Accurate indications, adverse reactions, and dosage schedules for drugs are provided in this book, but it is possible that they may change. The reader is urged to review the package information data of the manufacturers of the medications mentioned.

The Publishers have made every effort to trace the copyright holders for borrowed material. If they have inadvertently overlooked any, they will be pleased to make the necessary arrangements at the first opportunity.

The great tragedy of science:
The slaying of a beautiful hypothesis by an ugly fact
Thomas Huxley (1825-1895)
The Third International Consultation on Sexual Medicine (ICSM), which took place on July 10 to July 13, 2009 at the Palais de Congres in Paris, France was organized under the auspices of the International Consultation on Urological Diseases and the International Society for Sexual Medicine (ISSM). This year’s ICSM was a truly memorable scientific event full of impressive discoveries, never before seen studies backed by robust data and an overwhelming interest from the audience. After having watched and listened to each and every one of the presentations given during the four day meeting, we are pleased to affirm that the field of Sexual Medicine for both Men and Women is making enormous progress. This well deserved success is due to the dedication, perseverance and hard work done by the renowned experts in the field who selflessly devote their time, intellect and energy to promoting the results and findings obtained by their studies.

To successfully carry out a meeting and publication as important as this, careful preparation was necessary. In early 2008, Chairman Francesco Montorsi, Secretary Saad Khoury, Honorary President Tom Lue and Vice Chairs; Ganesan Adaikan, Rosemary Basson, Edgardo Becher, Anita Clayton, François Giuliano, Ira Sharlip all met together in person or by phone conference in Paris with the ISSM office representatives to brainstorm on how a reference such as the Recommendations for Sexual Medicine should be developed. Much thought and consideration went into deciding what topics should be considered as chapters and how the meeting and eventual publication would be organized.

Choosing the Chairpersons, Members and Consultants was not an easy task as the experts in these fields are many and each very distinguished. The identification of the members of all the committees started from a very rigorous assessment of the chairpersons and members of the 2003 Consultation as we clearly wanted to have on board again all those who had given a substantial contribution to that meeting and were still available to actively participate this further endeavour.

In addition, a very extensive PubMed search and a thorough evaluation of the scientific programmes of the most important international scientific meetings devoted to sexual medicine served to identify the names of the top experts from the five continents.

The topics that were discussed in the 2003 Consultation served as the basis to build the programme of the 2009 meeting. We considered the advances done in the field during the last six years and we identified all the areas which deserved to be specifically investigated by the experts of the new Consultation. In the end, we were able to produce a table of contents composed of 25 Chapters covering a vast spectrum of the critical topics concerning aspects of sexual medicine for both men and women.

The lists of topics and experts were then matched and the committees were formed. Although a few of those on each of our “wish lists” could not be included due to economic restraints, we were able to guarantee the participation of 186 experts to the final program.

The preparatory meetings held at the various major national meetings, the ISSM in Brussels and the American Urological Association 2009 annual meeting in Chicago, were essential to understand how each chapter was progressing and what the next steps should be. These meetings allowed everyone to finally meet face-to-face under the same roof to streamline ideas and final recommendations of their respective chapters. We were impressed to see the close collaboration the committees had with one another to make sure that ideas were shared without overlap.

The work of the various committees was indeed very hard and was witnessed by the exchange of a huge number of emails aimed at discussing the contents of the various chapters. We are very pleased to inform you that we were always able to touch with our hands the enthusiasm and passion for science shown by the chairs and members of the committees. Sometimes there were strong views which would be contrasting but at the end it was always possible to find a general consensus and the final editing of the chapters text was overall very smooth.

In Paris, the presentations of the committees were really top quality and it was clear to the audience that a huge amount of work was behind the slides that were shown. The discussion sessions were always very lively and many ideas that came out of these were used to improve the final text of the chapters.

In the end, we believe that our objective to create and update a set of standards from evidence based studies and years of research has been reached. This gratifying accomplishment could not have been made without the support from the previously mentioned organizations, the various sponsors and the ambitious staff of the Consultation.

We are grateful to everyone involved and especially to Ira Sharlip who was instrumental in maintaining the necessary geographical balance when identifying the top experts and also in obtaining funding for the meeting; to Tom Lue and all the Vice Chairs who were extremely active during all the preparatory phases and to David Casalod and his team who were the responsible persons for the very efficient logistics.

We are convinced that these contributions will be key in advancing our knowledge in the field of sexual medicine and ultimately in improving the care of our patients.

FRANCESCO MONTORSI  
Chairman, ICSM

CATHERINE J. PIERCE  
Assistant to the Chairman, ICSM

SAAD KHOURY  
Secretary, ICSM
Some of the members of the International
Committees Paris, France

INTRODUCTION

The International Consultation on Urological Diseases (ICUD) is a non-governmental organization registered with the World Health Organisation (WHO). In the last ten years Consultations have been organised on BPH, Prostate Cancer, Urinary Stone Disease, Nosocomial Infections, Erectile Dysfunction and Urinary Incontinence. These consultations have looked at published evidence and produced recommendations at four levels; highly recommended, recommended, optional and not recommended. This method has been useful but the ICUD believes that there should be more explicit statements of the levels of evidence that generate the subsequent grades of recommendations.

The Agency for Health Care Policy and Research (AHCPR) have used specified evidence levels to justify recommendations for the investigation and treatment of a variety of conditions. The Oxford Centre for Evidence Based Medicine have produced a widely accepted adaptation of the work of AHCPR. (June 5th 2001 http://minerva.minervation.com/cebm/docs/levels.html). The ICUD has examined the Oxford guidelines and discussed with the Oxford group their applicability to the Consultations organised by ICUD. It is highly desirable that the recommendations made by the Consultations follow an accepted grading system supported by explicit levels of evidence.

The ICUD proposes that future consultations should use a modified version of the Oxford system which can be directly ‘mapped’ onto the Oxford system.

1. 1st Step: Define the specific questions or statements that the recommendations are supposed to address.

2. 2nd Step: Analyse and rate (level of evidence) the relevant papers published in the literature.

   The analysis of the literature is an important step in preparing recommendations and their guarantee of quality.

2.1 What papers should be included in the analysis?

• Papers published, or accepted for publication in the peer reviewed issues of journals.

• The committee should do its best to search for papers accepted for publication by the peer reviewed journals in the relevant field but not yet published.

• Abstracts published in peer review journals should be identified. If of sufficient interest the author(s) should be asked for full details of methodology and results. The relevant committee members can then ‘peer review’ the data, and if the data confirms the details in the abstract, then that abstract may be included, with an explanatory footnote. This is a complex issue – it may actually increase publication bias as “uninteresting” abstracts commonly do not progress to full publication.

• Papers published in non peer reviewed supplements will not be included.

An exhaustive list should be obtained through:

I. the major databases covering the last ten years (e.g. Medline, Embase, Cochrane Library, Biosis, Science Citation Index)

II. the table of contents of the major journals of urology and other relevant journals, for the last three months, to take into account the possible delay in the indexation of the published papers in the databases.

It is expected that the highly experienced and expert committee members provide additional assurance that no important study would be missed using this review process.

2.2 How papers are analysed?

Papers published in peer reviewed journals have differing quality and level of evidence.

Each committee will rate the included papers according to levels of evidence (see below)

The level (strength) of evidence provided by an individual study depends on the ability of the study design to minimise the possibility of bias and to maximise attribution.

is influenced by:

• the type of study

The hierarchy of study types are:

- Systematic reviews and meta-analysis of randomised controlled trials
- Randomised controlled trials
- Non-randomised cohort studies
- Case control studies
- Case series
- Expert opinion

• how well the study was designed and carried out

Failure to give due attention to key aspects of study methodology increase the risk of bias or confounding factors, and thus reduces the study’s reliability.

The use of standard check lists is recommended to insure that all relevant aspects are considered and that a consistent approach is used in the methodological assessment of the evidence.

The objective of the check list is to give a quality rating for individual studies.

• how well the study was reported

The ICUD has adopted the CONSORT statement and its widely accepted check list. The CONSORT statement and the checklist are available at http://www.consort-statement.org

2.3 How papers are rated?

Papers are rated following a «Level of Evidence scale».

ICUD has modified the Oxford Center for Evidence-Based Medicine levels of evidence.

The levels of evidence scales vary between types of studies (e therapy, diagnosis, differential diagnosis/symptom prevalence study).

the Oxford Center for Evidence-Based Medicine Website: http://minerva.minervation.com/cebm/docs/levels.html

3. 3rd Step: Synthesis of the evidence

After the selection of the papers and the rating of the level of evidence of each study, the next step is to compile a summary of the individual studies and the overall direction of the evidence in an Evidence Table.

4. 4th Step: Considered judgment (integration of individual clinical expertise)

Having completed a rigorous and objective synthesis of the evidence base, the committee must then make a judgement as to the grade of the recommendation on the basis of this evidence. This requires the exercise of judgement based on clinical experience as well as knowledge of the evidence and the methods used to generate it. Evidence based medicine requires the integration
of individual clinical expertise with best available external clinical evidence from systematic research. Without the former, practice quickly becomes tyrannised by evidence, for even excellent external evidence may be inapplicable to, or inappropriate for, an individual patient: without current best evidence, practice quickly becomes out of date. Although it is not practical to lay our "rules" for exercising judgement, guideline development groups are asked to consider the evidence in terms of quantity, quality, and consistency; applicability; generalisability; and clinical impact.

5. 5th Step: Final Grading

The grading of the recommendation is intended to strike an appropriate balance between incorporating the complexity of type and quality of the evidence and maintaining clarity for guideline users.

The recommendations for grading follow the Oxford Centre for Evidence-Based Medicine.

The levels of evidence shown below have again been modified in the light of previous consultations. There are now 4 levels of evidence instead of 5.

The grades of recommendation have not been reduced and a "no recommendation possible" grade has been added.

6. Levels of Evidence and Grades of Recommendation

Therapeutic Interventions

All interventions should be judged by the body of evidence for their efficacy, tolerability, safety, clinical effectiveness and cost effectiveness. It is accepted that at present little data exists on cost effectiveness for most interventions.

6.1 Levels of Evidence

Firstly, it should be stated that any level of evidence may be positive (the therapy works) or negative (the therapy doesn't work). A level of evidence is given to each individual study.

• Level 1 evidence (incorporates Oxford 1a, 1b) usually involves meta-analysis of trials (RCTs) or a good quality randomised controlled trial, or 'all or none' studies in which no treatment is not an option, for example in vesicovaginal fistula.

• Level 2 evidence (incorporates Oxford 2a, 2b and 2c) includes "low" quality RCT (e.g. < 80% follow up) or meta-analysis (with homogeneity) of good quality prospective 'cohort studies'. These may include a single group when individuals who develop the condition are compared with others from within the original cohort group. There can be parallel cohorts, where those with the condition in the first group are compared with those in the second group.

• Level 3 evidence (incorporates Oxford 3a, 3b and 4) includes:
  - good quality retrospective 'case-control' studies where a group of patients who have a condition are matched appropriately (e.g. for age, sex etc) with control individuals who do not have the condition.
  - good quality 'case series' where a complete group of patients all, with the same condition/disease/therapeutic intervention, are described, without a comparison control group.

• Level 4 evidence (incorporates Oxford 4) includes expert opinion where the pinion is based not on evidence but on 'first principles' (e.g. physiological or anatomical) or bench research. The Delphi process can be used to give 'expert opinion' greater authority. In the Delphi process a series of questions are posed to a panel; the answers are collected into a series of 'options'; the options are serially ranked; if a 75% agreement is reached then a Delphi consensus statement can be made.

6.2 Grades of Recommendation

The ICUD will use the four grades from the Oxford system. As with levels of evidence the grades of evidence may apply either positively (do the procedure) or negatively (don't do the procedure). Where there is disparity of evidence, for example if there were three well conducted RCT's indicating that Drug A was superior to placebo, but one RCT whose results show no difference, then there has to be an individual judgement as to the grade of recommendation given and the rationale explained.

• Grade A recommendation usually depends on consistent level 1 evidence and often means that the recommendation is effectively mandatory and placed within a clinical care pathway. However, there will be occasions where excellent evidence (level 1) does not lead to a Grade A recommendation, for example, if the therapy is prohibitively expensive, dangerous or unethical. Grade A recommendation can follow from Level 2 evidence. However, a Grade A recommendation needs a greater body of evidence if based on anything except Level 1 evidence

• Grade B recommendation usually depends on consistent level 2 and or 3 studies, or 'majority evidence' from RCT's.

• Grade C recommendation usually depends on level 4 studies or 'majority evidence' from level 2/3 studies or Dephi processed expert opinion.

• Grade D "No recommendation possible" would be used where the evidence is inadequate or conflicting and when expert opinion is delivered without a formal analytical process, such as by Delphi.

7. Levels of Evidence and Grades of Recommendation for Methods of Assessment and Investigation

From initial discussions with the Oxford group it is clear that application of levels of evidence/grades of recommendation for diagnostic techniques is much more complex than for interventions.

The ICUD recommend, that, as a minimum, any test should be subjected to three questions:

1. does the test have good technical performance, for example, do three aliquots of the same urine sample give the same result when subjected to 'stix' testing?

2. Does the test have good diagnostic performance, ideally against a "gold standard" measure?

3. Does the test have good therapeutic performance, that is, does the use of the test alter clinical management, does the use of the test improve outcome?

For the third component (therapeutic performance) the same approach can be used as for section 6.

8. Levels of Evidence and Grades of Recommendation for Basic Science and Epidemiology Studies

The proposed ICUD system does not easily fit into these areas of science. Further research needs to be carried out, in order to develop explicit levels of evidence that can lead to recommendations as to the soundness of data in these important aspects of medicine.

CONCLUSION

The ICUD believes that its consultations should follow the ICUD system of levels of evidence and grades of recommendation, where possible. This system can be mapped to the Oxford system.

There are aspects to the ICUD system that require further research and development, particularly diagnostic performance and cost effectiveness, and also factors such as patient preference.

Today we have a clear concept of sexual medicine and how to define this medical discipline. But historically the unification of sexuality and medicine was not a given condition. Medicine was mainly focused on human reproduction and how to prevent and treat sexually transmitted diseases (STD). Hardly any other aspect would have met the interest of medical doctors for centuries. Perhaps the first true medicalization of sexuality, i.e. the fusion of medicine and sexuality, was the dreadful anti-masturbation campaign led by doctors, beginning with Tissot, since the middle of the 18th century. Therefore, we have chosen this period as the starting point for this article and only included the respective development before that time in some aspects.

We would like to point out that this article can only highlight developments and milestones of sexual medicine and is not intended to be encyclopaedic. The historical primary literature has not been referenced extensively, but the reader is referred to selected secondary literature sources that will provide detailed information on each respective topic. Moreover, the focus is on the medical perspective rather than on the interdisciplinary aspect that defines the discipline of sexology.

II. TERMINOLOGY

Sexuality: Before the 18th century only the adjective sexual (Latin: sexualis) was used in the sense of “belonging to the sex or gender”. To our knowledge the noun sexuality appeared after 1800 in the field of botanics and was first adopted in the title of a German monography by August Henschel “Von der Sexualität der Pflanzen (On the sexuality of plants)” in 1820 [1]. After its transfer to human sexuality the term was primarily reserved for the aspect of reproduction and not for sexual desire and emotionality. Even Paolo Mantegazza was still talking of love (amore) when he was referring to the sexual relation of two individuals. He never used the terms sexual or sexuality. However this changed in the late 19th century and culminated in the 2nd half of the 20th century by even reducing the term to the abridged version sex.

Sexology (“Sexualwissenschaft”): According to Sigusch [1] the term sexology appeared first in a book entitled “Sexology as the philosophy of life: implying social organization and government” written by Elizabeth Osgood Goodrich Willard and published in Chicago, Illinois, in 1867. It is a parafeministic monography with religious fundamentalistic tendency reflecting the human female and male interaction. In a lecture on “The woman’s question” from 1885 and published in 1888 the English mathematician, statistician and eugenicist Karl Pearson asked for a “real science of sexology”.

In the German literature the equivalent term Sexualwissenschaft was popularized by the dermatologist Iwan Bloch from Berlin in his famous book “Das Sexualleben unserer Zeit (The sexual life in our time)” officially published in 1907, but actually already on the market in fall 1906 [2]. A clear definition of the interdisciplinary approach of sexology is stated in this work. However, Sigmund Freud had used the same term earlier in 1898 in an essay dealing with the importance of sexual events for the development of neurosis, but without earning the same or even any public recognition. So did the writer Karl Vanselow in 1904...
and the sexologist Magnus Hirschfeld in 1906 [1]. “Sexualwissenschaft” was initially translated literally as “Sexual Science” but was rapidly transformed more adequately in “Sexology”. The subsequent development of sexology after 1907 and reference of later authors to the text of Bloch underline the importance of his book. Another founding milestone not only in terms of terminology is the journal “Zeitschrift für Sexualwissenschaft (Journal for Sexual Science)” founded in January 1908. Neither the introducing article “Über Sexualwissenschaft (On Sexual Science)” written by the journal’s editor Magnus Hirschfeld [3], nor another contribution in the journal’s first issue “Bemerkungen zur Nomenklatur der Sexualwissenschaft (Remarks on the Nomenclature of Sexual Science)” mentioned the term sexual medicine [4].

Sexual Medicine: However, the above mentioned first issue of the journal “Zeitschrift für Sexualwissenschaft” does contain an article entitled “Forensische Sexualmedizin (Forensic Sexual Medicine)” written by the lawyer Joh. Werthauer from Berlin [5]. The article is only reviewing legal cases that include some kind of sexual act or misconduct. Therefore, the modern definition of sexual medicine is in no way indicated in this publication. Although aspects of sexuality in medicine were addressed by many physicians and sexologists in the following decades the term sexual medicine was not established before the 1970’s. It is quite difficult to identify the exact time or even person who deserves the credit for introducing the term in its modern definition. One interesting question in this context might be the shift from the understanding of “Clinical Sexology” towards “Sexual Medicine”. In 1972 Volkmar Sigusch from Germany published a book “Ergebnisse zur Sexualmedizin (Results for Sexual Medicine)” in which he defines this new academic speciality but also complains about the fact that medical faculties and the majority of the medical community are still unwilling to accept the developing discipline of sexual medicine [6]. Since April 1972 the German journal “Sexualmedizin” and one year later the “British Journal of Sexual Medicine” were the first periodicals literally dedicated to the new discipline and several monographies and textbooks including the term sexual medicine in their title were published in the 2nd half of the 1970’s [7].

III. “THE TREATMENT OF ONANISM” - THE FIRST SYSTEMATIC MEDICALIZATION OF SEXUALITY

Around 1712 an anonymous author, most likely the quack doctor and medical pornographer John Marten [8], published the pamphlet “Onania; or, the Heinous Sin of Self Pollution, and all its Frightful Consequences, in both SEXES Considered, with Spiritual and Physical Advice to those who have already injured themselves by this abominable practice.” that experienced several re-editions and translations and resulted in a first public awareness for a new medical entity, i.e. masturbation which also included involuntary seminal loss often referred to as spermatorrhoea. This publication was indeed the beginning of an anti-masturbation campaign that lasted until the mid-20th Century. It was not only a socio-cultural and religious issue but increasingly gained interest of medical doctors.

In 1758 the Swiss physician Simon Auguste David Tissot (1728-1797) published a book entitled “L’Onanisme, Dissertation sur les Maladies produites par la Masturbation” (“Onanism, Treatise on the Diseases produced by Masturbation”) (Fig. 1).

(Fig.1) Simon Auguste David Tissot (portrait and frontispiece of his publication from 1758.

With this writing the young medical doctor from Lausanne became the most influential medical propagandist of the alleged dangers of masturbation. For more than 150 years, the fear of «masturbatory insanity» remained a dominant theme of disease prevention and adolescent sexual education. As outlined above Tissot was not the first to imagine that nocturnal emissions and masturbation were a medical problem, but he definitely anthropologized and summarized earlier thoughts on this subject. Tissot’s work helped reshape medicine’s attitude towards sexuality and provided an additional scientific basis upon which the process of pathologization of sexual anatomy and sexual functions could proceed. Tissot’s primary contribution was not as an innovator but as a skilful collator and editor of independently expressed, roughly contemporary medical views on masturbation. His highly original argument was carefully constructed and supported by references to earlier authorities, such as Galen, Aretaeus, Celsus, Boerhaave, Gaubius, Koempf, Sennert, Regis, Craanem, Zimmermann, G.M. Wepfer, and Veslin. Going through many editions, each of which
allowed Tissot to make additions, emendations, and annotations, his erudite book created the partly inaccurate impression that there existed a powerful consensus among the respectable and leading European doctors, in harmony with the views of classical authors, that masturbation was a dangerous disease and gathering threat to human welfare.

Tissot had a major impact on the development of the professional anti-masturbation movement from the second half of the eighteenth century onwards. Physicians adopted his theories and invented a wide array of severe surgical, medical, dietary, and behavioral therapies for the prevention of masturbation over the next 150 years.

Especially in the United States, where an unregulated organization of the medical profession pushed doctors towards radicalism and extremism in theory and practice, circumcision — in some cases executed without anaesthesia in order to combine “treatment” with punishment — became the most common surgical intervention against masturbation in boys during the 19th and 20th centuries. Some authors conclude that “extremist religion, and extreme anti-sexualism and anti-phallicism provided a fertile ground for the acceptance of an obviously anti-phallic, intentionally destructive surgery” [9].

Preputial infibulation, i.e. avoiding retraction of the foreskin by generally piercing the distal part with a metal clasp or ring, was also employed as a means of controlling male sexuality since antiquity. It experienced a revival during the Victorian Era as another clinical weapon in the medical war on masturbation. Although circumcision was the most commonly employed means of preventing masturbation in the United States and Britain, infibulation was frequently employed as an alternative procedure, being used in mental institutions and orphan asylums and receiving endorsement from leading medical authorities [10].

Even vasectomy was used to treat excessive masturbation. The first use of vasectomy by the physician Harry Sharp, later a well-known protagonist of eugenic sterilization in the US, in 1899 was on a 19 year male who had complained of excessive masturbation. Following the surgery, the patient is reported to have acquired a higher intellectual level in addition to reduced masturbation [11].

