheter versus surgical repair. The former risks diverticulum formation (Figure 2), and the latter may increase the amount of the periurethral fibrosis. This might compromise success of a new cuff. However, the new cuff should be positioned away from the erosion site. In case of the erosion of one of the cuffs of a double system removal of the eroded cuff can successfully convert a double-cuff system into a single cuff system [647]. It is logical that intra-operative urethral injury may precipitate cuff erosion if unrecognized. However, Petrou and colleagues [628] showed that early postoperative cuff erosion can occur even when no laceration is demonstrated by intraoperative intraurethral instillation of indigo carmine.

8. CONSENSUS PROTOCOL FOR FOLLOW-UP OF PATIENTS WITH AUS
As complications continue to be seen for years after implantation [648], it is helpful to have a structured follow-up plan. However, no standardized recommendations are available in the literature.

The consensus upon which the members of this subcommittee agreed and which is based on expert opinion are as follows:

1. Perioperative antibiotics are recommended. Gram-negative enteric bacteria and Staphylococcus epidermidis are the most frequently encountered microorganisms in infected prostheses [625].
2. Hospital stay should be kept to a minimum.
3. Urethral catheters, if inserted, should be withdrawn within 24-48 hours of surgery and the preoperative continence management continued.
4. In general the sphincter device should not be activated immediately postoperatively. In the initial period scrotal oedema and pain prevent patients from manipulating the pump adequately. When this subsides after 6 to 8 weeks the device can be activated. Earlier activation may also be acceptable. Irradiated patients may benefit from a longer initial period of deactivation, up to 12 weeks [179]. Nocturnal deactivation should be considered in high-risk patients 178.
5. Patients are reviewed at 3 months after activation to ensure the device is working adequately, and to assess the continence status.
6. Long-term follow-up is different in the neurogenic and non-neurogenic patient. With time, alteration in bladder function may jeopardize renal function in the neurogenic patients. Periodic ultrasound evaluation of the upper urinary tract and monitoring of renal function is essential. If changes occur, urodynamic studies should be done to rule out detrusor overactivity. In non-neurogenic patients, periodic ultrasound may not be necessary.
7. When changes in the continence status occur, diagnostic procedures depicted in Figure 11 should be considered. (Level of evidence 3; Grade of recommendation B-C)
XIII. SUMMARY AND RECOMMENDATIONS

1. EVALUATION

Prior to surgery a basic patient evaluation should consist of history and physical examination, urinalysis and postvoid residual urine (Level of evidence 1-2; grade of recommendation A). A voiding diary is helpful to assess functional capacity and total urine output (Level of evidence 1-2; grade of recommendation B). Pad tests may be useful in certain circumstances (Level of evidence 1-2; grade of recommendation B). Blood testing (BUN, creatinine, glucose) is recommended if compromised renal function is suspected or if polyuria (in the absence of diuretics) is documented. Additional testing with cystoscopy and appropriate imaging of the urinary tract are also helpful in guiding therapy (Level of evidence 2-3; grade of recommendation B). The committee felt that multichannel urodynamics are useful prior to invasive treatment for incontinence. (Level of evidence 3; grade of recommendation C)

2. INCONTINENCE POST-PROSTATECTOMY FOR BPO AND POST-RADICAL PROSTATECTOMY FOR PROSTATE CANCER

After a period of conservative management, which may also be from 6 to 12 months, the artificial sphincter is the preferred treatment for properly selected men who have stress incontinence after radical prostatectomy with the longest record of safety and efficacy. Male slings are an alternative with intermediate data support their safety and efficacy in men with more moderate degrees of PPI, although long-term data are beginning to accumulate. However, the literature contains results on many different kinds of slings. Injectable agents are a less effective option for some men with mild to moderate incontinence. (Level of evidence 3; grade of recommendation C)

3. AGE

Age is not a restriction for surgical treatment of urinary incontinence. Cognitive impairment and lack of dexterity may be restrictions for the artificial sphincter and must be determined preoperatively. (Level of evidence 3-4; grade of recommendation C)

4. INCONTINENCE FOLLOWING OTHER TREATMENTS FOR PROSTATE CANCER

The artificial sphincter is most widely used but radiation may be a risk factor for an increase in complications. Slings have variable results after radiation. Injectable agents have not been successful in this setting. (Level of evidence 3; grade of recommendation C)

5. INCONTINENCE FOLLOWING PELVIC TRAUMA

The artificial sphincter is most widely reported. Bladder neck reconstruction has also been reported on a limited basis. (Level of evidence 3; grade of recommendation C)