All these medical theories and resulting treatments were not only focused on male children, adolescents and adults but were also adapted to female sexuality, especially masturbation and nymphomania. The most extreme example probably occurred in Victorian England when the renowned gynaecological surgeon Isaac Baker Brown (1811-1873) suggested and performed clitoridectomy for the treatment of various nervous disorders. The public dispute on his respective book “On the curability of certain forms of insanity, epilepsy, catalepsy, and hysteria in females” from 1866 finally resulted in the downfall of Baker Brown [12] (Fig. 2).

Closure of the introitus vaginae as part of “female circumcision” procedures is also called infibulation and done with the intention to alter women’s sexual activity. This procedure is still practiced in some African and Muslim cultures today.

In conclusion the widespread medicalization and pathologization of masturbation following Tissot’s publication “l’Onanisme, Dissertation sur les Maladies Produites par la Masturbation” resulted in the fact that medical doctors for the first time became increasingly engaged in issues of human sexuality. Although inglorious in many aspects this part of history must be considered as one origin of sexual medicine.

IV. SELECTED EARLY PIONEERS OF SEXOLOGY

In Europe of 19th century sexual subjects were considered taboo and repression was the main position towards them. However many scientists and thinkers brought up new ideas about sexuality during this period and in the first part of 20th century.

It is generally assumed that modern sexual medicine was founded by German psychiatrists and dermatologists. However Paolo Mantegazza (1831-1910) (Fig. 3), an Italian professor of pathology and anthropology, was probably the founder of the modern sexual medicine. Decades before the studies of e.g. Albert Moll and Havelock Ellis, he had developed experimental work and had formulated new sexual theories, founding a new science, which Mantegazza called “science of embrace”; curiously he referred to love (amore) when he was talking of sexual relation. He never used the term sexual. Besides his interest
on physiology of «nervous» states (the beginning of neurophysiology) and the action of drugs (e.g. cocaine), Mantegazza wrote about female sexuality, sexuality in children, masturbation, erectile dysfunction, vaginism, and male and female infertility. He had tried gonad transplantations in frogs and he had measured the blood flow and temperature increase during penile erection [13].

Even before Mantegazza, scientists in Europe studied sexual function without considering this as a new field of its own in science or medicine. One outstanding representative is Conrad Eckhard (1822-1905), a German physiologist from Giessen, who followed the transformation that scientific medicine underwent in the 19th century. He conducted basic anatomical and physiological research on the erection process in animals and showed that it was possible to produce an erection through electrical stimulation of the nervous structures of the brain and spinal cord. He described the “nervi erigentes” and claimed that erection did not depend only on venous congestion, the general belief at his time [14] (Fig.4).

Richard Freiherr von Krafft-Ebing (1840-1902) (Fig.5) was an Austrian-German psychiatrist. His main work was “Psychopathia Sexualis” (1886), one of the first monographies to study sexual topics as clitoral orgasm and female sexual pleasure, consideration of the mental states of sexual offenders, and homosexuality. In contrast to the popular and scientific belief at that time, Krafft-Ebing was one of the first authors to point out that homosexuals did not suffer from mental illness or perversion [15].

Through the discovery and development of psychoanalysis as an important psychotherapeutic school Sigmund Freud (1856-1939) (Fig.6) from Vienna had also great influence on sexology, and his famous “Three Essays on the Theory of Sexuality” from 1905 is considered as his boldest and most impressing contribution. According to Hartmann: “It was Freud’s intention to establish psychoanalysis not only as a part of the medical science but as a comprehensive heuristic method that should make a new and unique contribution to the understanding of the conditio humana. By its transversal approach the psychoanalysis could contribute new concepts to many fields of knowledge and performed a profound influence on literature, philosophy and forming art” [16].

The most eminent person of a group of sexologists working in Berlin before 1933 was Magnus Hirschfeld (1868-1935) (Fig.7). He founded the the
first "gay rights organization" "Wissenschaftlich-humanitäre Komitee" (Scientific Humanitarian Committee) in 1897 dedicated to the scientific study of homosexuality. In 1908 he edited the first journal for sexology "Zeitschrift für Sexualwissenschaft" in Berlin. Although this monthly journal was only published for one year, sexology was formally launched and quickly developed into an academic specialty. In 1914 Iwan Bloch and Albert Eulenburg re-started the "Zeitschrift für Sexualwissenschaft" as the official organ of the newly founded «Ärztliche Gesellschaft für Sexualwissenschaft und Eugenik" (Medical Society for Sexology and Eugenics). As they state in their preface to the journal, it intended to serve «the study of medical, natural, and cultural problems of sexology». By organizing the first "International Congress of Sexology" in Berlin in 1921, Magnus Hirschfeld initiated an international cooperation of sexologists. In 1928, he co-founded the "World League for Sexual Reform" together with Havelock Ellis and Auguste Forel. Among his many publications was one of the first comprehensive textbooks of sexology entitled «Geschlechtskunde» (Sexual Knowledge) in 5 volumes published between 1926 and 1930. Hirschfeld was also the pioneer of educational sexual movies. His most important project was the establishment of the "Institut für Sexualwissenschaften" (Institute of Sexology) in 1919. It was a place for public information and education, treatment of patients and scientific research located in the centre of Berlin. Many scientist worked at the institute, most of them like Hirschfeld himself were Jewish, e.g. Felix Abraham and Ludwig Levy-Lenz (transsexual surgery), Arthur Kronfeld (psychiatrist), and Bernhard Schapiro (first hormonal treatment of cryptorchidism). Due to the political circumstances in Germany the institute and its co-workers increasingly came under pressure. Hirschfeld left Germany in 1930 for a world tour giving lectures and studying sexology in foreign countries. He never returned to his home country. In 1933 the institute in Berlin was plundered and its library destroyed by the national socialists. Hirschfeld, according to an American newspaper "The Einstein of Sex", died in 1935 in Nice, France [http://www2.hu-berlin.de/sexology/Entrance_Page/History_of_Sexology/history_of_sexology.html][14].

Henry Havelock Ellis (1859-1939) (Fig.8), an English physician who had never practiced medicine, devoted his life to scientific studies of sexual subjects. He was a supporter of sexual liberation and was one of the first modern thinkers to challenge Victorian taboos against the open and objective discussion of sex. His interest in human biology ended on the six volume "Studies in the Psychology of Sex", published between 1897 and 1910. Those books caused a huge controversy and were banned for many years. However, it is considered a comprehensive masterpiece of human sexual biology, behaviour, and attitudes. Ellis viewed sexual activity as the healthy and natural expression of love, and he became known as a champion of women’s rights and of sex education [http://adbonline.anu.edu.au/biogs/A040139b.htm][17].

Harry Benjamin (1885-1986) (Fig.9) was born in Berlin but developed his clinical and scientific research in the USA where he moved to in 1914. His special interest was hormonal research but his main work was devoted to what he himself later described as «transsexualism». He was a pioneer in the research and in the understanding of the transsexual phenomena, treated many patients, and opened a new area of research, at a time when even wearing clothes associated with the opposite sex in public was often illegal [1].
Ernst Gräfenberg (1881–1957) (Fig. 10) was another German-born physician who emigrated to the USA during World War II. He is known for developing the intrauterine device (IUD), and for his studies on the role of the woman’s urethra in orgasm, describing the controversial female ejaculation and an erogenous zone where the urethra is nearest to the vaginal wall, which was later named the Grafenberg spot or G-spot by John D. Perry and Beverly Whipple in his honour [18].

Benjamin and Gräfenberg are prominent representatives of what could be called the American link to Europe. Having left Germany at different times and for different reasons, they both built up a career in the U.S. and were part of the medical community restarting the discipline of sexology after it’s complete destruction in Europe between 1933 and 1945.

Historically, sexually transmitted diseases (STD) are the major link between sexuality and the medical profession since antiquity and until the 20th century and were commonly addressed as venereal diseases until the 1990s. Veneris is the Latin genitive form of the name Venus, the Roman goddess of love. Social disease was another euphemism [19]. Gonorrhoea was described by the ancient Egyptians, and was recognized by Greek and Roman medical writers [19]. Syphilis was apparently brought to Europe by Christopher Columbus’ sailors on their return from America; others argue that it originated in the Old World. An archeological find of the bones of an Essex woman suggested that she had advanced syphilis, between 1300 and 1450. This would predate Columbus’ voyage of 1492 [20, 21].

In October 1495 French soldiers of King Charles VIII coming back from Naples arrived in Lyons and the soldiers suffering from syphilis were treated in the Hospitalhôtel-Dieu, which became the first French Hospital to treat syphilitic patients. This hospital had been founded in 542 and at the beginning it was a place to receive and assist the poor and pilgrims and in the middle of the 15th century it received infectious patients during some epidemic periods. For three centuries the Hospitalhôtel-Dieu tried to move away syphilitic patients and it succeeded in 1802 as the Hospital L’Antiquaille was built [22].

The prevalence and spread of these diseases was exacerbated by war and growing of the cities. By the Middle Ages both gonorrhoea and syphilis were widespread. The term syphilis was not part of the English language until 1717, following the translation of an Italian work, it was called the pox. The clap referred to gonorrhoea, from the old French word clapier, meaning a brothel. The etymology of gonorrhoea is probably from the Greek for seed low that it was assumed that the urethral discharge was semen [21].

During years both diseases were considered just one, many authors believed that the symptoms of gonorrhoea were the early stages of syphilis. This view was substantiated by the British surgeon John Hunter, who self-injected his own penis with material taken from a patient with gonorrhoea in 1767. On developing the signs of syphilis he concluded the two infections were the same, although he did not realize that the patient actually suffered from both infections at the same time [19, 21].

In 1793, Benjamin Bell, an Edinburgh surgeon confirmed that the diseases were distinct as a result of experimentation on medical students. The eminent Guy’s surgeon Sir Astley Cooper recognized
the two diseases as distinct and in 1824 he wrote in The Lancet «a man who gives mercury (a drug used to treat syphilis) in gonorrhoea deserves to be flogged out of the profession because he must be quite ignorant of the principle in which the disease is cured» [21].

In the middle of the 19th century a French physician, Philippe Ricord determined the three stages — primary, secondary, and tertiary — of syphilis. Shortly afterwards Rudolph Virchow established that syphilis was spread through the body by the blood, explaining the known cardiovascular, muscular, and psychiatric complications. At the turn of the 20th century up to a third of inmates in mental asylums were reckoned to be suffering from tertiary syphilis [19].

The main orthodox treatment for syphilis from the Middle Ages until the early years of the 20th century consisted of the application of a mercury ointment. However, during the 17th through to the 20th centuries many useless "miraculous" treatments to cure the disease had appeared to exploit the sufferers [19].

Curiously, the legendary Giacomo Casanova was said to have invented the condom, fashioned from a sheep's intestine, not as a contraceptive but as protection against syphilis. However he might have used it with this intention but condoms appear in some of the pictures of "A Harlot's Progress" by William Hogarth (1697-1764). This series of paintings was completed in 1731, when Casanova would have been 6 years old [21].

During the nineteenth century an increasing number of public health measures, usually aimed at prostitutes, were taken to prevent or control the spread of STDs. The publication in 1847 of Regulations for the repression of the excesses of prostitution in Madrid inaugurated an era of regulated prostitution in Spain. In view of the spread of prostitution and venereal diseases, police measures, and especially medical measures were both considered in the development of these regulations, which had first been proposed by the Count of Cabarrús in 1792. Although completely confidential, the new system of regulations, drawn up in 1847, set the stage for the wide-reaching regulation of prostitution that came into effect in several cities in Spain during and after the mid-19th century, and which included city residence and periodic health surveillance for prostitutes [23].

In 1861 in Italy a repressive law was passed against prostitution to reduce syphilis transmission. After the constitution of the Kingdom of Italy there began a debate on this law which was harsh on prostitutes and failed to resolve the health problem in question. In 1880, in Italy, studies were promoted under the aegis of a royal commission to understand the social situation of prostitution and the epidemic spread of syphilis. In 1888 Crispi issued new regulations concerning prostitution, prevention and therapy of infectious diseases: three years later a new regulation was established which partly restored the 1861 law [24].

In 1864 the English Parliament passed the "Contagious Diseases Act". This legislation allowed policeman to arrest prostitutes in ports and army towns and bring them in to have compulsory checks for venereal disease. If the women were suffering from sexually transmitted diseases they were placed in a locked hospital until cured. It was claimed that this was the best way to protect men from infected women. Many of the women arrested were not prostitutes but they still were forced to go to the police station to undergo a humiliating medical examination. A vociferous campaign was mounted by women's groups, civil rights activists, and members of the medical profession, and the Acts were repealed in 1886 [19, 21].

During the First World War, with a great movement of the troops, STDs became very common. USA Army lost nearly 7 million person-days and discharged more than 10,000 men because of STDs. Only the great influenza pandemic of 1918–1919 accounted for more loss of duty during that war. The STDs remained a significant threat in the early years of World War II, prompting the American War Department to embark on a massive educational and prophylactic campaign. Numerous posters were produced, warning soldiers and sailors of the dangers of excessively sexual behavior [25].

Advances against the diseases were notably improved by the discovery of their causative microorganisms. That of gonorrhoea was found in 1879 and that of syphilis in 1905. Shortly after this the German bacteriologist Paul Ehrlich announced the efficacy of Salvarsan, an arsenic-based treatment for syphilis. The development of the sulpha drugs and more potent antibiotics provided a wider range of effective drugs against these diseases [19]. The discovery that penicillin can treat syphilis has revolutionized its management [21]. With the discovery of antibiotics, a large number of sexually transmitted diseases became easily curable, and this, combined with effective public health campaigns against STDs, and the recognition of the importance of contact tracing in treating STDs a great advance was made in the control of those diseases. By tracing the sexual partners of infected individuals, testing them for infection, treating the infected and tracing their contacts in turn, STD clinics could be very effective at supressing infections in the general population [http://family.jrank].

Herpes (from the Greek, to creep) is another STD with a long history. Herodotus, a Roman physician, described cold sores in the second century, and genital herpes was first described by John Astruc, a French physician in the 18th century, Shortly
thereafter, other physicians noted that genital herpes often afflicted a patient shortly after the onset of syphilis or gonorrhea [http://family.jrank].

In the 1980s, AIDS (Acquired Immunodeficiency Syndrome) emerged into the public consciousness showing that the battle against STDs were not completely won. AIDS was first reported June 5, 1981, when the U.S. Centers for Disease Control (CDC) recorded a cluster of *Pneumocystis carinii* pneumonia in five homosexual men in Los Angeles [26]. In the beginning, the disease was called GRID Gay-related immune deficiency by the public. The CDC called it the “the 4H disease,” because the disease was prevalent in four communities Haitians, homosexuals, hemophiliacs, and heroin users. In 1982 AIDS was introduced for the first time. In this year epidemiologic data defined that contamination occurred by sexual, blood and mother-to-child transmission. In 1983 Human Immunodeficiency Virus, HIV, was aisled in Pasteur Institute in Paris [27].

**VI. ENDOCRINOLOGY: THE ROLE OF THE TESTICLES AND THE DISCOVERY OF ANDROGENS**

Ancient knowledges on testicle function: Tales and myths about aphrodisiacs and especially extracts from testicular tissue or blood were reported from ancient times up to the present. As early as 140 BC Sushruta of India advocated the ingestion of testis tissue for the cure of impotence. A vague foreshadow of the endocrine function of the testis was speculated by Aretaeus of Cappadocia (2nd till 3rd century A.D.) and more vigorously in 1775 by de Bordeu. They proposed that each organ of the body produced a substance, which was secreted into the blood to regulate bodily function [28]. On the other hand the appearance of castrates with their typical body composition and characteristics can be looked at as an interesting in vivo model of androgen depletion at all periods of history. Some of them, especially some castrati singers of the baroque period, are reported of having been actively involved in love affairs and sexual activities.

Study of sexual differentiation: It was not until the 1930s, however, that testosterone, the primary androgen responsible for male physiology and behaviour, was biochemically identified. Prior to that, many attempts were made to study the sexual differentiation of male and female individuals and to slow or reverse the effects of aging in men and to rejuvenate them. As early as 1767, John Hunter (1728-1793) (Fig.11) performed first documented testicular transplantation experiments in animals and hereby opened the door to transplantation of far more interested in the technique of grafting and tissue acceptance than the secondary effects on sex characteristics. In 1849, Arnold Berthold (1801–1863) again made the connection between male sexual and behavioural characteristics and a substance secreted by the testes and concluded that transplanted testes affect behavioural and sexual characteristics by secreting a substance into the blood stream (Fig 12). In Vienna the physiologist Eugen Steinach (1861-1944) started experiments with testicular transplantation in animals at the turn of the century in order to study the sexual differentiation and the hormonal function of the gonads [28, 29].

Rejuvenation and early “modern” organotherapy: In 1889 Charles Edouard Brown-Séquard (1817-1894) reported the rejuvenating effects of self-administered subcutaneous injections of a mixture of extracts from sperm, testicular tissue and venous blood of young and vigorous dogs and guinea pigs (Fig.13). Although based on a placebo effect, this can be considered the birth of modern clinical androgen therapy. In his theory of «autoplastic» treatment of aging Eugen Steinach (Fig.14) postulated an increased incretory hormonal production following the cessation of the secretory output of the gonads after surgical ligation of the seminal ducts. With help from the urologist Robert Lichtenstern he successfully performed this surgical procedure in a human patient for the first time in 1918, resulting in a vasectomy boom over the next two decades.
especially to counter the effects of aging in «middle-aged, listless individuals». Steinach nicely summarized the results of his scientific life in his late biography: “It has frequently been said that a man is as old as his blood vessels. One may have greater justification for saying that a man is as old as his endocrine glands.”

In the 1920’s one of the main protagonists of testicular transplantation in Europe was Serge Voronoff (1866-1951) who grafted slices of primate testis to the capsule of human recipient’s testes. He claimed to have treated 300 patients and that hormonal secretion lasted for about 1-2 years, then decreased due to fibrosis of the graft. Testicular homotransplantation had been reported earlier in very few hypogonadal patients in America by Frank Lydston in 1914 and V. D. Lespinasse in 1915. None of these was performed with vascular anastomoses.

The methods proposed by Brown-Séquard, Steinach, and Voronoff were widely popular in their time throughout Europe and North America, despite never undergoing rigorous validation. Voronoff’s grafting technique, which was enthusiastically adopted in many countries for agricultural and medical purposes, was later proved to be scientifically unfounded. Steinach’s theories were also widely popular in their time and scores of men underwent Steinach operations, including Sigmund Freud and the Irish poet William Butler Yeats. Brown-Séquard’s miraculous results were not reproducible and most likely the result of a placebo effect. Nevertheless, his report gave rise to the lucrative industry known as «organotherapy», in which extracts from a variety of animal tissues were used to treat diseases and counter the effects of aging. Organotherapy remained popular until the early 20th century, when modern endocrinology emerged as a scientific discipline [30].

**Discovery of androgens in the 1930’s:** Ernest Starling and William Hardy first coined the term «hormone» in 1905. Pezard in 1912 reported that aqueous extract of pig testes maintained the comb and wattles of the capon. 18 years later, Gallagher and Koch developed the response in the capon into a quantitative assay procedure, which was adopted with minor modifications by most laboratories as the standard assay procedure for male hormone activity. As early as 1927, Lemuel Clyde McGee demonstrated the isolation of a biologically active extract of the lipid fraction of bull testicles. In 1933 McCullagh and co-workers reported in a very elegant paper that extracts from blood, urine or spinal fluid of men by using the chick comb assay for measuring androgenic activities are useful for treatment of the male hypogonadism. The authors called the substance which is produced in the testes “Androtiln”. The magnitude of the problem faced by steroid chemists has been illustrated by the fact that labor-intensive extracts from up to 100g of testes were required for a positive result in the so-called chick comb bioassay. It is not surprising, therefore, that 15 mg of the first known androgen – androsterone – was isolated under the leadership of Adolf Butenandt (Fig.15) in his age of 28 years - from 15000-25000 liters of policemen’s urine in 1931. The name of this relatively weak urinary 5α-reduced androgen comes from “andro” = male, “ster” = sterol, and “one” = ketone. The chemical synthesis of androsterone was performed by Leopold Ruzicka (Fig.16) and coworkers 3 years later. The Japanese Ogata and Hirano – not enough acknowledged by the Europeans and Americans – found in 1934 that the androgen from the urine (Butenandt’s androsterone) is not identical with the androgen extracted from boar testes. The androgenic properties of this crystal hormone were more active than any of the testicular preparations that have been reported heretofore.
One year later, Karoly David, Elizabeth Dingemanse, Janos Freud, and Ernst Laqueur reported the isolation of the main secretion product from the testes and the main androgen in the blood, testosterone, from several tons of bull testes. The term “testosterone”, coined by this Dutch group, combines “testo” = testes, “ster” = sterol, and “one” = ketone. In the same year, the chemical synthesis of testosterone was published by altogether three groups from Germany, Netherland, and Switzerland led by Adolf Butenandt, Ernst Laqueur, and Leopold Ruzicka. Ruzicka and Butenandt were offered the 1939 Nobel Prize for chemistry for their work, but Butenandt was forced by the Nazi government to decline the honour [28, 31, 32].

Substitution therapy with testosterone:
The biochemical identification and synthesis of testosterone and other steroid hormones was a “conditio sine qua non” for the further development of modern endocrinology and the basis for a rational therapy with sexual hormones. The first years obviously implied a too generous application of this new therapeutic option especially in regard to the problem of the “Climacteric in aging male” as was hinted at by an editorial in the “Journal of the American Medical Association (JAMA)” in 1942 [33]: “Recently many reports have appeared in medical journals claiming that a climacteric occurs in middle aged men. Brochures circulated by pharmaceutical manufacturers depict the woeful course of aging man. None too subtly these brochures recommend that male hormonal substance, like a veritable elixir of youth, may prevent or compensate for the otherwise inevitable decline. What of the postulated occurrence of a climacteric in men?” In the following years systematic studies like “The male climacteric, its symptomatology, diagnosis and treatment: use of urinary gonadotropins, therapeutic test with testosterone propionate and testicular biopsies in delineating the male climacteric from psychoneurosis and psychogenic impotence” from 1944 (Fig.17) finally opened the door for modern research projects in the field of “androgen deficiency in the aging male” [34].

Societal attitudes towards same-sex relationships have varied over time and place, from strong repression until acceptance. Many times the fight for liberation of homosexuality crossed with research and studies on sexual function. The increasing scientific interest in homosexuality in the 19th century can be interpreted as one promoter for scientists, including medical doctors, to investigate medical issues and questions related to sexuality in general and by doing so creating the new field of sexology and later sexual medicine.

In many cultures sodomy has been considered as a transgression against divine law or a crime against nature. However sexual relationships among same sex have been known for thousands of years and in every continent. It was an accepted practice in Africa and Americas before the European conquerors arrived and repressed those activities. Homosexuality in China, has been recorded since approximately 600 BC. In Japan it has been documented for over one thousand years and was an integral part of Buddhist monastic life and the samurai tradition. Similarly, in Thailand, has been a feature of Thai society for many centuries, and Thai kings had male as well as female lovers.

Throughout most of the history of ancient Israel, intercourse between males was condemned outright as an «abomination» and Mosaic Law demanded the death penalty for those men who «lie with a man as with a woman». In Greece male homosexuality was part of a normal man’s love life, besides the heterosexual relationships. Plato praised its benefits in his early writings but in his late works proposed its prohibition [35]. In Crete homosexuality was, according to Aristotle, officially supported as a “population control tactic” [36].

(Fig.17) Elevated gonadotropins in “Male Climacteric” reported in JAMA 1944.
In Ancient Rome there were common relationships between older free men and slaves or freed youths. Many Roman emperors had male lovers. Christianity followed the Hebrew tradition of condemnation of male sexual intercourse and certain forms of sexual relations between men and women, labeling both as sodomy [37]. In the year 528, the emperor Justinian I, responding to an outbreak of pederasty among the Christian clergy, issued a law which made castration the punishment for sodomy.

During the Renaissance, Florence and Venice were famous for their widespread practice of homosexual love. However, at that time, the authorities, under the aegis of the Officers of the Night court, were prosecuting, fining, and imprisoning a good portion of the homosexual practitioners. In the Europe of the 17th and 18th century repression had gained strength and executions for sodomy continued in the Netherlands until 1803, and in England until 1835.

Between 1864 and 1880 Karl Heinrich Ulrichs published a series of twelve books, entitled “Research on the Riddle of Man-Manly Love”. In 1867 he became the first self-proclaimed homosexual person to speak out publicly in defense of homosexuality when he pleaded at the Congress of German Jurists in Munich for a resolution urging the repeal of anti-homosexual laws. “Sexual Inversion” by Havelock Ellis, published in 1896, challenged theories that homosexuality was abnormal, as well as stereotypes, and insisted on the ubiquity of homosexuality and its association with intellectual and artistic achievement [38]. Magnus Hirschfeld created the Scientific Humanitarian Committee, which campaigned from 1897 to 1933 against anti-sodomy laws in Germany. Richard Freiherr von Krafft-Ebing probably was one of the first heterosexual professionals to see homosexuals as normal people with a different sexuality [39].

In the 1950s in the United States, homosexuality was taboo and many politicians treated the homosexual as a symbol of antinationalism. Senator Joseph McCarthy used accusations of homosexuality to stigmatize his opponents. Although there is societal tolerance to homosexuality, in 2001, 51% of the general public declared that «homosexual behavior» was morally wrong.

Homosexual relationships were decriminalized in many European countries such as Poland in 1932, Denmark in 1933, Sweden in 1944, and the United Kingdom in 1967, but a turning point was reached in 1973 when the American Psychiatric Association removed homosexuality from the Diagnostic and Statistical Manual of Mental Disorders, thus negating its previous definition of homosexuality as a clinical mental disorder [40]. In 1977, discrimination based on sexual orientation was prohibited for the first time in Canada, extended to many other countries during the 1980s. However, many countries today in the Middle East, Africa, Asia, the Caribbean and the South Pacific, outlaw homosexuality. In six countries, homosexual behavior is still punishable with life imprisonment and in ten with death penalty [http://www.ilga.org/statehomophobia/World_legal_wrap_up_survey_November2006].

VIII. CONTRACEPTION

Contraceptive methods have a long history and different levels of societal acceptance, depending upon cultural, religious, and political background.

Prehistoric societies had a slow population growing although they had total fertility rates of 4 to 6 [41]. Approximately half the children who were born died before they could reproduce. Furthermore puberty was in the upper teens, babies were breastfed for 3–4 years, which spaced pregnancies. With the first urban civilizations and settled agriculture, puberty began at an earlier age and breastfeeding was often shortened or supplementary food introduced earlier than in primitive societies. This increased the rate of fertility. Nowadays if a couple initiates sexual intercourse when the woman is 20 years old or younger and continues at least until her menopause, without artificially limiting fertility, she can expect to conceive and carry to term an average of 10 live-born children [42, 43]. Sooner or later, all human societies have to adopt restraints on family size [43].

There are references of contraceptive methods in many historical records [43]. Written records survive from the Egyptian Ebers Papyrus (1550 BC), the Latin works of Pliny the Elder (23–79 AD) and Dioscorides (De materia medica, c. 58–64 AD), and the Greek writings of Soranus (Gynecology, c. 100 AD). During the flowering of Arabic medicine in the 10th century, a variety of contraceptive recommendations were detailed, particularly in the works of Al-Razi (Razes, d. 923 or 924 AD, Quintessence of Experience), All ibn Abbas (d. 994 AD, The Royal Book), and Avicenna (Ibn Sina, d. 1037 AD) [43].

The evidence of ancient contraceptive knowledge, methods of birth control which are used before conception, is very large. A list of contraceptive methods include: withdrawal by the male (coitus interruptus); melting suppositories designed to form a barrier over the cervix; diaphragms, caps, or other devices which are inserted into the vagina over the cervix and withdrawn after intercourse; intrauterine devices; douching after intercourse designed to kill or drive out the sperm; condoms; and varieties of the rhythm methods. The main new acquisition was the birth control pill introduced in 1960 [43].

It were the ancient Greeks who first realized that male and female union caused pregnancy and since then many contraceptive methods have been used
with varying degrees of success. Probably the oldest methods of contraception (aside from abstinence of vaginal intercourse) are coitus interruptus, lactational, certain barrier methods, and herbal remedies [44].

There are historic records of Egyptian women using a pessary (a vaginal suppository) made of various acidic substances and lubricated with honey, oil or beeswax, which may have been somewhat effective at killing sperm or blocking its passage through the female genital tract [http://www.mnsu.edu/emuseum/prehistory/egypt/dailylife/midwifery.htm]. However, it is important to note that the sperm cell was not discovered until the late 17th century, so those methods were completely empiric at that time.

Another kind of pessary was a solid object to block the cervix. This method was popular in pre-industrial societies, especially Africa; here women used plugs of chopped grass or cloth. Balls of bamboo tissue paper were used by Japanese prostitutes, wool by Islamic and Greek women, linen rags by Slavic women. The sponge used by Ancient Jews was considered the most effective contraceptive in use until the development of the diaphragm. The sea sponge was wrapped in silk with a string attached [45].

During the 2nd century A.D., Greek gynecologists advised women to spread substances such as ginger or olive oil around the vagina to prevent pregnancy [45].

Coitus interruptus, where man withdraws his penis before the ejaculation, was practiced in Africa, Australasia, the Middle East, and in Europe. Though condemned by Judaism and Roman Catholicism, its practice was common enough in Medieval Europe and later [42].

Coitus obstructus was a method recommended in several Sanskrit texts which required pressing on the urethra on its scrotal part; the pressure could prevent semen flow through the urethra forcing it into the bladder. Coitus reservatus is a method whereby the male avoids ejaculation entirely. This method was used by the Hindus [43].

The rhythm methods (based on calculating the woman’s fertile period and abstaining from intercourse during it) have been used since the 19th century. However the female fertility cycle was completely understood in 1920. Before that time it was common believe that ovulation occurred either during menstruation or just before it, which made this a very ineffective contraceptive method earlier on [43].

Condoms had been known since the 17th century and were made from animal intestines. Initially it was fully advocated in campaigns against sexual transmitted diseases, but in the 1920’s and 1930’s it was the second contraceptive method used in USA, after coitus interruptus [43]. Leather and linen versions were used early on. By the start of the 19th century, condoms were openly sold in drugstores, pubs and other businesses throughout the world. In 1844, rubber was invented, and condoms were able to be mass-produced for the first time, making them accessible to a wider population [43].

At the beginning of 19th century female barrier methods were well established. In 1838, in Europe, Wilde proposed the cervical cap and later Mensinger advised a diaphragm without spermicide. By 1915, Rutgers proposed the use of diaphragms with spermicides and individual fitting by a physician [43].

At that time, attempts were made to block the cervix with metal pessaries. The devices required an intra-uterine portion to hold them in place, and sometimes they broke, when it was noted that they still acted as successful contraceptives. In 1909, Richter, in a German medical journal, described a flexible ring made of silk that he placed in the uterus of women seeking contraceptive help. By 1923, Proust claimed to have distributed 23,000 intrauterine devices (IUDs). At about the same time, Grafenberg presented IUDs of silk and later of silver wire [46].

The biologic possibility of imitating early pregnancy to inhibit ovulation was well understood by the Austrian physiologist Haberlandt when he published a series of papers, beginning in 1921, on what he called “hormonal sterilization.” Ovaries from pregnant does were transplanted into nonpregnant rabbits, rendering them infertile for several months. By 1927, Haberlandt was exploring the possibility of oral contraception, and he collaborated with a pharmaceutical firm in Budapest to produce a preparation called “Infecundin” [43].

In 1959, the first hormonal birth control pill, “Enviod”, was approved by the FDA for contraception. Though very effective, this early birth control pill produced major side effects, such as blood clots and high blood pressure. By the 1980s, low dose pills were widely available with fewer side effects and high efficacy. In the 1990s, the “Depo-Provera” hormone injection was created, and was able to prevent pregnancy for several months at a time. In 1999, the FDA approved “Plan B” (the morning after pill) for sale by prescription only. This emergency contraceptive gives women the chance to prevent pregnancy after having unprotected sex, and can be used as a backup if contraception methods fail. By 2003, “Plan B” was available over-the-counter throughout the U.S.A [47].

Sir Astley Cooper experimented with vasectomy in dogs in 1830. Harrison recommended the operation as a cure for enlarged prostate in 1889. Male medical sterilization was first carried out in Indiana in 1899 and spread in the USA until 22 states had sterilization laws in 1929 based on genetic and eugenic indications. In the same year, Switzerland was the first country in Europe with a sterilization
law; Denmark introduced a test law which became final in 1935. Between 1933 and 1945 the totalitarian regimes used forced sterilization for genetic diseases and on undesired races. Only in the 1950’s family planning was introduced as a basis for male sterilization, initially in Asian countries [11].

Tubal ligation for female sterilization was first proposed by Blundell in 1823 in London. Lungren was the first to ligate a woman’s tube in 1880 in Toledo, Ohio, USA. In 1936 in Switzerland, Bosch performed the first laparoscopic tubal occlusion as a method for sterilization. Prior to the 1960s, female sterilization in the United States was generally performed only for medical indications (when additional pregnancies would be hazardous to the mother). Many centers used a formula (endorsed by the American College of Obstetricians and Gynecologists until 1969) in which age multiplied by parity had to be greater than or equal to 120 before elective sterilization could be considered [48, 49].

Infanticide, the killing of newborn babies, was the most universal solution to periodic overpopulation in pre-industrial societies. It was used to control population and, at times, the sex ratio where the sexual division of labor dictated. Some groups practiced infanticide because, in the absence of medical techniques, it was less risky and painful than abortion. Among some Australian tribes and among the Cheyenne and other Northern Plain Indians, infanticide was practiced so the tribe could maintain its mobility. The Pima of Arizona practiced infanticide when a child was born after the death of its father—thereby relieving the mother of the added economic burden [45]. It is significant to note that infanticide was not just a ‘primitive’ practice; Aristotle and Plato recommended it for eugenic reasons. And if infanticide is not acceptable today, it may be because we have better birth control methods [45]. Infanticide and abortion were considered criminal practices during the 18th and 19th centuries and their practice is documented in the transcripts of trials and in newspapers. This evidence suggests that both practices were widespread. Three cases of infanticide have been found reported in the Maryland Gazette on one day in 1761 [45].

Women have wanted to abort undesired pregnancies since ancient times. A standard method of inducing abortion (ancient and modern) is the abortifacient or potion. Abortifacients are part of a folk culture of herbal medicine handed down among women for thousands of years. In German folk medicine mar-joram, thyme, parasely and lavender in tea form were used. The root of worm fern was used by German and French women and was also prescribed by a Greek physician in the time of Nero; in French it was called the “prostitute root”. Other ancient recipes called for a paste of mashed ants, foam from camels’ mouths, tail hairs of blacktail deer dissolved in bear fat. In modern times, women have been reported to use turpentine, castor oil, tansy tea, quinine water in which a rusty nail has been soaked, horseradish, ginger, epsom salts, ammonia, mustard, gin with iron filings, rosemary, lavender, and opium [45, 50].

Aside from internal abortifacients, women have attempted external methods such as severe exercise, heavy lifting, climbing trees, hot baths, jumping and shaking. As late as the 20th century, Jewish women of the Manhattan Lower East Side attempted to abort by sitting over a pot of steam (or hot stewed onions), a technique described in an 8th century Sanskrit source [50].

The majority of women before the 19th century and many in the 19th century did not consider abortion a sin. Until the early part of the century, there were no laws against abortions done in the first few months of pregnancy. Prior to the 19th century, Protestants and Catholics held abortion permissible until ‘quickening”—the moment the fetus was believed to gain life [45].

Massage abortion is a technology that has been described in Burma, Thailand, Malaysia, the Philippines, and Indonesia. The procedure is usually attempted when the woman is 12–20 weeks pregnant. She lies on her back with her knees drawn up and the traditional birth attendant attempts to fix the uterus and then presses as hard as possible with her fingers, the heel of her bare foot, or even the wood pestle used to grind rice. This practice still occurs tens of thousands of times a year in this part of Asia [51].

A number of methods were available for performing abortion in the 19th century. The operation of dilation and curettage was established and, as early as 1863, Simpson described a procedure for “dry cupping” the uterus. Today it would be called vacuum aspiration. Vacuum aspiration using a hand-held syringe and a flexible plastic cannula was first described by Karman and Potts in 1972 [52].

The acceptance of a contraceptive behavior (which included contraceptive methods, abortion techniques and sometimes infanticide) over time depended upon cultural, economical and religious background. Abortion has not always been seen as a sin or a crime. It presented an easier moral problem for the ancients than today, because they assumed that life started after birth. In the Roman Empire there was an incentive to have small families. The custom that required the equal division of the estate among one’s children was the main reason usually advanced to explain why Roman families were so small. Even the intermittent attempts of the state to encourage population growth proved futile [36].

Christianity propagated the idea that the child was sent by God and, unlike other religions, made few
concessions to the social realities that justified the avoidance of pregnancy. If one had too many children it had to be viewed as a cross to bear [36].

Some idea of Medieval attitudes towards contraception can be obtained from the Penitentials—the religious compilations used by many priests as a framework for their work in the confessional. Sexual sin exceeded all others in the Penitentials. Noonan has categorized the sexual content of Penitentials from the 6th to 11th century. A nocturnal ejaculation warranted 7 days’ fasting, while contraception, fellatio, and anal intercourse attracted penances from 3–15 years. Religious records are supplemented by civil cases from 14th and 15th century Venice. Men guilty of homosexual anal intercourse were being burned alive between the Columns of Justice in St. Mark’s Square. But anal intercourse in marriage was also sometimes prosecuted with exile for a few years. Ruggiero concluded anal intercourse was a form of birth control that was practiced by some people at every social level, from nobility to humble fishermen. In the Penitentials, the punishment for abortion was sometimes less than that for contraception and was similar to that for coitus interruptus, although St. Jerome was particularly uncharitable in describing women who died from attempting an abortion as a “threefold murderess: as suicides, as adulteress to their heavenly bridegroom Christ and as murderess of their still unborn child” [53, 54]. In 1557, Henri II declared that any concealed pregnancy that ended with the death of the child would be presumed to be murder. A similar statute was passed in England in 1624 [36].

By 1860, the U.S. had banned all abortions except those deemed necessary to save a woman’s life. In 1873, Congress passed the Comstock Act, which made any and all forms of contraception illegal. The ban also prohibited anyone from providing information about birth control or abortion. In 1918, a woman named Margaret Sanger was charged under this Act with providing information on contraceptive devices. She appealed and won, with the courts finding that contraception was necessary to protect a woman’s health. Sanger would go on to found Planned Parenthood in the 1930’s [36, 43].

Based on Sanger’s victory and other challenges, the Comstock laws were repealed at both the state and federal levels during the 1930’s. It took another 40 years before women won the right to choose abortion as a method of contraception. From 1860 to 1973, abortion was illegal in the U.S., with few exceptions. The landmark Supreme Court case of Roe v. Wade in 1973 found that laws prohibiting abortion were unconstitutional. This ruling gave women the right to choose abortion in the U.S. freely within the first trimester [36].

By the 1980s, something like 90 per cent of married couples in most western countries were employing contraceptives. An international survey of contraceptive users found that 33 per cent had been sterilized, 20 per cent employed the oral contraceptive, 15 per cent the IUD and 10 per cent the condom [36].

IX. MALE SEXUAL DYSFUNCTION

The crucial function in male sexuality is penile erection. Besides different forms of ejaculatory disorders, penile deformities and other hypoactive and hyperactive sexual dysfunctions, the male erection has always been of main interest in medicine and therefore the below overview will concentrate on this aspect [14, 55, 56].

Early physiology and pathophysiology of male erection:

In “De aëre aquis et locis” Hippocrates (5th-4th century BC) described the high incidence of impotence and infertility in the people of the Scythians and explained it by continuous perineal trauma due to excessive horse riding. Aristotle (384 till 322 BC) - like the other Greek authors - outlined the physiological concept of “pneuma” (= wind, air) as the initiator of erection.

In respect to Arabian medicine the famous Avicenna (980-1037 AD) - also known as Abu Ali al-Hussein Ibn Abdallah Ibn Sina or “Medicorum princeps (Prince of Physicians)” – was perhaps rather a philosopher than a physician. Although his notes on anatomy and physiology of the genital tract are full of errors he was a very subtle observer of human sexual behaviour, especially when writing about the difference between male and female orgasm.

Leonardo da Vinci (1452-1519) – the great artist and genius of the Renaissance - can not only be considered as the founder of modern medical illustration but was also the first author to describe the increased blood inflow to the penis as the cause of erection. He drew this conclusion from his own observations and dissections in human corpses.

Although the “Musculi erectores penis” (i.e. Mm. bulbospongiosi and ischiocavernosi) had already been described by Galen in the 2nd century AD, this knowledge was lost at the time of Costanzo Varolio (1543-1575), who re-discovered them and gave an astonishingly correct description of the mechanisms of erection.

The book “De la generation de l’homme” (On the generation of man), written by the master of French Renaissance surgery Ambroise Paré (1510-1590) in 1573, constitutes a real guide to good sexual practices. In this book Paré described in very vivid language and with many details how to perform sexual intercourse to ensure the greatest chances of fertilization and moreover how to diagnose
pregnancy, how to follow pregnancy and finally how to conduct delivery.

In his “Tractus de virorum organis generationi inservientibus, de cysteribus et de usu siphonis in anatonia” (1668) the Dutch physician Regnier de Graaf (1641-1673) (Fig.18) succeeded in causing an erection in a corpse by injecting water into the hypogastric artery. At that time a very meaningful example of experimental science.

Although the “Nodus penis” had been described centuries before, Francois de LaPeyronie (1678-1747) gave the first extended clinical report on the disease named after him in his article “Sur quelques obstacles qui s’opposent à l’éjaculation naturelle de la semence” (On some obstacles to the natural ejaculation of the semen) from 1743. In his opinion the plaque was predominantly caused by venereal diseases.

The famous surgeon and anatomist John Hunter (1728-1793) (Fig.19) from London is well-known for his contributions on venereal diseases, the prostate and urethral strictures. He also dedicated an interesting chapter on impotence in his book “A Treatise on the Venereal Disease” (1786) in which he clearly defined an impotence depending on the mind and an organic impotence as “from want of proper correspondence between the actions of the different organs”.

In 1863 the German physiologist Conrad Eckhard (1822-1905) (Fig.20) from Giessen published his results on animal experiments inducing penile erections by applying electrical stimulation at different levels of the nervous system (also see above). More detailed contributions on the neurophysiology of erection were made by J.N. Langley and H.K. Anderson from England in the mid 1890’s.

**Conservative treatment:**

Aphrodisiacs have been adopted for the treatment of all kinds of sexual dysfunction since ancient times and are still in use in our days.

In 1896 the chemist Leopold Spiegel (1865-1927) from Berlin performed chemical characterization of yohimbine from the bark of the African yohimbe tree. He was well aware of the aphrodisiac effect that the bark was said to have in its country of origin and clinical application followed immediately in Europe.
Spiegel patented his chemical discovery in the UK in 1900 and this resulted in a more than 100 years story of oral drug treatment of erectile dysfunction especially in psychogenic and mild organic disorders.

The essay with the remarkable title “Über die allgemeinste Erniedrigung des Liebeslebens (The most prevalent form of degradation in erotic life)” was published in 1912 and is one of the few publications in which Sigmund Freud (1856-1939) (Fig.21) deals directly with male erection disorders. Here he introduced the term “psychical impotence” into his writings and stressed the high prevalence of this condition which is manifested by “a refusal of the sexual organs” to execute the sexual act [16]. Historically, there was a certain negative impact of Freudism through the resulting focus on a psychogenic understanding of sexual dysfunction. Especially in erectile dysfunction organic concepts of pathophysiology as well as new approaches of somatic therapy were inhibited for many decades.

The first milestone in effective medical treatment of severe organic erectile dysfunction was the intracavernous injection of vasoactive drugs. By accident the French vascular surgeon Ronald Virag from Paris discovered the proerectile effect of papaverine during a revascularization surgery of the penis and suggested therapeutic injection into the corpus cavernosum in 1982.

One year later Giles S. Brindley reported a list of experiments where he described the possibility of getting an efficient erection through what he called “cavernosal alpha-blockade”. He reported that large doses of oral phenoxybenzamine caused penile tumescence that lasted for 24 to 48 hours. He also produced erections with parenteral and penile injection of phentolamine and phenoxybenzamine. He proposed the therapeutical use of intracavernous injection for patients with erectile dysfunction and he stated that intracavernous injection could be a diagnostic tool; he believed that a good response could rule-out a vascular cause, but not a neurogenic one. Brindley also made history with his dramatic presentation of the effect of intracavernous injection of the alpha-receptor antagonist phenoxybenzamine into his own penis at the 1983 meeting of the American Urological Association (AUA) [57].