6. INCONTINENCE IN ADULT EPISPADIAS-EXSTROPHY COMPLEX

Patients should be treated in centres of excellence. A patient-directed approach should be taken. The choices include further bladder neck reconstructive surgery, bladder neck closure, bladder reconstruction or diversion with bowel. The data are insufficient for a specific recommendation. Transition is important between the pediatric and adult urologist. Life-long follow-up is mandatory in terms of continence, voiding efficiency, upper tract status and other urological complications. (Level of evidence 3; Grade of recommendation C)

7. REFRACTORY URGENCY INCONTINENCE AND DETRUSOR OVERACTIVITY

Botulinum toxin-A bladder injections is a minimally invasive treatment with some efficacy. Neuromodulation is a treatment option with success reported in a limited number of male patients. Detrusor myectomy has also been reported to be successful in a small number of male patients. Augmentation cystoplasty is potentially successful in controlling symptoms but may be associated with unacceptable side effects. Urinary diversion is a final option. (Level of evidence 3; grade of recommendation C)

8. REDUCED CAPACITY BLADDER

Augmentation cystoplasty has been successful in most etiologies apart from radiation. (Level of evidence 3; grade of recommendation C)

9. URETHROCUTANEOUS FISTULA AND RECTOURETHRAL FISTULA

Etiologic factors causing acquired urethrocutaneous fistulae are demonstrated by clinical, endoscopic and imaging studies. Surgical reconstruction is applied as required. Similar diagnostic maneuvers are applied to rectourethral fistulae. In those that do not close with or without temporary urinary and fecal diversion, surgical reconstruction may be carried out. Most repairs are now carried out after prior fecal diversion. Various techniques are available for closure and can be done in collaboration with colorectal surgeons. (Level of evidence 3; grade of recommendation C)

10. MANAGEMENT OF AUS COMPLICATIONS

Incontinence may result from alteration in bladder function, urethral atrophy, or mechanical malfunction. Infection and/or erosion of components demand surgical removal of all or part of the prosthesis. A treatment algorithm is presented to aid in management and in follow-up of patients. (Level of evidence 3; grade of recommendation C)
11. NEW TECHNOLOGIES

Evidence for the adjustable balloons is accruing and the early high complication rate appears to have been resolved. However, more evidence is required before specific recommendations can be made. (Level of evidence C; grade of recommendation D)

FUTURE RESEARCH DIRECTIONS

- New technologies, bulking agents, sling materials, prosthetic devices should continue to be evaluated
- Accuracy in reporting of early research results is mandatory
- Mechanisms of post-prostatectomy incontinence and device effects need further research

CLINICAL TRIAL RECOMMENDATIONS

- Randomized trials (AUS and slings)
- Standardized workup and outcome measures including QoL
- Complete reporting of complications and outcomes especially those of slings
- Reporting of procedures to salvage failures
- Long-term results (>2 years)
- Standardized reporting of durability

INTRODUCTION

Surgeons have been criticised for the lack of rigour with which they have analysed their results. This chapter highlights the progress made, particularly in surgery for stress incontinence where more randomised controlled trials have been reported, and illustrates areas where more studies are needed. The section on outcome measures illustrates that whilst the measurement of subjective and objective outcome may clarify the value of an operation some standardisation of outcome measures is required in order to meaningfully compare different procedures.

I. SURGERY FOR STRESS INCONTINENCE

1. PROCEDURES EXCLUDING MID-URETHRAL TAPES

The practice of surgical treatment for stress urinary incontinence has changed dramatically over the last decade; the number of procedures undertaken appears to be increasing, and the shift in relative numbers of different procedures has been remarkable. In England between 1997-’98 and 2005-’06 the annual number of operations undertaken for stress urinary incontinence (SUI) increased by 28%, despite over 90% reduction in the numbers of colposuspension and needle suspension procedures, and 50% reduction in bladder neck buttress, sling and urethral bulking procedures. The increase was entirely due to the rapid dissemination of the Tension-free Vaginal Tape (Gynecare®, Ethicon, Somerville, NJ) in 1998, and similar minimally invasive synthetic sub urethral sling procedures subsequently (Hilton, 2008) [1]

Whilst these trends may be in line with currently available evidence, other changes in practice seem to proceeding in advance of high quality evidence; the drivers behind such changes in practice have recently been reviewed (Hilton, 2008)[1].