Finally, Adrian W. Zorgniotti from New York introduced drug combination of papaverine and phentolamine in 1985 [58].

With his biochemical research, as outlined in the paper “Fractionation and characterization of a cyclic adenine ribonucleotide formed by tissue” from 1958, the American Earl W. Sutherland (1915-1974) discovered the physiological significance of cyclic nucleotides in the regulation of cell and tissue function. This basic knowledge – for which he was awarded the Nobel Prize in Medicine and Physiology in 1971 – was fundamental for the understanding of the first effective oral treatment of erectile dysfunction with PDE-5-inhibitors at the end of the 20th century.

Vacuum constriction devices:
The curative application of negative pressure to different parts of the body was well established in 19th century medicine. The American physician John King was the first to suggest a continuous and repeated application of a vacuum device to the penis for the cure of impotence in 1874. Finally, the Viennese physician Otto Lederer (1872-1944/45) made the significant improvement of adding a compression ring to the use of the vacuum device to facilitate an on-demand erection in 1913 (Fig.22); long before Geddings D. Osbon constructed his modern device in 1960.

Surgical treatment:
Ambroise Paré (1510-1590) suggested an “artificial penis” made of a wooden pipe or tube for patients after traumatic penile amputation in order to facilitate a proper micturition in the standing position. Although not intended for sexual activities one might call this device a 16th century “penile prosthesis” as per definition a prosthesis – in contrast to an implant - replaces the whole organ or part of the body.

In 1873 the Italian physician Francesco Parona (1842-1907) injected the varicous dorsal penile vein of an impotent young patient with hypertonic saline in order to cause sclerosis and by this reduce the excessive venous outflow. More then two decades after this first case report several American doctors started performing surgical dorsal vein ligation or resection as e.g. Frank Lydston in 1908.

Since the early 1930’s Oswald S. Lowsley (1884-1955) (Fig.23) from New York was the main protagonist of surgical treatment for corporovenoocclusive dysfunction. He combined simple dorsal vein plication with a surgically more advanced perineal crural technique in which he plicated the...
bulbocavernous and ischiocavernous muscles with several mattress sutures.

The first penile implant to facilitate an erection was used in a phalloplasty procedure performed by the Russian surgeon Nikolaj A. Bogaraz (1874-1952) (Fig.24) in 1936. He used the patient's rip cartilage and in later years he even performed this operation in patients with morphologic intact penis but suffering from erectile dysfunction [59].

In 1948 the French surgeon René Leriche (1879-1955) (Fig.25) firstly mentioned arterial vascular impotence in thrombotic obliteration of the aortic bifurcation, a syndrome he had already described in detail in the 1920's and which today is named after him. During the following time several strategies were outlined to save or reconstruct the internal iliac artery during abdomino-pelvic vascular surgery to maintain or restore erectile function.

In 1973 Václav Michal from Prague reported the first microsurgical treatment of vascular erectile dysfunction by performing a revascularization with direct anastomosis of the inferior epigastric artery to the corpus cavernosum. He was one of the first researchers to observe that failure of the hemodynamics of erection played an important role in the pathogenesis of impotence in many patients. He also discussed the use of phallo-arteriography with saline-filled erection to visualize the proximal arterial disease. In the 1980's further techniques were introduced later by Michal himself, as well as by Ronald Virag from Paris and Dieter Hauri from Zurich.

The very breakthrough of penile implant surgery was initiated by F. Brantley Scott (Fig.26) from Houston, Texas, together with his colleagues William E. Bradley and Gerald W. Timm when they implanted the first silicone inflatable device on February 2nd, 1973.
This was one of the first effective treatments of erectile dysfunction. The authors were very imaginative for that time, describing a completely new concept, instead of rods, using inflatable cylinders which could be filled – on the man’s demand – through pressing a pump positioned subcutaneously in the scrotum, transferring the fluid from a reservoir implanted in the Retzius space to the cylinders promoting penile rigidity. This device – the basis of the modern ones - had had an extraordinary evolution since this publication in 1973. Scott is also recognized for the creation the urinary artificial sphincter which revolutionized the treatment of urinary incontinence [60].

Alfred Kinsey:

Alfred Charles Kinsey (1894–1956) can be considered the pioneer in the quantitative and epidemiologic study of human sexuality collecting sexual histories from a large number of men and women, resulting in a final sample of around 18,000. His interest in human sexuality fortuitously began when in 1938 he was responsible for a course on marriage at the University of Indiana and found that little survey research was available on human sexuality. In 1941, Kinsey obtained a grant from the “National Council’s Committee for Research in the Problems of Sex”, which was at the time funded by the Rockefeller Foundation. He assembled a multidisciplinary research team that included Clyde E. Martin, a student assistant who became a research associate; Wardell B. Pomeroy, a clinical psychologist; and Paul H. Gebhard, an anthropologist. Kinsey and his colleagues established the “Institute for Sex Research” in 1947 as a separate, nonprofit organization.

Kinsey published «Sexual Behavior In The Human Male» in 1948, which came to be known as the «Kinsey Report». It sold more than 250,000 copies and was translated into a dozen languages. In 1953 the Institute published "Sexual Behavior In The Human Female", which also sold more than 250,000 copies and was translated into several languages. These two reports sharply challenged many myths about sexual behavior in American society and revealed findings on various previously taboo topics, such as extramarital sexuality, homosexuality, bisexuality, oral sex, masturbation, and prostitution. Only relatively few male individuals with erectile dysfunction were analyzed. Although those studies were devoted only to white, young Americans they contributed strongly for the change of sexual behaviour in the USA in the second part of the 20th century. Despite the wide-spread acceptance of the scientific study of sexuality in U.S. society, conservative forces continued to attack the work pioneered by Kinsey as well as on-going studies by the Institute for Sexual Research, which resulted in the suspension of the research grants and ended up the work [http://www.pbs.org/wgbh/amex/kinsey/peopleevents/p_kinsey.html] [1].

X. SEXUAL MEDICINE AS A TRUE SPECIALITY AFTER WORLD WAR II

After World War II and mainly after Kinsey’s reports the field of Sexual Medicine experienced a fast development. It is impossible to cover all the individuals who contributed to that research, but four of the early pioneers from the 1950’s and 1960’s should be cited in detail.

F. Brantley Scott (portrait and illustration of first inflatable penile implant from 1973)
Giuseppe Conti:
The Italian anatomist Giuseppe Conti from Padua was a pioneer in scholarly research into erectile function. His seminal report “L’erection du penis humain et ses bases morphologico-vasculaires” (The erection of the human penis and its morphologic-vascular basis) was published in 1952 and represents one of the earliest attempts to scientifically and precisely characterize penile hemodynamics and structure as they relate to the phenomenon of erection.

Conti found that the penile arteries contained areas of subintimal longitudinal smooth muscle that protruded into the lumen. Busche referred to these structures as “Polsterkissen”; i.e. cushions or polsters near branch points of the deep penile artery. Based on composition and location Conti postulated that these structures permitted selective shunting of arterial blood to either “nutritive” arteries or anastomotic arteries that communicated with the cavernous spaces. Depending on their opening or closing an erection or detumescence would result. This theory persisted until 1980. Counter to his contemporaries, Conti proposed that rather than a single mechanism, a number of events are responsible for penile erections. Specifically, he hypothesized that the interplay of arterial inflow with the shunting of blood into the corpora cavernosal spaces and the obstruction of venous outflow resulted in the engorgement of the penis [61].

James Semans:
James H. Semans (1910-2005), a Duke University surgeon and urologist combined a career as a leading medical scientist and physician with a passion for the arts and charitable causes. He was a pioneer in rehabilitative and urinary surgery.

The cultural climate of the southern United States in the immediate period after World War II was quite reserved and conservative, not in a political sense, but in a social sense. Deeply religious and very homogeneous the south was not progressive in any sense, particularly when it comes to sexual matters. In this environment Semans published in 1956 a classical article on the treatment of premature ejaculation. He was the first to describe a direct, behavioral treatment for premature ejaculation, the stop-start technique.

This article is one of the first major open discussion of the behavioral issues surrounding sexual dysfunction to appear in the literature. For the first he pointed out that premature ejaculation could lead to erectile dysfunction. The paper consists of an observational series of cases, each discussed individually which together form the basis for a recommend technique to decrease the stimulation leading to a retarded ejaculation [62].

William Masters and Virginia Johnson:
William Howell Masters (1915-2001) was one the first to study the anatomy and physiology of human sexuality in the laboratory, and the publication of the reports on his findings created much interest and criticism. Since then, he and his colleague and wife, Virginia Eshelman Johnson (born 1925), have become well-known as researchers and therapists in the field of human sexuality, and together they have established the Reproduction Biology Center and later the Masters and Johnson Institute in St. Louis, Missouri.

In 1954 Masters started his research on human sexual response. He was concerned that the medical profession had too little information on sexuality to understand clients’ problems. As Kinsey had based his research on case histories, interviews, and secondhand data, Masters decided to study human sexual stimulation using measuring technology in a laboratory situation.

In 1956 he hired Virginia Johnson, a sociology student, to help in the interviewing and screening of volunteers. The study was conducted over an eleven-year period with 382 women and 312 men participating. Masters and Johnson described a four-phased cycle relating to male and female sexual responses. To measure physiological changes, they used electroencephalographs, electrocardiographs, color cinematography, and biochemical studies. They estimated that they had observed «10,000 complete cycles of sexual response». Their findings about female sexual arousal described the mechanisms of vaginal lubrication and orgasm and proved that some women were capable of being multiorgasmic.

In 1966 Masters and Johnson published “Human Sexual Response” and in 1970 “Human Sexual Inadequacy”, where they discussed sexual problems such as impotence [14].

Epilogue
Around 1970 many physicians were dealing with issues of sexual medicine and the term itself and it’s modern definition became established in the medical community, as has been outlined in the introducing chapter on terminology of this article (see above). Several societies had already been or were about to be founded in the field of sexology at that time [7]. A key event for the formation of another important society was the “First International Conference on Corpus Cavernosum Revascularization” in New York in October 1978. Adrian W. Zorgniotti, a visionary urologist from the Cabrini Medical Center in New York, identified and invited experts on vasculogenic impotence from all over the world for this meeting. From the subsequent activities and meetings of this group arose the “International Society of Impotence Research” (ISIR), that later opened it’s arms to other
specialities as e.g. psychiatrists, psychologists, gynecologists, general practitioners to be renamed as the "International Society for Sexual Medicine" (ISSM). This evolution has been outlined in detail in a recent article by Lewis and Wagner [63].

I. GENERAL INTRODUCTION

Epidemiological data are the basis for assessing the impact of a condition on a given society. The two components of epidemiology, descriptive epidemiology (incidence and prevalence by persons, place and time) and analytical epidemiology (the search for disease or condition risk that may serve to increase prospects for prevention) are the main components for this chapter, in addition to defining the sexual disorders in women and men. Incidence is defined as the number of new cases with a certain condition during a specific time period in relation to the size of the population studied. Prevalence characterizes the proportion of a given population that at a given time has the condition. Therefore, it is important that epidemiological studies are reasonably valid, and particularly that they cover representative samples. In case of sexual dysfunctions, incidence and prevalence are usually measured using self-reports. Lack of consensus in definition of the condition and in scaling does, however, lead to considerable problems for comparing incidence and prevalence of sexual conditions described in different investigations. Different methodological rationales, such as the time period studied (1 month, 3 months, 6 months, 1 year, life-time), different age strata included and (self-) selection biases are other problems in comparative analysis. Some reports included only one particular sexual dysfunction, most prominently for studies of erectile dysfunction, while some include different conditions in both genders, making it possible to perform cross-gender epidemiological calculations. This heterogeneity in the literature means that we are often unable to disentangle true population effects from differences in reported prevalence that are simply due to inconsistent use of definitions. For example, where researchers follow DSM-IV definitions [1] then only persons who experience both sexual dysfunction per se and sexual distress are classed as having a sexual dysfunction. [2-4] Studies that only measure sexual function per se are likely to report higher prevalence estimates compared to studies based strictly on DSM-IV definitions. Those reading the literature might erroneously conclude that the higher prevalence is due to population differences when in fact a large part of the difference in prevalence may simply be due to the inconsistent use of definitions.

Thus, a uniform nomenclature including categorizations as well as quantifications is necessary in order to pave the road for valid and reliable: 1) comparative studies between nations and regions 2) identification of risk factors/co-morbidities 3) primary and secondary preventions and 4) evidence based interventions.

A major thrust of this and the last [5] consultation was to use evidence based medicine standards for inclusion of material analysed and cited. [6] For the summary of descriptive epidemiology, this committee has adhered to the classification of epidemiological validity described by Prins et al [7], who identified 15 dichotomizable (yes/no) points for being recognized as valid from the prevalence or incidence point of view (see Table 1). In this chapter only nationally or regionally representative studies published in peer-reviewed journal or in books, and judged to be at least reasonably valid, i.e. reaching at least 10 of 15 possible yes-answers on the Prins et al assessment, are included. Articles cited in the analytical section are mainly scored 10 or higher using the evidence based criteria. [6]
**Recommendation 1:**

In rating level of evidence for epidemiological studies, there is probably a need to expand the point allowed for percentage of responders. The current score of 1 for percentage of 70% or greater is probably too narrow for modern epidemiological studies. We may wish to have more flexibility for this point such as maximum points for 70% and greater, mid-range for 40-70%, low-range for 20-40%, and subtraction point for those with response rate of less than 20%. **Grade C.**

---

**II. INTRODUCTION TO DEFINITIONS OF SEXUAL DYSFUNCTIONS**

At present, the two most widely used sets of definitions of sexual dysfunctions are those given by the World Health Organization (WHO), 1980 [8] in the ICD-10, and by the American Psychiatric Association, (DSM-IV) in 1994. [1] In sexual medicine, the ICD-10 has mainly been used within somatic care and the DSM-IV psychological/model. Both sets of definitions are mainly built upon the physiological model of genital...
responses and symptoms disturbing coital intercourse first described by Masters and Johnson [9]; later modified by Kaplan. [10] Both sets add to the sexual response “cycle” in which, for women, vaginismus is included. Both sets regard sexual dysfunctions (ICD-10)/disorders (DSM-IV) as involving combinations of physical and psychological constituents but believe it possible to separate these.

A basic feature of the ICD-10 definitions is that sexual function per se is defined as the various ways in which an individual is able to participate in a sexual relationship as he or she wishes. The ICD-10 uses definatory categories, which are sub-categorized into organic (N-series) and non-organic (F-series) dysfunctions; but several inconsistencies are built into the system. For example, female arousal disorder is included in the ED-definition. The ICD-10 does not include delayed ejaculation as a category by itself, presumably regarding retarded ejaculation as equivalent to lack of orgasm.

The DSM-IV has two defined (A and B) categories describing psychogenically based disorders: The A category focuses on defining sexual disorders per se. The common denominator of all being: “persistent or recurrent”. It is explicitly pointed out that each disorder must be separated from a dysfunction exclusively due to a general medical condition or a substance-induced sexual dysfunction. Here, a set of subtypes is introduced. The latter set of definitions is valid only if the dysfunction is fully explained by the medical condition or the physical effects of a substance/drug, respectively. When combinations of psychological and organic conditions are judged to be causal for a certain dysfunction, the DSM-IV advocates the subtype: “due to combined factors”. The B category of the DSM-IV definitions add to all dysfunctions, a distress dimension: “The disturbance causes marked distress or interpersonal difficulty”. These A and B sets of definitions enable distinguishing a dysfunction per se from its emotional impact (but only if marked) – intra- as well as interpersonally. The B category does not leave a possibility for inclusion of mild or sporadically occurring distress. The DSM-IV has been criticized for its lack of operational criteria for the diagnosis of sexual dysfunction. [11] It has been suggested that criteria specifying severity and duration be added in order to distinguish sexual disorders requiring medical intervention from transient alterations in sexual function related to life stress or relationship difficulties. [12] These alterations should lead to more homogenous groups for clinical research and to revised estimates of the prevalence of sexual dysfunction in the general population. At this time, the criteria for the sexual dysfunctions are being evaluated for DSM-V and ICD-11.

Some years ago a consensus panel [13] recommended a new diagnostic and classification system for women’s sexual dysfunctions incorporating both physiological and psychological pathophysiology and personal distress. An important feature of the DSM-IV and the Basson et al sets of definitions is a classification into lifelong vs. acquired (after a period of “normal” functioning). Moreover, the DSM-IV calls attention to another dimension, namely whether the dysfunction is generalized (occurring in different situations) vs. situational (occurring only in certain situations). It is underlined that the clinical evaluation should include etiological factors. There is a discussion on the adequacy of the ICD-10 and DSM-IV definatory systems which to many experts, and perhaps particularly pertaining to women’s sexuality, appear too “medicalized” [14] ironically labeled biological innocence. Leiblum [15] and Basson [16] from the perspective of women’s sexuality criticize the concept of a linearly progressing sequential Desire → Arousal → Orgasm model which does not regard women’s sexuality. They suggest that many cases of impaired sexual response or interest are not dysfunctions per se, but are adaptive reactions to problems in sexual relationships. [17] It has also been suggested [18] that women’s sexual dysfunctions may be best conceptualized as a global inhibition of sexual response due to intrapersonal factors, an inhibition which may also be true for male sexual disorders. In epidemiological research it has been found that, for women and men alike, all sexual dysfunctions are generally significantly associated. [19–21] Hence, whereas definitions from a classificatory and differential diagnostic point of view are necessary, it appears unsound to assume that one sexual disorder per se can, a priori, be expected to be a solitary phenomenon for any given individual.

A number of serious problems can arise for research when presumed etiology is incorporated into definitions. While it is important to recognize that sexual problems can stem from a wide range of causes, this approach of including – or excluding – possible etiology in the definition of sexual dysfunction may undermine research aimed at improving our understanding of women’s and men’s sexuality. Problems arise because including etiology in the definition means that the case definition is inextricably entangled with the potential risk factors of interest. This makes it difficult to undertake a valid analysis of risk factors or demonstrate causal relationships between these risk factors and sexual responses. For example there is evidence that relationship factors play a very important role in female sexual responses. [2] We therefore might be tempted to exclude low sexual function that is a product of a poor relationship from our definition of FSD. If we did, we would not be able to assess the impact of poor relationships on FSD because couples with poor relationships who experienced sexual difficulties would no longer be classified as having FSD. If we include various relationship factors as
part of sexual dysfunction definitions in this way then it will not be possible to assess the impact of these relationship factors in future epidemiological studies. Furthermore, while certain factors may appear particularly important today this may change in the future or between populations. Currently much of the literature relating to FSD, and to some extent to MSD, is based on western populations. The etiological factors that are important in western societies may be very different to those in other cultures. In some instances it is not clear whether factors associated with FSD are the cause or the consequence of the sexual difficulties. Consequently we could run the risk of including in the definitions of sexual dysfunctions factors that are actually a consequence of FSD rather then part of the etiology or factors that are simply markers for the true underlying causes that we have not yet fully investigated.

Recommendation 2.:

There is a need to recognize that definitions for sexual dysfunction may be different for epidemiological studies versus those needed for clinical applications. Epidemiology studies may ask the incidence or prevalence of a disorder in a community but for clinical definitions further expansion such as duration and severity may need to be part of the defined disease evaluated and treated. The latter in epidemiological studies go beyond the per se definition of the disorder itself. There is a need to keep these parallel as possible. Grade C.

III. DEFINITIONS OF SEXUAL DYSFUNCTION FROM THIS CONSULTATION

On the basis of these deliberations, this committee has selected the following definitions. These do not generally separate organic from psychological caused dysfunctions which should (if adequate) be clarified through the etiology and they are not mutually exclusive.

1. DEFINITIONS OF SEXUAL DYSFUNCTIONS IN WOMEN

The definitions of sexual dysfunction in women came primarily from deliberations by the work by Basson et al [22] and the members of chapter 16 of this consultation.

a) Sexual interest/desire dysfunctions are diminished or absent feeling of sexual interest or desire, absent sexual thoughts or fantasies and a lack of responsive desire. Motivation (here defined as reasons/incentives), for attempting to become sexually aroused are scarce or absent. Sexual aversion disorder is anxiety and/or disgust at the anticipation of/or attempt to have any sexual activity.

b) The area of sexual arousal disorder is divided into three subtypes. Genital sexual arousal dysfunction are absent or impaired genital sexual arousal; self-report may include minimal vulval swelling or vaginal lubrication from any type of sexual stimulation and reduced sexual sensation from caressing genitals. Subjective sexual excitement still occurs from non-genital sexual stimuli. Subjective sexual arousal dysfunction is the absence of or markedly diminished feelings of sexual arousal, (sexual excitement and sexual pleasure), from any type of sexual stimulation. Vaginal lubrication or other signs of physical response still occur. Combined genital and subjective arousal dysfunction is absence of or markedly diminished feelings of sexual arousal (sexual excitement and sexual pleasure) from any type of sexual stimulation as well as complaints of absent or impaired genital sexual arousal (vulval swelling, lubrication).

c) Persistent genital arousal dysfunction is spontaneous, intrusive and unwanted genital arousal (i.e. tingling, throbbing, pulsating) in the absence of sexual interest and desire. Any awareness of subjective arousal is typically but not invariably unpleasant. The arousal is unrelieved by one or more orgasms and the feeling or arousal persists for hours or days.

d) Orgasmic dysfunction in women is lack of orgasm, markedly diminished intensity of orgasmic sensations or marked delay of orgasm from any kind of stimulation. There is a self-report of (high) sexual arousal/excitement in this disorder.

e) Dyspareunia is persistent or recurrent pain with attempted or complete vaginal entry and/or penile vaginal intercourse. Vaginismus is the persistent or recurrent difficulties of the woman to allow vaginal entry of a penis, a finger and/or any object, despite the women’s expressed wish to do so. There is often (phobic) avoidance and anticipation/fear of pain. Structural or other physical abnormalities must be ruled out/addressed.

For clinical studies and relevance to clinical situations, various descriptors are recommended for the various sexual dysfunctions in women and men. They include degree of distress scales, life-long or acquired status, situational or generalized occurrence, and other relevant conditional states.

2. DEFINITION OF SEXUAL DYSFUNCTIONS IN MEN

a) Sexual interest/desire dysfunction has to some extent been neglected in epidemiological research but is quite commonly seen in clinical practice. This committee suggests a definition identical to the one for women (see above).

b) Erectile dysfunction (ED) is defined as the consistent or recurrent inability of a man to attain
and/or maintain penile erection sufficient for sexual activity. A 3-months minimum duration is accepted for establishment of the diagnosis. In some instances of trauma or surgically induced ED (e.g. post radical prostatectomy), the diagnosis may be given prior to or 3 months. Objective testing (or partner reports) may be used to support the diagnosis of ED, but these measures cannot substitute for the patient’s self-report in classifying the dysfunction or establishing the diagnosis.

c) In August, 2007, the International Society for Sexual Medicine (ISSM) convened a panel of experts to review criteria for premature ejaculation. This panel proposed the following evidence-based definition of lifelong premature ejaculation: “ejaculation which always or nearly always occurs prior to or within about one minute of vaginal penetration, and the inability to delay ejaculation on all or nearly all vaginal penetrations, and negative personal consequences such as distress, bother, frustration and/or the avoidance of sexual intimacy.” The panel concluded that there was insufficient evidence to propose definitions for acquired premature ejaculation [23].

**Recommendation 3.** 

This committee recommends using the ISSM derived definition (from the convened panel of experts) for lifelong premature ejaculation as the new epidemiological definition. **Grade B.**

d) **Anejaculation** is the absence of ejaculation during orgasm.

e) **Orgasmic dysfunction** is inability to achieve an orgasm, markedly diminished intensity of orgasmic sensations or marked delay of orgasm during any kind of sexual stimulation. There is a self-report of (high) sexual arousal/excitement in this disorder and orgasmic dysfunction can occur together with ejaculatory function.

f) **Dyspareunia** is persistent or recurrent genital pain during sexual activities.

### 3. CLASSIFICATION OF SEVERITY

To make studies comparable, it seems to be of importance not only to have uniform definitions but also to use uniform scales. The two grade scales (yes/no), for example used by Laumann et al [20], Kadri et al [24], and Smith et al [25], may be too rigorously undifferentiated and may lead to exaggeration of the severity of any given dysfunction. In the USA, a four-graded (No/Mild/Moderate/Complete) scale has been used [26], while in Sweden [27] in another large prevalence study a 6-graded scale (Never/Hardly ever/Rather rarely/Rather/often Never/hardly ever/Rather rarely/rather often/Often/Always, Nearly always) has been used applying single questions both for characterization of dysfunction per se and for dysfunction-caused distress. This scale has been trichotomized: No dysfunction (never), Mild dysfunction (hardly ever, rather rarely) and Manifest dysfunction (rather often, often, always, nearly always).

The common mode used in population-based epidemiological research is single variables, each intended to cover one particular sexual dysfunction. The possible adequacy of using single question self-assessment was looked upon by Derby et al [28], who found close correlations between the prevalence of erectile dysfunction, tapped simultaneously by the IIEF erection domain, three erectile domain items of the BSMFI [29] and the one four grade (No, Mild, Moderate, Complete) item used by Feldman et al [26] in their now classical treatise of the prevalence of ED.

During recent decades different clinically well validated questionnaires, some examples being for men the IIEF [30] and for women FSFI [31], have been introduced. Furthermore, aggregated scores have been questioned [32-33] as a summed score may obscure a sexual aspirations-achievement gap within pertinent sub-domains. Furthermore, newer scales for measuring FSD have some advantages over single item questions. Recently, the Standardization Committee of International Society for sexual Medicine has completed a thorough review of the questionnaires constructed to assess female and male sexual function. (in preparation)

Of the questionnaires taken into consideration, for women the FSDS [34] and the SFQ [35-36] were recommended for both clinical and research use. Problems can arise when single questions are used in epidemiological studies. For example in a number of studies respondents are simply asked to report problems (or difficulties) with sexual desire that occurred for one month or more in previous 12 months. [20,37-38]. Both distress (i.e. problem or difficulty) and sexual function (desire) components are therefore combined into the one question. This makes it difficult to separate out the relative contribution of distress versus low function or recognize which factors are associated with the each of these two components. Moreover, we cannot be sure to what extent distress has been taken into account in participant responses or whether some participants have incorporated distress in their answers and others have not.

Overall, it appears that the field lacks questionnaires able to measure sexual function for women not in a relationship and no questionnaire has been further validated on non-heterosexual women, although some preliminary data exists on the FSFI in lesbian women. Although several epidemiological studies have used single items to assess sexual function in different domains, currently there is a lack of empirical evidence for the discriminant validity of single-item measures of sexual dysfunction in women.
We now have good evidence that a single item question can produce very different prevalence estimates than a validated multi-item scale when measuring FSD. In recent study prevalence estimates produced by simple non-validated questions were compared against those obtained using validated multi-item scales in the one sample of women. [39] When instruments with the same recall (the previous month) were examined side by side, simple questions produced significantly different prevalence estimates for desire, arousal, orgasm and pain disorders compared to the validated multi-item scales that incorporated sexual distress. [39] Furthermore, that investigation provided evidence that compared to validated multi-item scales, simple questions identify different sub-groups of women as experiencing FSD. [39] Compared to a single question, validated, multi-item scales such as the FSFI, [31] and PFSF [40-41] that simply examine sexual function have the advantage of being able to examine both frequency and intensity of sexual experiences with out asking women to self diagnose or guess what is normal sexual function. Some multi-item scales [36] have the added advantage of providing cut off scores for a number of different sub-categories (or sub-domains) of sexual function. These instruments have been translated into a variety of different languages [42-43] and are beginning to be more widely used in epidemiological, observational studies. [44] Although self-reported questionnaires such as IIEF, FSFI and BSMFI have demonstrated their utility for the evaluation of male and female sexual dysfunctions, they do not provide any pathogenetic information. SIEDY (Structured Interview on Erectile Dysfunction) is the only case history tool sufficiently validated for this purpose. [45] This is a 13-item structured interview composed of three scales, which identify and quantify three domains simultaneously present in ED patients (organic: Scale 1, relational: Scale 2 and intrapsychic: Scale 3). Organic, relational, and intrapsychic factors are often to be found together and mutually interacting in ED patients. Hence, an anamnestic instrument which simultaneously and quantitatively evaluates them can provide an interesting option to overview them. In addition, SIEDY can predict with 70% sensitivity and specificity the presence of an organic component of ED. SIEDY is therefore a unique, validated anamnestic and diagnostic instrument available to physician confronting ED. [46]

IV. DESCRIPTIVE EPIDEMIOLOGY

1. INCIDENCE OF SEXUAL DYSFUNCTIONS IN MEN

There are few epidemiological surveys addressing the incidence of sexual disorders. For erectile dysfunction there are five population-based studies that describe the incidence of erectile dysfunction, two from the USA [47-48], one from Brazil [49]; one from the Netherlands [50], and one from Finland [51, 52] (See Tables 2 and 3.) Two other papers have been identified that report on incidence in a preventive medical care clinic in the USA [53] or in a group of general practices in the UK [54]. The most important conclusion that can be drawn from these studies is that incidence is strongly associated with age. In the study from the UK the incidence of ED varied between 8-10 cases per 1000 man years in the period 1999-2000 (in men aged 40-79). This incidence had more than doubled from about 4 cases per 1000 man years in the period 1996-1997, that is, before the introduction of Sildenafil.

The first published, population-based study on incidence came from the MMAS (Massachusetts Male Aging Study) [47]; the participants were predominantly white. Analyses were performed on 847 ED-free men at baseline (with a baseline age between 40 and 69 years; average 52.2 years). After an average follow-up of 8.8 years a crude incidence rate of 26 cases per 1000 man-years was found (95% CI: 22.9-29.9). The annual incidence rate increased with each decade of age (table 2). The age-adjusted risk for ED was higher for men with lower education, diabetes, treated heart disease, and treated hypertension.

The Brazilian study was conducted in the city of Salvador, the third largest city of the country, with a racially diverse population. [49] Analyses were performed on 428 ED-free men at baseline (with a baseline age between 40 and 69 years; 53% of the men were below the age of 50 at baseline). After an average follow-up of 2 years (range 1.7-2.3) a crude incidence rate of 65.6 cases per 1000 man years was found (95% CI: 49.6-85.2). The annual incidence rate increased with each decade of age (table 2). The age-adjusted risk for ED was higher for men with lower education, diabetes, treated heart disease, treated hypertension, depression and benign prostatic hyperplasia. Based on an analysis of baseline characteristics of men in the study, the authors conclude that the analysis sample was similar to the sample of men lost to follow-up.

In Europe, the Krimpen study was conducted in the town of Krimpen aan den IJssel (The Netherlands), this is a commuter town near Rotterdam with a predominantly Caucasian population. [50] Analyses were performed on 1487 “clinically-relevant-ED”-free men and 1432 ED-free men (see table 2, for definitions of ED) at baseline (with a baseline age between 50 and 78 years; therefore, in comparison with the other two studies, all men were above the age of 50 at baseline). Inasmuch as this study consisted of a baseline measurement and 2 follow-up measurements after an average of 2.1 and 4.2 years, respectively, it was possible to determine
Table 2. Incidence rates of erectile dysfunction in population based cohort studies.

</table>
incidence rates based on two different follow-up periods. After an average follow-up of 2.1 years (range 1.8-3.3), a crude incidence rate of 32.8 cases per 1000 man-years was found (95% CI: 28.0-38.4). Furthermore, after an average follow-up of 4.2 years (range 3.6-5.8) a crude incidence rate of 19.2 cases per 1000 man-years was found (95% CI: 16.1-22.9). The annual incidence rate increased with each decade of age (Table 2).

In this study, an attempt was made to determine the incidence rate of “clinically relevant”- ED which means that “concern” of the man was considered in the definition. This analysis showed that the age-specific incidence rates as compared to the rates based on the usual definition of ED, were higher in the men aged 50-59, slightly lower in men between 60 and 69, but considerably lower in men above 70 years of age (Table 2). Based on an analysis of lost to follow-up cases, the authors conclude that the influence of this problem on age-specific incidence rates is negligible.

In another European study a target population of 3152 men born in 1924, 1934, or 1944 residing in Tampere, Finland, or 11 surrounding municipalities received by mail a questionnaire during the first quarter of 1994 with two questions regarding erectile dysfunction, trouble getting an erection or maintaining the erection once intercourse had begun.[51, 52] A similar questionnaire was sent in May, 1999. Analyses were performed on 1442 (46%) men responding at both time periods and answering the erectile questions. The erectile dysfunction was stratified into minimum (some difficulty in obtaining and/or maintaining erection), moderate (fairly frequently) or complete (intercourse does not succeed at all). Incidence rates varied for age groups and types of ED as shown in Table 2. The effect of age showed increasing incidence of ED and in this study diabetes was a major predictor of ED.

The most recent study was a longitudinal study of a group of men in the Olmsted County Study from Mayo clinic. [48] Men who had a history of prostate or bladder surgery, urethral surgery or stricture, or medical or other neurological conditions that could affect normal urinary function were excluded. These men were studied biennially from 1996 (when the brief male sexual function inventory (BSMSF) was first used in this population study) to 2004. Incidence rates for sexual dysfunctions were expressed as incidence per 1000 person years. Of the 2,213 men (mean age at baseline 58.39 years) who participated in the Olmsted county study, 1,827 men (83%) had complete data on sexual function. The person-years of follow-up ranged from 8,357 years for the sexual satisfaction domain to 9,815 years for the sexual problem assessment domain. Incidence data were stratified for decades of age from 40 years to 70 plus years. Results are shown in Table 3. Men who had ED at baseline experienced smaller declines in all sexual function domains compared to men who did not have ED at baseline. Other baseline characteristics, including education level; smoking status; and presence of diabetes, hypertension, or coronary heart disease, were not significantly associated with the rate of decline in sexual function. Change in erectile function was significantly correlated with change in all other sexual function domains. Correlations among changes in erectile function, sexual drive, and ejaculatory function were consistent across age groups. However, significantly smaller correlations between these measures, and sexual satisfaction and problem assessment were observed among older men, suggesting that while sexual function may worsen among these men, older men may be less likely to perceive this as a problem and be dissatisfied compared to younger men.

It is clear that there are large differences in incidence rates between these studies. Some of the differences can be explained by the design of the different studies. A younger baseline age (such as in the MMAS and Brazil study compared to the Krimpen study) would result in a population that is on average healthier. Surveys conducted as at home interviews might result in a baseline population that is less healthy than in a study where the men have to make an effort to visit a health center or clinic. An eligibility criterion such as in involvements with a sexual partner (MMAS) also theoretically results in a potentially healthier baseline population. Differences in socio-economic status (SES) between studies have probably played an important contribution to the variance in incident rates. In Brazil, more than one third of the men had less than 4 years of education. It is well known that level of education is a good proxy for SES.

The comparison of the different follow-up periods in the Krimpen study highlights that a longer follow-up leads to decrease of the crude incidence rate. There are several reasons why this is the case. ED may be a self-limiting problem in some men. After a longer follow-up, more men may have died or have become so ill that they cannot participate any further, leaving a healthier population for the follow-up measurements.

The above-mentioned factors and biases may work in one direction or the other, making it very difficult to compare studies in which one or more of the factors or biases may be at work. It is clear that it is impossible to identify “THE” incidence of ED. The most important common theme of the studies is the fact that incidence increases with age but also that concern in men above 60 and certainly above 70 is generally less, explaining the decreasing incidence of “Clinically-relevant”- ED. But there is also a censoring problem- differential mortality of the sick and less-well purges the older population of the potentially interested.

Table 2

Table 3
In the Krimpen study the crude incidence of 14.1 cases per 1000 person years for “Clinically relevant”-ED after a follow-up of 4.2 years is strikingly similar to the incidence of ED (8-10 cases per 1000 man years) that was recorded in general practices in the UK in men aged 40-79 years, which is somewhat younger than the Krimpen population. [54] The crude incidence rates for ED were very similar between the two studies from the United States but both included men who were mostly Caucasian. [47, 48] However the two year incidence rate for clinically relevant ED from the Netherlands was also very similar to these latter studies. [50]

2. INCIDENCE OF SEXUAL DYSFUNCTIONS IN WOMEN

In the early 1990’s, about 45% of Finnish women and 40% of men aged 18-74 reported decreased sexual desires during the past 5 years. [55] This incidence was closely age-related as less than 20% of women and men among those younger than 25 but 70-80% of those aged 55-74 reported decreased desire. Similar 5-year incidence (40% of women and 36% of men) was found in the mid 1990’s in Sweden. [56] In the latter investigation, 11% of women and 5% of men reported markedly decreased desire. One explanation for this decrease may be that with longer duration of partnership, desire tends to decrease [57] and, as discussed in Chapter 24, sexual desire, to a greater degree than sexual interest, may be seen as a partner-related aspect of sexuality, not really separable from arousal.

Recommendation 4. : 

There is a need for more incidence studies, from all regions of the world, for sexual dysfunction in men and women, even more so for all types of dysfunctions in women and other that ED in men. Grade C.

3. PREVALENCE OF SEXUAL DYSFUNCTIONS IN WOMEN AND MEN

As mentioned above, prevalence tables for sexual dysfunctions for women and men, Tables 4-6, were constructed from reports in peer review journal articles or books which met strict inclusion criteria of at least 10 of 15 possible assessment points from the Prins et al article. [7] One of the chairmen of this committee and at least one other of the members of the committee have screened all to meet the criteria. The literature was located through data-bases, the two previous chapters on epidemiology of Sexual Dysfunction from the past consensus consultations [5, 58], and surveys from Spector and Carey (1990) [59], Simons and Carey (2001) [60], Lewis [61], Kubin et al. [62] and Melman and Gingell. [63] A few of the references were found by crosschecking the bibliographies from the articles sourced by the methods stated above. All of the articles included in the tables furnish evidence at the lb hierarchical level. [6] There is, by and large, (in spite of different numbers of dysfunctions registered, different classifications of severity and different age strata studied) reasonably valid descriptive epidemiological data indicating that about 40-45% of adult women and 20-30% of adult men have at least one manifest (as opposed to mild – i.e. sporadically occurring – or none) sexual dysfunction defined according to the DSM-IV A- category. Assuming an approximately even distribution in societies worldwide, this means that about one third of all adults, at least in the western hemisphere where these investigations were conducted, have a manifest sexual dysfunction per se.

4. PREVALENCE OF WOMEN’S SEXUAL DYSFUNCTIONS

An overview of the reasonably valid studies on prevalence of women’s sexual dysfunctions, when feasible, dichotomized into mild/sporadic (MiD) and manifest (MaD) is given in table 4 which includes investigations with a reported response rate ≥ 40%. Among these eighteen descriptive epidemiological studies seven were from Europe, four from the USA, three from Australia, and one each from Canada, Iran, Morocco, and Puerto Rico. There were pronounced methodological differences between these studies. Thus, ten used face-to-face interviews. Five of the studies used mail questionnaires. Telephone interviews of varying length were utilized in three studies. While interviews, whether face-to-face or by telephone for pragmatic reasons, can be regarded reliable [25], there is in the literature some doubt about the reliability of mailed questionnaires. A main reason for this is that a mailed questionnaire may be answered in consensus between partners. Such a questionnaire may also yield a relatively low response rate. However, it is also possible that interviewees may be particularly prone to social desirability bias, where the presence of an interviewer results in respondents being more likely to give answers that they think will be socially acceptable.

Another difficulty is the difference in the age strata studied. As can be seen in table 4, the Icelandic investigation covered a very narrow age span – but included half the population at this age. Some focused only on elderly women while others cover an age span from the teens and up to old age. Two studies, the Finnish and the Swedish, from the sample selection and definatory points of view, can be regarded as twins. However, these two countries are neighbors with rather small total populations.

Even the time frame of having had sexual functions/ dysfunctions differs considerably. Thus, while some studies describe life long prevalence, others address the past year or even briefer periods (as three months or last month).

</table>

MiD = mild, sporadically occurring dysfunction. MaD = manifest dysfunction occurring at least quite often. NG = Not given. *excitement **anorgasmia
Also definitions and classification of severity vary considerably ranging from DSM-III or DSM-IV based face-to-face interviews which post hoc are transformed into a yes/no dichotomy and up to strictly structured questions applying 4, 5, or 6 graded scales. Regardless of the method used, there appears to be reasonable consensus at the turn of the century [20, 65, 70] that the prevalence of women who report at least one manifest sexual dysfunction is in the order of about 40-50%.

a) Interest/Desire

As pointed out in chapter 24, the defined category “desire” is probably not separable from the psychological aspects of arousal – yet another argument for universal consensus. Furthermore, interest and desire seems to be equivalent for several authors.

Using different methods and scaling, descriptive epidemiological investigations have found that the prevalence of manifest low level of sexual interest varies between 17% (GB) in 35-59 year old women [64] through 33-35% (USA 18-59 years old, Sweden 18-74 years old, Iran 20-60 years old) [20, 65, 75] and up to 55% in Australia [37,]. Neither in the USA [20] nor in Sweden [56] is there an age dependency up to the age of about 60-65. In Australia 16-19 year old teenagers had significantly lower level of sexual interest dysfunction than older cohorts. A major difference between the USA and Sweden in this respect was that the oldest Swedish women had considerably higher prevalence than the 18-59 year old USA women but clearly lower prevalence among the youngest women. In Sweden, 54% of the 18-74 year old women reported mild (sporadically occurring) dysfunction during the preceding year. This is very close to the French 55% prevalence [69] of mild desire dysfunction. Both those with manifest and those with mild dysfunctions had significantly lower level of overall sexual satisfaction than had those with none of these dysfunctions [27].

Low level of sexual desire was reported in Puerto Rico in as much as 41% of 40-59 year old women [72]; however, the definition utilized by the authors does not provide enough information to determine whether symptoms were mild or manifest. This “loss of libido” was associated with greater symptoms of depression. Manifest low desire dysfunction was reported in as much as 39% in the large scale investigation of American women 18-102 years old [70] and in 35% of Finnish women aged 18-74 [55]. Shifren et al. [70] found desire dysfunction to be more prevalent in the 45-64 age-cohorts. In this study 15-25% of women younger than 55 had this dysfunction; but the prevalence increased to about 50% in women aged 55-74. Lower levels of manifest desire dysfunction – about 10% - were reported from Sweden, France, USA, and Australia (of 18-74 year olds [27, 68, 71, 73] Hayes et al [2] found 16% of Australian women with manifest desire dysfunction and a Danish study by Epol et al [74], found that 19% of women 16-67 year old have a manifest desire dysfunction. Greater desire levels were found in younger women, physically active, unmarried, with no children under 15 years, in good physical and mental health and without medication. Concerning age related desire dysfunction the Swedish prevalence (11%) doubled to 22% in those 50-65 years of age and again doubled to 47% in the 66-74 year olds. These numbers appear to agree rather well with those reported in Iceland [66] and in Morocco [24], while in France [69] clearly fewer have manifest, but 55% have mild desire dysfunction.

b) Arousal and Lubrication

As previously mentioned, the traditional biologic definition of arousal nearly exclusively covers genital events, foremost lubrication. However, these genital events may not at all be accompanied by psychosexual pleasure (i.e. “arousal”). The obvious need of redefining arousal in relation to desire is discussed in chapter 24.

Using the DSM-IV definition, 16% of 55-57 year old Icelandic women were found to have low levels of excitement [66]. Furthermore, arousal disorder was found to have occurred in 26% of American (aged 18-102) and in 30% of Iranian (aged 20-60) women. However, most valid epidemiological research has focused on genital response in terms of vaginal dryness/insufficient lubrication. Even in this aspect, there are considerable differences between epidemiological data (table 4). Generally, manifest lubrication dysfunction is prevalent in 8-15%, while Laumann et al [20] and Richters et al [37] reported this to be the case in 21-28% of sexually active women. These investigations used a dichotomous yes/no scale. Safarinejad [75] found 34% of lubrication dysfunction in Iranian women. Öberg et al [27] found that 49% of Swedish women aged 18-65 years had mild (sporadically occurring) lubrication insufficiency. Some studies have evidenced that with increasing age, in particular age >50 years, lubrication insufficiency becomes more prevalent [64, 68], while others have not found age dependency in this respect [20].

c) Orgasm

The prevalence of manifest orgasmic dysfunction varies considerable in the available epidemiological reports. Again, this may to a great extent be due to de facto incompatibilities of reports. Nevertheless, it appears that in Australia [37,], Sweden [65], the USA [20, 70, 71] and Canada [76] the prevalence of manifest orgasmic dysfunction is about 16-25% and in Iran as high as 37% [75]. In most of these countries, age dependency has not been traced; while in Australia for about the same overall
prevalence, 50-59 year old women were more likely to report orgasmic dysfunction than were those aged between 16 and 49 years. An age-dependency was also found in the Iranian sample. Also, in the USA orgasmic dysfunction was more prevalent among women 45 or older. A somewhat higher prevalence of orgasmic dysfunction (30%) has been reported from Finland [55]. A significant higher prevalence (41%) of manifest orgasmic dysfunction among 51-62 year old women has been reported from Massachusetts [68]. In other studies [24, 39, 64, 68, 71], the prevalence of manifest orgasmic dysfunction is much lower (11-16%), while that of mild orgasmic dysfunction is remarkably high (about 60%) in the two Nordic countries, where identical methodology were used. Thus, in these two countries, more than 80% of all sexually active women aged 18-74, age independently; report some degree of orgasmic dysfunction.

In Swedish women it was found that women reached orgasm more easily through stimulation of both clitoris and vagina, and furthermore, experienced women reported more pleasurable orgasms during intercourse when the penis was in the vagina. During masturbation a small minority stimulated only the vagina. For American women use of marijuana and alcohol was associated with greater orgasmic dysfunction.

Dyspareunia and Vaginismus

These conditions are discussed in Chapter 25. The syndromes are clearly less prevalent in the general population. Thus, 6% of the Moroccan [24] and Swedish [64] women reported some degree of vaginismus, which does not appear to be related to age. The prevalence of manifest dyspareunia has been reported as low as 1% in Australian women [72] and 2% in elderly British women [66] while another studies [20, 37, 68, 71, 75, 76] found that dyspareunia prevailed in as many as 14-27%. Mild (sporadically occurring) dyspareunia is 4-8 fold more common than is manifest. Several investigations have described increasing dyspareunia with increasing age [21, 65, 78] while in Australia the opposite has been found with a systematic decrease of reported physical pain during intercourse from the age of 30 years and onwards [37].

5. PREVALENCE OF MEN’S SEXUAL DYSFUNCTIONS

a) Desire/Interest

Altogether we have identified 24 epidemiologically valid reports (table 5) that include men’s interest and/or desire. Whereas in Sweden [65] and the USA [20] the prevalence of low or decreased level of sexual interest during the last 12 months by and large are remarkably similar and age independent up to the age of about 60 years, a sharp increase appears to emerge at older age. It is, therefore not surprising that the elderly population of men, with greater prevalence of, for instance, ED (see below) is not more sexually distressed than their younger peers. In Australia [37], Argentina [82], Southeast Asia [85], Korea [94], and Italy [92], a clearly higher prevalence of desire/interest dysfunction, without any pronounced age effect, of about 25% was reported by 16-59 and 40-80 year old men. In the study from the Netherlands [100], a very high incidence of desire problems were reported, 41-58% from ages 58-78 years. Generally dysfunction of sexual desire/drive is much less prevalent than dysfunction of interest, whether life-long (France [69] and Iceland [66]) or during the past year (Sweden [65]) or so. However, at higher ages (50-65 and >70) both Panser et al [77], the Swedes [65] have demonstrated sharp increase also in this prevalence. A national random sampled population of men in China reported a prevalence rate of 53% at anytime within the previous year and 11% for persistent lack of interest for the most part increasing with age. [84] In summary the populations’ level of sexual interest appears quite stable from the late teens and up to about 60, where after it decreases markedly. The same may be true for sexual desire/drive which may in many men, however, start to decline already around the starts of their 6th decade of life. In general studies reported in this chapter since the last consultation for prevalence of desire/interest have been reported for 40-80 year olds without age adjustment to range from 8 to 18% around the world except for the citations presented above. (See Table 5)

b) Ejaculation Dysfunctions

Ejaculation is distinct from orgasm, which is a purely cerebral cortical event. If current understanding of ejaculation is limited, the knowledge regarding orgasm remains even more obscure. It is not until very recent time that is was accepted that ejaculatory disorders may have a neurobiological origin rather than being a pure psychological issue. [102]

We have been able to locate [22] descriptive epidemiological investigations of ejaculatory disturbances fulfilling our validity criteria. These are given in table 5. The prevalence varies from 8% and up to 30% for all age groups covered by the tabulated data for early or premature ejaculation. Two exceptions to this were a prevalence of 55% in 50 to 59 year old men in one US study [20] and a very low prevalence in 18-75 year olds surveyed in London where the rate of 3.7% was seen [81]. The 15% life-time prevalence found in France [69] covers 5% who often had experienced ejaculation prior to penetration and 10% who often had ejaculated too rapidly after vaginal intromission. The 2-3 fold higher prevalence expressed as “climax too early” and still higher for 50-59 year old men reported from the USA may be a result of the dichotomous scale (yes/no)
Table 5. Valid epidemiological investigations (arranged according to publication year) of prevalence of men’s sexual dysfunctions. Erectile dysfunction not included.

Table 5. Valid epidemiological investigations (arranged according to publication year) of prevalence of men’s sexual dysfunctions. Erectile dysfunction not included. (continued)
used by Laumann et al [20] while the European investigations used pluri-step scales. However, more recent surveys reported in Table 5 from the last consultation have shown higher prevalence rates for early or premature ejaculation from around the world and particularly from Asia and Latin America. An exception was the study from China in which a rate of persistent premature ejaculation was 8% (≥ 2 months), a rate of 69% of any occurrence of the complaint within the previous year. In a recent study not shown on the Table 5 Ahn et al reported from Korea in 1,570 men aged 40-79 years of age. A prevalence rate of 24.9% for not being able to control their ejaculation time, further broken down based on self-reported intravaginal ejaculation latency time a rate of 11% for a 2 minute cutoff time and 33.1% for a 5 minute cutoff time increasing significantly with aging. [103] Still fewer investigators have reported on the prevalence of delayed ejaculation. [64, 68, 80, 82, 84, 101] (See Table 5) Rates for this disorder vary from 1 to 10%.

It is, in fact, probable that many men who have difficulties in maintaining an erection during vaginal intercourse also report delayed ejaculation. Hence the already relatively low reported prevalence may be exaggerated. These prevalence studies applied various frequently non-validated definitions of and methodologies for evaluation of early ejaculation. However, it should be emphasized that normative data on ejaculation latency time obtained by the stopwatch method in the general male population are mandatory to really establish the prevalence of early ejaculation. Obviously, an accurate definition of early ejaculation is necessary, not only for clinical diagnosis and treatment, but also for comparing data from different studies and performing epidemiological studies. [102] Unfortunately, there is a real paucity of studies dealing with either clinical or non-clinical samples from which we can really draw valid figures in keeping with the Prins’ criteria listed elsewhere. Since definitions regarding ejaculatory, orgasmic and desire disorders in males, broadly known and accepted, were lacking, this “scenario” was in some way expected.

One of the problems of surveys regarding early ejaculation is the inconsistency of how the condition is defined. Some investigators have defined PE as ejaculation which occurs within one minute of vaginal penetration whereas others have defined PE as ejaculation which occurs within seven minutes of penetration. [23] Other investigators have defined premature ejaculation based on the number of thrusts between vaginal penetration and ejaculation. [104] or sense of control over ejaculation. [105] Giuliano et al [106] proposed that PE be defined by a combination of direct measures of ejaculatory latency and patient reported outcomes. In 2007, the International Society for Sexual Medicine convened an international panel to review current evidence and to recommend an evidence-based definition. This committee proposed that lifelong PE in heterosexual men be defined as ejaculation which always or nearly always occurs prior to or approximately one minute after vaginal penetration on all or nearly all vaginal penetrations with negative personal consequences. [23] It is recommended that future research adopt this definition. There is insufficient data at this time to precisely define acquired PE or PE in other sexual activities.

c) Orgasm

It is, at least in men, quite difficult to assess the prevalence of orgasmic dysfunction. The simple reason being that, in contrast to many men with complete spinal cord injury, some men may be unable to distinguish between ejaculation and orgasm. In the USA 8% age independently reported that they had been unable to achieve orgasm (cf Table 5) during the last year. [20] A much lower prevalence (<1%) was reported in 55-57 year old Icelandic men [66]; while in France [69] the (life-time) prevalence of men’s organic dysfunction was (7%). Since the last consultation 13 of the 23 published prevalence data for male dysfunctions other than ED have reported orgasm problem analysis in their surveys. Most of the studies report a prevalence rates in the range of 11.8-19.4%. (See Table 5) Nicolosi’s world-wide report showed 5-8% for all areas of the world except for East and Southeast Asia where the prevalence was 10-15%. [85] Five of the surveys reported lower rates, Nazareth from London reported a prevalence rate of 2.4% [81], Enzlin from Belgium, a rate of 1.8% [83], Moreira from Germany, a rate of 5.6% [87], Corona from Italy, a rate of 4.4% [101], and Parish from China a rate of 5% [84]. This last study reported a rate of 52% for occurring anytime in the previous years versus the 5% rate for persistent greater than 2 month’s occurrence.

d) Dyspareunia

The prevalence of genital pain in men during sexual intercourse has only been fragmentarily studied (Table 5). In France [69] 5% of the adult male population (of 18 to about 70 years) report that they at least quite often suffer such pain. This rate from 3-6% was reported in seven studies (see Table 5) Clearly lower prevalence of 1% -2% have been found in Finland [55], Sweden [65], China [84], the Netherlands [79], London [81], and Germany [87]. The China study reported a rate of 25% when occurring anytime within the previous year but only 2% for persistent greater than 2 month’s occurrence [84]. With this low prevalence it is hardly surprising that no age-dependency of men’s dyspareunia has been found. Nickel and al reported a prevalence rate of painful ejaculation on a world survey of 16.8%. [89]
e) Erectile Dysfunction

Tables 6A-F are compilations of the data from 59 studies around the world regarding prevalence of ED (male sexual arousal dysfunction) from 1993 to 2009. At the time of the first consultation on ED there were very few studies that would meet this more stringent evidence-based criteria. In fact, 24 studies in this table were presented in the last chapter, only six were included in the first consultation chapter. [5, 58] There continues to be a better global representation. Again it should be stressed that in order to adhere to the most scientifically valid studies to be included only those studies that obtained a Prins score of 10 or above are included in these tables. There have been several other epidemiologic studies that have been published regarding prevalence of ED but they do not meet this standard for scientific validity. The Prins scores are included in Table 6 in the first columns so that the readers can be aware of those with higher scientific validity. There are 5 studies from Asia and 4 from Australia (Table 6A and B). There are 30 studies from Europe (6C), 7 papers from South and Central America, 7 from North America, and 6 studies classified as worldwide representing data collected in different regions of the world and published as a single paper. For the European studies; 4 each were from the Netherlands and the United Kingdom, 3 each from Finland, France and Germany, 2 each from Denmark, Sweden, Spain and one each from Italy, Belgium, Turkey, Croatia, and Portugal. Two of the studies were European multinational. Most of the Latin American studies were from Brazil except one study from Columbia, Venezuela, and Ecuador. The North American studies were all from the US except one Canadian report.

Design of the studies included survey questionnaire only (survey) or cross-sectional study with additional measurements (CS) and the table shows 30 of the former and 28 of the latter. Richter’s data from Australia was conducted by telephone and was a single question only. [37] Self-administered questionnaires was the instrument used in 40 of the survey designed studies and interviews in the remaining 19 of these. In the cross-sectional studies all studies used the instrument of self-administered questionnaires except one study from Wales [127] which used an interview. A unique feature of a study from Denmark was that 100 of the men who had not reported ED on the self-administered questionnaire were subsequently interviewed in an office setting and seven of these reported at the interview ED of a significant nature, thus increasing the original 4% percentage of ED in this group of 51 year old Danish males by 7% in these 100 men. [112, 113]

However, as in the case for women’s dysfunctions, there is great variety in methodologies of the studies. The authors of this chapter have eliminated many reported categories of mild ED reported in some of the studies, since that particular description is so varied. The definition of ED used for the particular study and reported on the table is included in table 6 A-F. The reader can see that the definition of ED varied among the studies and thus comparison between studies is from the beginning hampered. Time period covered by the questions about ED varied from one month to one year, and 10 of the studies did not specify a time period questioned about ED.

Most were random population studies, some stratified by age or region. The Japanese study from Masumori included all men 40-79 years of age in a fishing village with 42.3% participating the study. [107] In the study from Denmark reported by Solstad and Hertoft [112-113], all men of the age of 51 year from selected communities were sent questionnaires with an 81% response rate. Five of the studies were from general practice (GP) settings; three that included all men registered in the general practice. These three included one from the United Kingdom, 40 years and older, with a 65% response rate [117], one from the Netherlands, 50-75 years of age, with a 47% response [79, 124-125], and one from Wales, UK, 55-75 years of age, with a 50% response rate [127]. Two of the other studies were random population studies of the GP registrations, one from the United Kingdom, 18-75 years of age, with a 39% response [78, 119] and one from Italy, age 18 years and older, with a 82% response rate [120]. The percentage of response was determined from data presented in the paper or chapter regarding the eligible number who were scheduled to be screened and ranged from 17 to 82%. Only eight of the fifty-nine were under 500 participants in number. Eight of the studies reported no differences between responders and non-responders and another 12 did report differences as summarized in the table. Thirty-nine did not address this issue.

All the studies which were stratified by age showed rising prevalence of ED as the population aged. Two of the Asian studies showed doubling of the prevalence rate at age 60-70 with almost another doubling at age 70-79 years. [107-108] The study not stratifying from Korea reported a 31.9% prevalence rate for ages 40-80 which seemed to represent a mean of the stratified studies. [94] The more recent Korean report stratified by age showed a tripling of the prevalence for the 60-69 age group compared to those younger whether self reported or scored by IIEF. [103] In that same study using IIEF-5 diagnosis of \( \frac{17}{17} \) as defining ED tripled the self-reported ED in the younger age groups and the total group and doubled it for the older age groups. [see Table 6A]

One of the Australian reports did not show much of a difference in prevalence over stratification from 16-59 years until age 40 was reached and then the prevalence was low for the 40-49 and 50-59 year decades of 13 and 19%. [37] The other stratifying for

</table>
older ages showed marked increasing rates with each of the three decades beginning with age 60. [109-110] The study that did not stratify for age reported a 21.1% prevalence rate for ages 40-80 years again reflecting a blend of the stratified studies. [97] The most recent report from western Australia [111] had a older age range in their study and reported an overall prevalence rate of 40.3%, almost 4 times the prevalence from the other age stratified study with an overall rate of 10% [37]. In the younger age groups the former study reported higher rates for ED until the decade of 40-49 where the rates were almost the same but in the next decade again the former study reported higher rates. (See Table 6B)

Prevalence studies from Europe were difficult to compare. (See Table 6C) In the Scandinavian studies, the prevalence seemed to rise sharply after the age of 65 years, with rates of 20% or greater after this age and this rate doubling when reaching the age of 70 years or older. The only exception to this trend was the study from Finland where much higher prevalence rates were reported beginning with age 50 and continuing with an upward slope for every five year cohorts. [129-130] This study used the NIH definition for ED and inquired about activity the previous four months. The prevalence of ED before the age of 61 years in the continental northern European studies were generally quite low except for the study mentioned above. In a recent study by Corona 8 centers from the European Union participated in the study 9. [135] (See Table 6C). Prevalence rates tripled from the decades in the 40’s to 50’s and doubled for each succeeding 10 year cohort. Moreira’s study from the UK and Europe did not stratify for age and reported a prevalence rate for ED of about 18%. [96]

In two studies from the United Kingdom not stratified for age prevalence rates were quite different although similar ages (18-75 years were reported), 8.8% and 26% respectively. [78, 81, 119] Dunn’s study asked for lifelong compared to last three months prevalence for ED and the rates increased for the former to 39% from 26%. [78, 119] In the other two studies from the United Kingdom, both derived again from general practice groups there was a marked difference in prevalence rates for ED although for one group the definition was for complete erectile failure and one was difficulty in attaining and maintaining an erection and were stratified for different age ranges. The prevalence rates for the stricter definition ranged from 7 to 22% for the three periods stratified from age 55 to 70 years of age. [127] For the less strict definition prevalence rates ranged from 9 to 79% from four decades reported, ages 40-79 years. [117]

In the four studies from the Netherlands stratification by age was different in all papers but in general prevalence rates for ages before 60 were in the teens and increased after that for each age period quoted up to age 70 where rates varied from 26 to 42%. [79, 100, 122-125, 131] In the Korfage study age stratification ranged from three to eight years and was reported for different age groups beginning with age 58 and ending with age 78 years. For the five different age groups prevalence rates varied from 12 to 26.3%. [100]

In the three studies from France two were non randomized, the study reporting on ages 18 to 69 years was 7% prevalence rate and the study reporting on ages 40 to 80 years was 15%. [68, 134] In the study stratified for age by decades beginning at age 50 the prevalence rates were 20%, 33%, and 38% for each of the ensuing decades. [116] Of the 3 studies from Germany one was not reported stratified for age but reported a 7.9% prevalence rate for ED over the last year for ages 40-80 years. [87] The two studies stratified by age showed prevalence rates in the teens for those 49 years and younger. For each ensuing decade though rates were half as much in the Braun study compared to the May study. [121, 132] In the two studies from Spain, the one not stratified for age showed a prevalence rate of ED of 12.7% for ages 40-80 years. [88] In the stratified for age study rates were low until the decade of 60-70 years were the rate of 21% was reported. [126] In the single study from Belgium the rates doubled every decade from 40 to 69 years from 19.4% to 65.9%. [128] In the study from Croatia the prevalence rate for ED was low before age 50 but stayed about 18% from ages 50 to 69 years and almost doubled to 38% age 70 and beyond. [91] In the single study from Portugal prevalence rates for ED were high beginning with 30% for the 40 to 49 year decade to 50% to 70% for the next two decades. [133] For the single Italian study rates were very low before age 50 but were reported as 16%, 27% and 48% for the three decades beginning at age 50 years. [120] In the single Turkish study the unstratified for age prevalence rate for those 15 to 60 year of age was almost 60%. [90]

There were seven studies from Latin America, almost all from Brazil. (See Table 6D) In the single report from three non Brazilian countries, Columbia, Ecuador, and Venezuela, the prevalence rates for each of four decades beginning at age 40 and ending as age 79 from each of the three countries were almost the same with a 33 to 38.5% for the first decade, 40-50% for the next, increasing by about 25% for the 60-69 years of age decade to 73-75%, increasing about another 5% until age beyond 79 where rates ranged from 84 to 93%. [140] In the 6 studies reporting on more than 300 patients, the prevalence rates for ED were not stratified for age in one study and the prevalence rate in that study was 13.1% for ages 40-80 years. [86] The four random population and community based population studies reported prevalence rates for ED in the teens before age 50, varying from low of about 12% to 22% in the decade of 50-59 (with one exception mentioned in the
next sentence), increasing from about 32% to 58% in the decade ages 60 to 69 years. [136, 138,139, 141] In one study of 2000 men prevalence rates were much lower than the other random population studies using the IIEF as defining ED from 0.2% beginning with age 20-40 years of age, 1% for those 41 to 50 years of age, about 3% for 51 to 60 years of age and 7% in those greater than 60 years of age. [141] In a study of 965 men participating in a free screening program for prostate cancer, ages 45 to 90 years using IIEF-5 of scores below 21 as defining ED rates of prevalence for the disorder were much higher in this group from almost 37% for those 40 to 49 years of age, increasing by 5.5% for the next decade and by just beyond 20% for those 60 to 69 years of age. For those 70 to 79 years of age the rate was 79.4% and 100% for those 80 and above. [137] Rates were higher when IIEF scores were used to define ED.

In the studies from the United States, (see Table 6E), the methods used and populations varied but two of the studies showed fairly consistent prevalence rates for the various ages, the Massachusetts Male Aging Study (MMAS) and the study from Ansong. [26, 28, 142-143] The Laumann data included men who were younger and reported less than half the prevalence rate for the men 50 to 59 years of age compared to the other two studies from the United States. [20] The Olmsted County study from the United States also showed a lower prevalence rate by a large amount for the ages 40-49 and half the prevalence rate for the decades 60-69 years but similar rates for the decades 70-79 as the MMAS data. [77] In the 3 studies reported from North America that were not part of the last chapter two were not stratified for age and prevalence rates were 16 and 22.5% for ages 40 to 80 years of age. [95, 98] One study reported prevalence data from a survey of health professionals and semistratified by age with the following prevalence rates for those less that 60 years of age, those 60 to 69 years of age, those 70 to 79 years of age and those greater than 79 years of age of 10, 26, 50 and 60% respectively. [145]

There are 6 studies classified as world-wide reports. (see Table 6F) The first was a study by Rosen et al that included the US and 6 European countries. The prevalence rates were stratified for three decades beginning with age 50 years and through age 80 and were about 31%, 55%, and 76% respectively. The overall rates were similar for all countries and Europe only. [80] Nicolosi et al compared prevalence rates in Brazil, Italy and two Asian regions in 40 to 70 years of age. These were not age stratified and the prevalence rates of 15 and 17% were similar for the non-Asian studies and were higher in Asia, 22.4% in Malaysia and 34.4% in Japan. [146] Rosen et al in a second world-wide study again compared prevalence rates in the US, Brazil, and Mexico as well as 5 European countries. Including all of the countries the prevalence rates for ED were stratified by five decades and a single six year group of 70-75 years of age. Rates were in the teens for the three decades beginning with age 20 through age 49 years. For the next two decades beginning with age 50 to 69 years prevalence rates of 22 and 30% were reported with a prevalence rate of 37% for the six years of 70 to 75. Overall prevalence rate was 16% and the individual rates from the seven countries except the US were below this rate with the overall prevalence rate of ED in the US of 22%; half again the total group rate and double to 8% above the other countries. [147] In a second study from Nicolosi et al regional prevalence rates for age 40 to 80 years from around the world were reported. Rates were stratified for age for all of the countries and were low before age 60, were reported as 15.2% for the seventh decade of life and 22% above age 70 years. The regional prevalence rates were similar for all of the regions and ranged from 8 to 15% except for Southeast Asia where the prevalence rate was almost double to 22%. [85] Shabsig et al reported in 2005 non-stratified for age prevalence rates for ED from a large number of men from the US and five European countries. The rates for France, Italy, and Spain were similar, 12 or 13 %, while the UK, Germany, and the US were higher, 19, 22, and 25% respectively. [146] In the same year Laumann reported prevalence rates in a large number of men from various regions of the world. The rates were 13 to 14% in Northern Europe, Southern Europe, Central/South America, and the Middle East. In non-European West the rate was higher at 21% but again as shown above in the Nicolosi studies the highest prevalence rates for ED were in two regions in Asia, 27% in East Asia and 28% in Southeast Asia. [149]

The same tools and methods were used in a United States study and a Japanese survey. [77, 107] Thus these two could possibly provide for the best comparison between two cultures. The Japanese study showed almost double the prevalence rate for the four decades reported on compared to the American study. In contrast, the study from Thailand showed half of the prevalence rate for the age group 40-49 years compared to the Japanese study but almost equal rates for the other older decades reported.

One important issue to be addressed in future research is the validity and reliability of self-report data on ED generated in response to a single question (e.g., the NHSLS’s [20] question, “During the last twelve months has there been periods of several months or more when you...had trouble achieving or maintaining erection?”) when compared to results from the well used validated, multi-item International Index for Erectile Function (IIEF), [30] which is, of course, also a scale based on self-reports. The question of
which of the two instruments may be more useful and accurate for large population studies remains controversial. A good correlation of each criterion in population samples has been reported. [28] A single self-assessment direct question to evaluate ED was applied to the population-based samples of the MMAS follow-up evaluation, in addition to the Brief Male Sexual Function Inventory (BMSFI) and the IIEF. Prevalence was similar to that determined on the IIEF, agreement was moderate (0.56 to 0.58) and association with previously identified risk factors were similar for each classification. The single question correlated well with these other measures (r= 0.71 to 0.78, p<0.001). However the incidence of subjects not classified due to missing data was 9% on the MMAS single question, 8% on the BMSFI, and 18% on the IIEF. Based on these data, the direct self-assessment question may be a practical and accurate for large population studies remains practical tool for population studies, in which detailed clinical measures of ED are impractical.

The Global Survey of Sexual Attitudes and Behavior (GSSAB) [85, 149] have reported prevalence data based on two items, the first item corresponding exactly to the NHSLS question while the second asks if the respondent has reported a problem of achieving and maintaining an erection for two months or more, he is then asked, “how often would you say this has occurred during the last 12 months?” The choices are either occasionally, sometimes, or frequently. The GSSAB regarded only respondents reporting periodic, i.e. sometimes or frequently, difficulties as indicating moderate or severe ED. Across 7 world regions, between 22% and 44% reported only having occasional problems with ED of several months duration. These respondents were excluded from the prevalence estimates of having ED. Various systematic review of population-based estimates of sexual dysfunction note the considerable variation in the items asked to establish the presence of ED in the respondent (see Table 6A-F) and the resulting difficulties posed in establishing the comparability of the estimates across studies. [7, 60] It is imperative that research evaluating the relative efficacy of different measurement strategies be undertaken to establish recommended “best practice” for future studies. Consideration of “best practice” should be mindful that useful epidemiological data can often be generated with brief questions that would not be especially effective in identifying more narrowly defined clinical conditions.

In summary, the prevalence of erectile dysfunction on a world wide basis shows a great deal of variation but the way the information is collected, the way the population is sampled, the tools used for the survey, and, most importantly, the way ED is defined vary greatly. Below the age of 40 years the prevalence is 1-10%. In the decades from 40-49 the prevalence ranges from 2-9% to as high 15%. The 50-59 year age group showed the greatest range of reported prevalence rates. Most of the world show a rather high rate from 20-40% for the ages 60-69 years, some increasing after age 65 years, except for most of the Scandinavian reports where the age of 70 years and older is the decade of major prevalence rate change except the one report from Finland that showed high rates beginning at age 50. [129-130] Almost all of the reports show high prevalence rates for those men in their 70’s and 80’s, ranging from 50 to 100% prevalence of ED in these decades.

**Recommendation 5.**

- There is a need for more prevalence and incidence data studies on sexual dysfunctions in men and women from Africa, India, and Asia. **Grade C.**

**Recommendation 6.**

- Prevalence and incidence studies need to be more parallel in data collected and meet as many standards as possible [7]- duration for disorder screened for should be at least three months or more. Researchers should include severity scales for the disorder in the survey. **Grade C.**

**Recommendation 7.**

- There is a need to study the effect of excluding non-sexually active individual from the prevalence data reports. **Grade C.**

**h) Concurrence of sexual dysfunction**

Both in the descriptive and analytical epidemiological literature there is very little on simultaneous occurrence of different sexual dysfunctions within and across genders. In French men, aged 18-69, it has been reported that 7% of those with manifest ED also are early ejaculators. [150] In an older sample (50-78 year olds) from the Netherlands about 50% of the men with early ejaculation also reported ED. [79] To which extent this simply indicates that incapacity to maintain erection is a sequel to early ejaculation remains to be analyzed. From France it has been reported that 37% of 18-70 year old men with ED have lost their “libido”. [21] It has been found in a Swedish study that within both genders (aged 18-74) nearly all own sexual dysfunctions are closely associated (generally at a p level of < 0.001). [19] The only exception is that for the men with early or delayed ejaculation quite logically were not significantly correlated. Moreover, a high degree of cross-gender concurrence was found. In fact all women’s dysfunctions studied were closely (p <0.005- 0.001) coherent with all male partners’ functions/dysfunctions as perceived by the women. Men’s sexual dysfunctions had precisely the same close associations with men’s perceptions of their female partner’s functions/dysfunctions. These findings firmly suggest that it is important to think in terms of sexual partner relationship, none the least in
therapy-pharmacological or psychotherapeutic. [151] Laumann et al also examined the co-occurrence of dysfunctions for the set of dysfunctions discussed in the latent class analysis, but the actual percentages of overlap were not given in the article. [21]

g) Sexual dysfunctions and personal distress:
It is of paramount importance to know to what extent sexual dysfunctions are accompanied by distress.

Commonly overall level of sexual distress is nowadays measured by one single question or by an aggregative questionnaire such as the FSDS (the Female Sexual Distress Scale) [34, 70]. Given the close coherence of different sexual dysfunctions – intrapersonal as well as interpersonal – we have here chose to focus on the extent to which specific dysfunctions lead to dysfunctional distress (personal problems). Among women and men with manifest dysfunction per se generally less than half experience that it is accompanied by manifest personal distress (Table 7). Moreover, only small minorities of those with mild/sporadic dysfunction report manifest distress. In Sweden 26% and 17% of women and men reported at least one distressing self or partner's sexual dysfunction. However, among the manifestly personally distressed, the vast majority were not satisfied with their sexual lives. This can be compared with the sexual satisfaction rate of 55% in the total population. [19] In general agreement with this and defining sexual distress (one overall pluri-item aggregated variable) using the FSDS [71] have found that 22% of women in the USA aged 18 and above reported sexual distress. This is about half of the 43% who had an – age adjusted – sexual dysfunction. However, these authors did not explicitly ask for distress caused by specific sexual dysfunctions. Measuring women's sexual distress using the FSDS, Rosen et al [152] have reported that among women with low sexual desire level of distress decreased with higher age and those in partner relationship had relatively high level of distress as had those with arousal and orgasmic dysfunctions. Furthermore Bancroft et al., [153] found that neither relative frequency of sexual thoughts, frequency of orgasm, nor lubrication problems were predictors for women having significant or manifest versus no, or mild versus no distress concerning their own sexuality. They further reported that the best predictor of sexual distress was relatively low emotional well-being. In reasonable consensus with other studies Öberg and Fugl-Meyer [154] confirmed that low level of satisfaction with partner relationship is closely associated with women's manifestly distressing dysfunction of sexual interest, lubrication and orgasm. However, the causality is unclear. Thus, a distressing sexual dysfunction may be caused by a disharmonious partner relationship but a sexual dysfunction may contribute to a not satisfying partner relationship.

V. ANALYTICAL EPIDEMIOLOGY

1. RISK FACTORS FOR WOMEN

In this part, we shall first address women’s sexuality in relation to health issues. Subsequently findings relating social and demographic factors to sexual function will be discussed. Besides the investigations referred to, we have not been able to locate reliable and reasonably evidence-based investigations of risk factors for women's sexual functions. Thus, the need for more research concerning women’s sexuality must be underlined. When dealing with risk factors, co-morbidities and socio-demographic items, descriptive epidemiology gives best evidence. However, analytical epidemiology may be an adequate way to identify the relative risk of sexual dysfunction caused by (sets of) medically or psychologically identified particular diagnostic categories.

Recommendation 8:

There clearly is a need for more analytical epidemiological studies about women's sexual dysfunctions. Grade C.

a) General Health-related risk factors

Richters et al [37] found that, compared with women with excellent health, those reporting good, fair or poor health were more likely to have a sexual dysfunction. Significant odds ratios were 1.9, 3.1 and 5.7 for those with good, fair or poor health, respectively. Simultaneously Laumann et al. [20] and Fugl-Meyer & Fugl-Meyer [65] reported that less-than good health leads to greater risks of sexual dysfunctions concerning desire/sexual interest and genital pain. Self-reported health and levels of physical activities have been confirmed to be an important correlate of sexual function, as more orgasm problems were found among women who reported no physical activity [154], and higher level of sexual desire among those who reported higher self-perceived health and more physical exercise. [74] Perceived poor health was also a predictor for women’s sexual desire, arousal, orgasm and dyspareunia. [70, 71, 154]

b) Diabetes

Kadri et al [24] in their descriptive epidemiological study of Moroccan women reported (univariate) significant associations for diabetes with orgasmic dysfunction, dyspareunia and sexual aversion. Also Danish women with diabetes have been found to have
low sexual desire significantly more often than non-diabetic women [74]. In a well-controlled age matched analytical study Enzlin et al. reached the conclusion that sexual problems are frequent in women with diabetes mellitus. Among the sexual function variables, “libido”, lubrication, orgasm and genital pain only decreased lubrication was significantly (univariately) associated with being diabetic. [155] Moreover, women with “more” diabetic complications reported significantly more sexual dysfunctions. However, more recent large epidemiological studies conducted on women representative of the US 2005 census, Brazilian women, and Australian women, did not find a significant relationship between diabetes and desire, arousal, or orgasm. [37, 70, 156-157]

d) Urinary tract diseases

Stress urinary incontinence has been found by Osborn et al. [64] to negatively influence all aspects of women’s sexual function (sexual interest, desire, arousal, lubrication, orgasm) and to be significantly
correlated with dyspareunia and vaginismus. In a small scale analytical investigation [160] urinary stress incontinence was (unvariably) significantly associated with sexual interest, lubricative insufficiency, orgasmic dysfunction and dyspareunia. Along these lines, Laumann et al. found that having urinary tract symptoms were predictors of lubrication insufficiency, orgasmic dysfunction, and dyspareunia while ever having had STI (sexually transmitted infections) was a negative predictor for sexual interests and for lubricative function [20].

e) Gynaecological factors

Hysterectomy has in a few epidemiological studies been found to affect women's sexuality. Dennerstein et al. [73] found that 16% of surgical menopausal women had low sexual desire compared to 7% of menstruating women and the former being more likely to feel distressed. Hormonal therapy improved levels of desire but did not change distress. Furthermore, Shifren et al. [70] reported, despite desire, arousal and orgasm function were lower among women who were hysterectomized. Similarly, McPherson found that sexual arousal, but not vaginal dryness, was impaired in women who received hysterectomy as compared to women with oophorectomy. [161]

f) Psychiatric/psychological factors

There is little doubt that part of the psychological distress experienced by individuals with mood or anxiety disorders affects sexual function. Unfortunately, research on the epidemiology of sexual dysfunction has yet to provide information on the commonality between psychological vulnerabilities that are associated with sexual disorders. By latent class analysis Laumann et al. [20] deduced that emotional problems or stress are sizeable predictors of low desire, arousal disorder and sexual pain (all three defined according to the DSM-IV).

Ten years ago Dunn et al [119] demonstrated significant likelihoods (Odds ratios ranging from 1.8-4.5) depression and anxiety to predict all their investigated parameters: arousal, insufficient lubrication, orgasmic dysfunction and dyspareunia. Accumulating evidence [64, 70-72, 74] confirmed these associations between anxiety and depression with sexual dysfunction. An interesting study by Sievert et al [162], however, with a response rate of only 29%, found that loss of desire for women under the age of 40 correlated with depression symptoms; for women in the age-cohort 40 to 60 with menopausal symptoms and for those older than 60 with somatic and psychological problems – a mutual denominator could be mood changes/depressive symptoms.

The effect of different antidepressants giving negative “changes in sexual function” were, by Clayton et al [163,], found to be significantly more likely to occur (Odds ratios 2.2-2.9) with SSRIs (selective serotonin re-uptake inhibitors) or venlafaxine than with buprion or netazodone in women and men on monotherapy. Moreover, the WHO collaboration center for international drug monitoring has reported that out of a total of nearly 215,000 reported adverse effects of antidepressant during the period 1968-1997, 5000 were sexual in nature. [164] Using the somewhat outdated response cycle phase definitions, about 1500 adverse reactions were related to each of the “desire” and “excitement phases”, while 200 occurred during the “phase of orgasm”. The most typical female SSRI adverse reaction was orgasmic dysfunction. Although the sheer number of reports to the WHO is great, these anecdotal reports cannot be taken as evidence.

g) Social stressors as risk factors

Some epidemiological investigations have addressed the impact of sexual abuse on women’s sexual behaviour and it has been clearly shown that women’s current sexual life can be detrimentally influenced by abuse. [20, 38, 74, 119, 165, 166] Studies that ask people to self-identify as sexual abuse survivors usually report lower rates of sexual abuse as compared to studies that utilize behavioural definitions. [167] Having ever been sexually forced by a man predicts low levels of desire and greater arousal disorder in American women. Also, having ever been sexually harassed predicted arousal disorder and sexual pain [20]. In Sweden, 12% of 18-74 year old women had at some time of their life been sexually abused [165]. Women with a history of sexual abuse had a significantly higher number of sexual dysfunctions than had women with no history of abuse and nearly all different types of sexual abuse were significantly (univariately) associated with orgasmic dysfunction. Having been genitaly abused was also significantly associated with low level of sexual interest. Satisfaction with sexual life was lower in those who had been abused and, in particular, if abused more than once. Furthermore, data from the same representative Swedish sample showed that obesity was not associated with a history of sexual abuse and sexual satisfaction. In Moroccan women [24] having been sexually abused negatively influenced sexual interest. Interestingly, only one study reported rates of sexual function among men with a history of child sexual abuse [38] and they found a less strong relationship between sexual abuse and sexual function compared to the relationship observed in women.

Incidentes of emotional and physical abuse during childhood are highly coremorbib with a history of sexual abuse and some studies have found initial evidence of a stronger relationship between emotional and physical abuse and sexual function as compared to sexual abuse [168]. No epidemiological studies that
we know of have examined this research question which requires the simultaneous assessment of different types of childhood trauma along with measures of sexual function.

Being single is (univariately) associated with dysfunctions of sexual interest, vaginal lubrication, orgasm and with dyspareunia [65]. Low levels of sexual interest, arousal, orgasm and also dyspareunia are significantly most common in women with marital difficulties [64, 119]. There is a close relationship between male partner’s sexual dysfunctions and women’s own dysfunctions; particularly if distressing [19]. Furthermore, low levels of overall sexual satisfaction and satisfaction with partner relationship predict low level of satisfaction with life as a whole. (See Table 7) In a large-scale-analytical epidemiological investigation of a gynaecological sample, Raboch and Raboch reported that a number of “intra-familiar” aspects of life (early loss of mother and father, not having a happy childhood, having three or more siblings or not having a happy marriage) univariately were significant features of women with orgasmic dysfunction, in particular if the dysfunction caused personal distress [169]. In Morocco, relatively low education is common in women with low level of sexual interest [24]. This is also the case in the USA [20] and in Eastern Europe [169] for orgasmic dysfunction and, additionally, in the USA for dyspareunia [20]. In the USA women with more than 20% financial household decrease during the year prior to the investigation have low level off interest and lubrication and also relatively high prevalence of dyspareunia [20]. Furthermore, stress at work or unemployment have been reported to accompany low sexual desire in women [170,171] but was associated with a higher desire of foreplay in French women. [171]

2. RISK FACTORS FOR MEN

a) Age, Health and Social Related Risk Factors

Less than good overall health is likely to concur with men’s low level of sexual interest/desire and with ED [20, 65]. Furthermore, Laumann et al [20] identified a (significant) odds ratio of 2.4 for the likelihood of poor to fair health being a predictor of early ejaculation. Also Richters et al [37] reported that Australian men who are not in excellent or good health are most likely to have a sexual dysfunction (not further specified). Having been sexually touched before puberty predicts lower level of interest/desire (odds ratios 2.2), ED (odds ratios 3.1) and early ejaculation (odds ratios 1.8). [20] Moreover, men who ever have forced a woman sexually are more likely (odds ratios 3.5) to have ED than are those who never have done so. Neither of these two descriptive investigations has found ejaculatory disturbance correlates of sexual abuse. Both in the USA [20] and in Sweden [65] partnerless men are more likely to have low levels of sexual interest/desire and of ED than are those who have a steady partner relationship. In the USA relatively low level of educational attainment is associated with early ejaculation. [20]

The Health Professional Follow-up Study (HPFS) is a cohort of male dentists, optometrists, osteopaths, podiatrists, pharmacists, and veterinarians in the United States who responded to a mailed questionnaire in 1986 (original response rate 32%). This U.S. study of prevalence and risk factors for erectile dysfunction found a 10-fold difference in relative risk for erectile dysfunction associated with older age, regardless of health status or previous erectile function. [145] Follow-up questionnaires were mailed every two years. At the time of the 2000 questionnaire, 43,235 men, age 53 to 90 years, were alive and actively participating in the study. The questionnaire was mailed up to four times to non-respondents with a response rate of 79%. This group of 31,742 health professionals, with no known history of prostate cancer, ranged in age from 53 to 90 years at the time of the 2000 questionnaire. Men in the oldest age group were less likely to be married, smoke, or engage in physical activity and were more likely than younger men to have comorbid conditions. When men with prostate cancer were excluded, the age-standardized prevalence of erectile dysfunction in the previous 3 months was 33%. Men with a healthy lifestyle and no chronic disease had the lowest risk for erectile dysfunction; the greatest difference was seen for men 65 to 79 years of age. Comorbid conditions, such as diabetes, cancer, stroke, and hypertension, were also associated with increased risk for erectile dysfunction, whereas physical activity, leanness, moderate alcohol consumption, and not smoking were associated with decreased risk. Men included in this study had lower rates of obesity and less diabetes than same-age men in the general population. In addition, participants in our study were more likely to be white, have higher educational attainment, have higher incomes, and have better health care access than similar-age men in the general population. Therefore, the findings probably reflect a more favorable profile for sexual function across the life course compared with the general population. The study found an inverse association between physical activity and erectile dysfunction. The study also found that younger men (<60 years of age) benefit more from exercise than older men (>80 years of age).

The National Social Life, Health, and Aging Project (NSHAP) is a nationally representative US probability sample of 1,550 women and 1,455 men aged 57-85 at the time of an interview. In this report the weighted response rate was 75.5%. [172] Data on sexual problems were collected through seven dichotomous response items inquiring about sexual problems experienced over several months during the previous 12 months. Items asked included lack of interest in
sex, arousal problems, too early climaxing, inability to obtain an orgasm, pain during sex, unpleasurable sex, and performance anxiety. There was little if any increase in sexual problems with age for either gender except for orgasm and erectile problems in men- both positively correlated with age. Hispanic women reported (OR=2.4) more reports of sexual pain compared to white women. Black men are more than twice as likely to report lack of sexual interest and premature climax (OR 2.3 and 2.90), and almost four times (OR=3.8) likely to report lack of sexual pleasure as white men. Lack of pleasure is sharply lower among widowed or never married (OR=0.1) than married men while divorced and separated men report twice as likely complaints (OR=2.0). Reports of anorgasmia and lack of sexual pleasure decline with men’s higher education in contrast to erectile problems which are sharply elevated (OR=1.9) among men with some college education. Health conditions strongly affect the likelihood of sexual problems in women but less among men, except an association between any lifetime history of STD’s and non pleasurable sex (OR=5.4) and between urinary tract syndrome and erectile problems (OR=3.7). Poor mental health is associated with both women’s and men’s reports of sexual problems; anxiety raising lack of sexual pleasure for men and women and depression selectively associated with men’s anorgasmia and erectile problems. Finally, satisfaction in a relationship was associated with fewer sexual problems. In the healthier, older respondents age patterns suggested maintenance of sexual capacity rather than decline. Increasing biological age does not result in more sexual problems for either sex except for men’s erectile and orgasmic problems. Sexual problems among the elderly seemed more a response to stressors in multiple domains of life from physical health to features of an intimate relationship.

Most epidemiological studies on ED underrepresented minority groups. In a cross-sectional population-based survey conducted between May, 2001 and January, 2002 facilitated equivalent representation was achieved for non-Hispanic whites (N=901), non-hispanic blacks (N=596) and Hispanic males (N=676) 40 years and older by using targeted phone lists to oversample the minority. [173] Overall prevalence rate for ED was 22%; 21.2% for whites, 24.4% for blacks and 19.9% for Hispanics, all categories increasing with older age. Overall sampled ED probability increased with diabetes, hypertension, and moderate or severe lower urinary tract symptoms (LUTS); in whites >70 years of age and diabetes; in blacks with severe LUTS; in Hispanics greater than age 60, moderate LUTS, hypertension, and depression. Probability of ED decreased with level of exercise, higher level of education overall; in blacks with exercise, good relationship quality and lower level of alcohol intake; in Hispanics with high school or college education.

Cross-sectional analysis of data from 2126 adult male participants in the 2001-2002 US National Health and Nutrition Examination Survey (NHANES). Erectile dysfunction assessed by a single question during a self-paced, computer-assisted self-interview. These data are nationally representative of the noninstitutionalized adult male population in the US. [174] The overall prevalence of erectile dysfunction in men aged 20 years and greater was 18.4% (95% confidence interval [CI], 16.2-20.7), suggesting that erectile dysfunction affects 18 million men (95% CI, 16-20) in the US. The prevalence of erectile dysfunction was highly positively related to age but was also particularly high among men with one or more cardiovascular risk factors, men with hypertension, and men with a history of cardiovascular disease, even after age adjustment. Among men with diabetes, the crude prevalence of erectile dysfunction was 51.3% (95% CI, 41.9-60.7). In multivariable analyses, erectile dysfunction was significantly and independently associated with diabetes, lower attained education, and lack of physical activity.

The National Health and Nutrition Examination Survey collect data by household interview. The sample design is a stratified, multistage, probability sample of clusters of persons representing the civilian noninstitutionalized population. Data include medical histories in which specific queries are made regarding urological symptoms (including ED). [175] These items were selected for analysis in 3566 men, 20 years and older. In men 20 years and older, ED affected almost 1 in 5 respondents. Hispanic men were more likely to report ED (odds ratio [OR], 1.89), after controlling for other factors. The prevalence of ED increased dramatically with advanced age; 77.5% of men 75 years and older were affected. In addition, there were several modifiable risk factors that were independently associated with ED, including diabetes mellitus (OR, 2.69), obesity (OR, 1.60), current smoking (OR, 1.74), and hypertension (OR, 1.56).

In the Boston Area Community Health (BACH) Survey ED was assessed in 2,301 men aged 30-79 using the 5-item IIEF-5 (defining ED as a score ≤16). [176] Overall prevalence of ED was 20.7% with a higher rate among blacks (24.9%) and Hispanics (25.3%) compared to whites (18.1%), even after adjusting for age, comorbid conditions, and behavioral risk factors. However after controlling for socio-economic factors the association between race/ethnicity and ED disappeared.

b) Smoking or Other Tobacco Use

It is logical to assume that erectile function, a process which relies on normal arterial vascular performance to operate correctly, would be adversely affected by cigarette smoking. A recent review on cigarette
smoking and erectile dysfunction appeared in 2008. [177] In that article epidemiological and clinical data as well as a discussion of causative factors are well reviewed. In a previous literature review, McVary et al presented the results of an exhaustive review of the literature conducted by the Subcommittee on Smoking and ED of the Socioeconomic Committee of the Sexual Medical Society of North America. [178] These authors found strong indirect evidence that smoking may affect erections. Their conclusions were: “Available evidence on the association of smoking with ED is not complete insofar as association is likely due to the consistency of the relationship of smoking and endothelial disease, and the strength of the association of ED with other endothelial disease”.

Tengs and Osgood performed a complete Meta analysis of available literature over the last 20 years prior to 2001 by searching MEDLINE to identify the prevalence of smoking among impotent men. [179] These authors reviewed over 1000 articles and identified 19 that reported the smoking habits of 3819 men. They found that 16 of these articles, including the 6 largest studies, found the prevalence of smoking to be higher than in the general population. Their meta-analysis revealed that 40% of impotent men were current smokers, which they compared to 28% of men in the general population. These authors concluded that: “Based on almost 2 decades of evidence, tobacco use is an important risk factor for impotence. Anti-tobacco advertisements featuring impotence as a reason to avoid or cease tobacco use are well grounded in scientific fact”.

In the previous consultation there were two articles cited that did not find increased risk for ED in association with smoking. Mak et al performed a population-based study in Belgium. [128] These investigations interviewed a random sample of the population, which included 799 men aged 40 – 70 years. They did not find a correlation between smoking and ED, either in current smokers or in ex-smokers. Similarly, Morillo et al reported on the prevalence of ED in Columbia, Ecuador and Venezuela. [140] This study questioned 1946 randomly selected men aged 49 and older. Using univariate analysis, the authors did not find any association of cigarette smoking with ED.

There were two studies in cross-sectional populations and one in a special clinical population of diabetics included in the last consensus chapter that found a positive correlation between smoking and ED. Miron et al performed a cross-sectional study on the prevalence and risk factors for ED in the general population in Italy. [180] This random sample included 2010 men from the practices of 143 general practitioners. The researchers found that current smokers had an odds ratio of ED of 1.7 (95% confidence interval 1.2-2.4) compared to never smokers. Ex-smokers had an odds ratio of 1.6 (95% confidence interval 1.2-2.3). The authors also found the association of smoking and ED risk to be present in men without a history of any cardiovascular disease, cardiopathy, hypertension diabetes and neuropathy. Nicolosi et al studied the epidemiology of ED in four countries. [146] The countries that were included in the study were Brazil, Italy, Japan and Malaysia. From each country, a random sample of approximately 600 men between the ages of 40 and 70 were interviewed. The authors found an odds ratio of ED of 2.12 (95% confidence interval 1.26-3.56) in men who smoke >30 cigarettes/day compared to men who did not smoke. Bartolotti et al reported on 9670 diabetic men who were categorized as: never smokers (30%), current smokers (30%), or ex-smokers (40%). [181] These participants were randomly selected from 178 different diabetic centers in Italy. The effect of age was considered when the results were analyzed. These researchers found that current smoker had an odds ratio of ED of 1.4 (95% confidence interval 1.3-1.6) compared to never smokers and ex-smokers had an odds ratio of 1.5 (95% confidence interval 1.3-1.6) compared to never smokers. The authors further found that in ex-smokers, the risk of ED was inversely related to the number of years since the patient quit smoking.

A recent epidemiological study of high evidenced-based criteria attempted to identify the association between cigarette smoking and ED and further analyzed the data by adjusting for presence or absence of cardiovascular disease. [182] The Western Australia Men’s Health Study (WAMHS) is based on a stratified sample of the male population obtained from the Western Australia (WA) electoral roll for June 2001. This publication was based on 1,580 participants who had returned their questionnaires and included smoking data and year of birth (89.3% of those returning the questionnaire). The report demonstrated statistically significant increases in the odds of ED among current smokers compared with never smokers even after adjustment for age and cardiovascular disease. Although not statistically significant, the corresponding odds among ever smokers and former smokers were also increased implying a possible adverse effect of previous smoking on erectile function. Cardiovascular disease did not confound the relationship between smoking and ED. This study also suggested that cessation of smoking before middle age may avoid the increase in the risk of ED.

Most studies who report on the association of smoking and ED contain populations with other diseases that are clear risk factors for ED. However, a study of 7,684 Chinese men showed that smoking was associated with ED in men without clinical vascular disease. [183] The same study also demonstrated increased odds of those men who smoked more than 20 cigarettes per day. A. dose
related association has been also reported in other studies. [184, 185] It has also been shown that the magnitude of the association between smoking and ED decreases across increasingly older age groups, suggesting that smoking may have a more apparent impact on erectile function in young rather than older smokers. [186]

Thus it would appear that the preponderance of evidence available at this time would identify cigarette smoking as an independent risk factor for ED. We have, on the other hand, not identified descriptive or analytical literature which links smoking to other male sexual dysfunctions or to any female sexual dysfunctions. Those of us who are clinicians, should use and expand this information to enlighten our patients and to encourage them to add ED to the long list of reasons why they should strive to quit smoking.

c) Diabetes Mellitus

From the Netherlands, Enzlin et al reported that men with complications of type I diabetes had significantly greater prevalence of decreased desire than had those without complications [187]. This was also the case for prevalence of orgasmic dysfunction. Diabetes mellitus has also been associated with retrograde and anejaculation. [188]

Erectile dysfunction has been reported to occur in at least 35-90% of men with diabetes mellitus with the onset of ED occurring in an earlier age (10 to 15 years before) than those without diabetes mellitus [189-202]. In the MMAS study, the age-adjusted probability of complete ED was three times higher in men who reported having treated diabetes mellitus than those without diabetes. [26]

Weinhardt and Carey in 1996 published a comprehensive review of empirical literature, regarding the prevalence of ED among men with diabetes mellitus; they suggest that 26-35% of diabetic men will develop ED. They present an excellent discussion of the methodological limitations of published research and make suggestions for changes to produce more reliable and useful information [203]. Whitehead and Klyde reviewed a large amount of the associations between ED and diabetes mellitus in their literature review of 1990 [189]. Some of their observations are reported in Table 8.

In a separate paper from the Health Professionals Follow-up Study (HPFS) included in the prevalence of ED table, Bacon et al report on the association of type and duration of diabetes with ED in this large cohort of men [204]. Men with diabetes had an age-adjusted relative risk of 1.32 (95% CI 1.3-1.4) for having ED compared to men without diabetes. Men with type 2 diabetes had an increasingly greater risk of ED with increased duration since diagnosis, particularly for men diagnosed >20 years previously. In 178 diabetic centers in Italy, data was collected using interviews regarding erectile dysfunction in 9,868 men [205]. The patients ranged in age from 20 to 69 years. The prevalence of ED was 35.8% for the entire group, ranging from 4.6% for men 20-29 years of age to 45.5% for men 60-69 years of age. For men with insulin dependent diabetes mellitus, diabetes present for over ten years, with fair or poor control based on glycosylated hemoglobin 7.5-9% and > 9% respectively, those managed with agents other than diet control, and history of diabetes mellitus-related arterial, renal, or retinal disease and neuropathy and those who were smokers, all showed a higher odds ratio for ED.

A subset of 1,010 of these men from the Italian group above without ED at baseline were followed prospectively for 2.8 years to determine the incidence of ED associated with diabetes [206]. The crude incidence rate was 68 cases per 1000 men years (95% CI 59-77). The incidence of ED increased with increasing age, duration of diabetes, and deteriorating metabolic control. The rate was higher for type 2 than in type 1. The relative risk increased

---

Table 8. Associations of Diabetes Mellitus (DM) with Erectile Dysfunction

| - Erectile Dysfunction is usually present within 10 years of diagnosis of DM |
| - Usually occurs at a younger age group in insulin dependent DM |
| - ED may be first sign of DM in as high as 12 % of cases in males |
| - Poorly controlled DM may produce a reversible temporary ED once controlled |
| - ED in almost all patients with DM related neuropathy |
| - DM macrovascular complications related to neuropathy |
| - DM microvascular complications related to duration of DM and glycemic control |

also with obliterative arterial disease of the lower legs, ischemic heart disease, renal disease, autonomic neuropathy, sensation and motor neuropathy, and diabetic foot and retinal disease. The Massachusetts Male Aging study reported ED incidence of 51 cases/1000 man years [28]. Also, the incidence rate of erectile dysfunction is higher for each decade of diabetic men compared to non-diabetics, up to twice expected in the general population without diabetes mellitus.

Diabetic men with sexual dysfunction, including ED, are older and have a longer duration of diabetes [199, 200, 204, 205]. ED in men with diabetes is more severe and associated with poorer quality of life [175, 194] and poor glycemic control [200]. Hyperlipidemia, hypertension, and obesity are conditions common in diabetic men and also independent risk factors for ED.

Interestingly, Gazzaruso et al. [207] reported that ED itself could be considered the most efficient predictor of silent coronary artery disease in a diabetic population, independently of glycometabolic control and ED severity. In particular, among a consecutive series of 160 subjects with apparently non-complicated type 2 diabetes, they demonstrated that the prevalence of ED was 7-fold higher (35% vs 7%) in subjects with silent coronary artery disease. Similar results were confirmed during longitudinal studies by the same group [208] and other authors. [209] Accordingly, Corona et al. demonstrated that penile vascular insufficiency was inversely related to the risk of silent coronary artery diseases in the diabetic population. [210]

In a recent publication, Rosen and others report an analysis of risk factors in a subset of 373 men of the look AHEAD trial of type 2 diabetes [199]. Of these 373 men 268 were sexually active (68.7%). About 75% of these 373 men had mild, moderate, or severe ED using the erectile function domain of the IIEF (65% of the sexually active men). Of the sexually active men 42.5% had consulted with a physician about sexual problems. Only 7.3% of the sexually active men had severe ED. Risk factors influencing ED were the following: the existence of metabolic syndrome, hypertension history, and other cardiovascular disease. Men with improved levels of fitness were about 40% less likely to have ED. Cardiorespiratory fitness was measured by a symptom-limited graded exercise treadmill test to voluntary exhaustion [199].

d) Obesity metabolic syndrome and erectile dysfunction.

Until the last decade, the risk associated with overweight and obesity had been widely underestimated. Large prospective epidemiological investigations including the Framingham [211], the National Health and Nutrition Examination Surveys [212] and the Prospective Cardiovascular Munster studies [213] have clearly demonstrated that overweight and obesity are independent factors associated with an increased mortality in men and that this is due largely to coronary atherosclerosis or other cardiovascular diseases. Moreover, the same studies have shown that the prevalence of obesity has dramatically increased both in the US [211, 212] and Europe [213] creating a new important burden for the medical community.

The link between obesity and male potency dates back to the Byzantine era, when it was thought that a large stomach impaired a man’s ability to have sexual intercourse. [214] So far, however, the association between obesity, sedentary lifestyle and erectile dysfunction (ED) has not been completely clarified. [215, 216] Baseline data from the Massachusetts Male Aging Study (MMAS) failed to find any association between BMI and ED. [26] More recently, cross-sectional analysis of data from the NHANES survey [174], involving 2126 non-institutionalized men representative of the US adult male population, demonstrated an attenuated association between obesity and ED after adjustment for cardiovascular risk factors. However, longitudinal studies have clearly demonstrated a direct association between these conditions at baseline and the subsequent development of ED. [49, 217] In particular, the Health Professionals Follow up Study [145], including 22,086 US health professional men, showed that after a 14-year follow-up study period, ED was most likely to occur in men who were obese (OR=1.7 [1.5-2]) and who lived a sedentary lifestyle (OR= 0.7 [0.7-0.8] for subjects with physical activity greater than 32.6 vs. less than 2.7 METs/week). In addition, prospective data from the MMAS demonstrated that cigarette smoking and BMI significantly predicted the risk of developing ED even after controlling for confounding factors. [28, 218]

Yet how obesity affects ED is not entirely clear. Early endothelial dysfunction and impaired nitric oxide synthesis, necessary for stimulating smooth muscle relaxation and increased blood flow which is in turn necessary for erection, have been considered the major associated pathogenetic issues. [215-216, 219-220] Corona et al. [214] recently confirmed this hypothesis in a large cross-sectional trial including 2,435 male patients seeking treatment at an outpatient clinic for sexual dysfunction between 2001 and 2007. The results of this study showed that obesity was significantly associated with a higher physical contribution to ED, while there was no difference seen among relational or psychological determinants. As the severity level of obesity increased, penile blood flow decreased (one half of patients with morbid obesity had pathological penile blood flow). In addition, as previously reported [215-216, 219-220], an inverse association between testosterone levels and BMI was also found. In these
patients, hypogonadism can exacerbate sexual dysfunction because of its typical symptoms, such as decreased sexual desire and mood disturbances [214-216, 219-220]. This evidence might be a useful motivator for men to improve their health-related lifestyle choices. Accordingly, Esposito et al. [221] in a randomized trial in obese men, has shown that decreasing BMI and increasing exercise significantly improved ED in approximately a third of cases suggesting that lifestyle changes can reverse ED. Kratzik et al [222] demonstrated that the risk of severe ED is decreased by 82.9% for males with physical activity of at least 3000 Kcal/week. In addition, the same authors reported that an energy expenditure of as little as 1000 Kcal/week significantly reduces the existing risk of ED. Some examples would be bicycling 4 miles (6.4 km) in 15 minutes, social dancing for 30 minutes, running 1.5 miles (2.4 km) in 15 minutes or gardening for 30-45 minutes. [222]

Furthermore, a Mediterranean diet based on olive oil as the major fat source and including more fish, legumes, vegetables and fruits has been recommended as an extremely successful and conservative way to treat obesity since the time of Greco-Roman writers. [223] A large body of evidence has demonstrated that a greater adherence to a Mediterranean diet is associated with a significant improvement in health status, as well as a significant reduction in overall and cardiovascular disease mortality. [224] Hence, in line with these data, the protective role of a Mediterranean diet on erectile function is not surprising. [225] In addition, both clinical and experimental studies have confirmed that combining physical exercise with the reduction of caloric intake provides additional benefits to erectile function. [226]

Recently, it has been reported that central obesity (high waist circumference) may be a better predictor of increased cardiovascular risk than obesity per se [227]. Although this issue is under debate, Cornier et al [228] demonstrated that waistline should be considered at least the best predictor of medical care costs. Central obesity is a key element of metabolic syndrome (MetS), a cluster of metabolic abnormalities related to a state of insulin resistance and an increased risk of developing cardiovascular and metabolic diseases [216, 227]. Although several definitions for MetS have been proposed [216], the criteria defined by the National Cholesterol Education Program-Third Adult Treatment Panel (NCEP-ATPIII) are the most widely used in clinical practice and research. Recently it has been demonstrated that not only the individual components of MetS but also MetS itself is significantly associated with ED. [215-216, 229-230] In addition, prospective data from the Massachusetts Male Aging Study in a population-based cohort observed at three different time points over approximately 15 years showed that ED could also be predictive of MetS with an unadjusted relative risk of 1.35. [231] The prevalence of ED in subjects with MetS ranges from 27% [232] to 80% [233] strictly associated with the number of MetS components and the endothelial function impairment. [215-216, 229-230]

In particular, among subjects with ED, those with MetS are characterized by the worst erectile function, (essentially due to impairment in penile blood flow) and report a prevalent difficulty in obtaining vs. maintaining erection, a gradual onset of the disorder, and a decreased number of nocturnal erections, all of which were demonstrated to be associated more with an organic than a psychogenic origin of ED. [234-236] Corona et al., [234-236] demonstrated that elevated blood pressure and hyperglycaemia, which are well known cardiovascular risk factors, are associated with impaired penile vascular flow to a greater extent than the other components of MetS. The association between hypogonadism and MetS is emerging even in subjects with ED. [215-216, 219-220, 229-230] Abdominal adiposity and hyperglycaemia [215-216, 219-220, 229-230] represent the most important factors involved in the pathogenesis of hypogonadism in MetS. The presence of hypogonadism in men with MetS increased symptoms of sexual dysfunction such as low sexual desire. [215-216]

**Recommendation 9:**

There is still a question whether obesity and the metabolic syndrome per se are additional risk factors for erectile dysfunction or that the diseases cardiovascular and diabetes themselves that are part of these conditions are the risk factors that account for this association. Further research is needed to answer this question. Grade C.

c) Cardiovascular Disease and Hypertension

Endothelial dysfunction is a condition present in many cases of erectile dysfunction and thus there is a common etiologic pathway for other vascular disease states, such as cerebrovascular accidents, myocardial infarction, heart disease, hypertension, hyperlipidemia, low serum levels of high density lipoproteins (HDL), arteriosclerosis, and peripheral vascular disease and thus an association with these other conditions is to be expected. Wabrek and Burshell reported that 64% of 131 men, aged 31 to 86 years, hospitalized for acute myocardial infarction were impotent. [237] Sjögren and Fugl-Meyer reported an 18% prevalence of ED in 49 men before experiencing a myocardial infarction compared to a prevalence of 45% after the event, with a 43% new onset or increase in ED in this group of men. [238] These authors also found that low level of sexual desire increased after myocardial infarction from 14% to 35% and orgasmic problems from 4%
to 25%. In fact 21% reported anorgasmia after the myocardial infarction. In another study ED was present prior to myocardial infarction (MI) in 64% of 131 men and before coronary bypass surgery in 57% of 130 men [239]. In still another study of 132 men attending day case angiography, 40% had experienced ED before their coronary diagnosis had been made. [240] In addition, Montorsi et al. [241] demonstrated that, in subjects with angiographically document coronary artery disease, ED becomes evident prior to angina symptoms in almost 70% of the cases, with a mean interval of more than three years. Accordingly, Thompson et al. [242] in the Prostate Cancer Prevention Trial, reported that incident ED was associated with a 25% increase in risk of subsequent CV events, during a nine year follow-up, after an adjustment for confounders.

Treated heart disease (worse in smokers), treated hypertension (again, worse in smokers), and low serum levels of HDLs were significantly correlated with impotence in the MMAS report. [26] Values of HDL more than 90 mg/dL were associated with no probability of complete ED and conversely when the level of HDL dropped to 30 mg/dL the probability of complete ED was 16%. Complete ED was present in 15% of men with treated hypertension and this incidence was associated with the duration and severity of the hypertension in the MMAS report, as well hypertension increasing the age-adjusted incidence of ED. In another study the prevalence of ED was not increased among hypertensive and pre hypertensive men compared with normotensive men aged 25-40 years. [243] These authors concluded that it takes years for hypertension to cause ED in this generally healthy and younger group of men. Wei et al [53] found that a high level of total cholesterol and a low level of HDL are important risk factors for ED. In an analysis of the two MMAS studies of 1987-89 and 1995-97, it is suggested that ED and coronary heart disease share some behaviorally modifiable determinants in men who are free of manifest ED or predisposing illness at baseline. [244]

Since the last publication of this chapter there has been a stress on the association of cardiovascular disease and risk factors and ED. It is now thought that ED may be a harbinger of silent coexistent or subsequent coronary artery disease. [245, 246] Almost all of the cross-sectional studies tabulated in Tables 6A-F that collected data on coexistent cardiac disease or risk factors found increased prevalence of ED compared to those without these risk factors.

In a recent cross-sectional observational study the intimate nexus between ED and cardiovascular disease was presented. [247] In a group of 1,514 men with an age range of 20-99 years cardiovascular risk factors were more prevalent with increasing age and among participants with ED and severe ED. The age-adjusted odds of ED were significantly higher among men with hypertension (OR= 1.47), ischemic heart disease (OR=1.8), and stroke (OR=1.47). With these latter three conditions and peripheral arterial disease in combination in patients grouped together as cardiovascular disease the odds ratio was 1.85. The age-adjusted odds for severe ED (IIEF-5 <8) was 2.62 in men with peripheral vascular disease with no significant odds ratio for ED in general (IIEF-5< 22). When diabetes mellitus, hypertension, and hyperlipidemic were present in the same patient the odds ration of ED was 3.21. The authors concluded that the relevance and importance of careful cardiovascular risk evaluation in men with ED could not be overemphasized. The authors also emphasized that the associations described in this paper are cross-sectional and that data concerning the interval between the onset of ED and the diagnosis of significant cardiovascular events or recognition of biomedical risk factors were unable to be addressed thus making the temporal relationship between ED and cardiovascular disease and risk factors unanswered.

**Recommendation 10:**

Although the association of ED and Cardiovascular disease and risk factors are well established there is a need for longitudinal studies in patients who have manifest ED or cardiovascular disease and do not have the opposite manifest associated condition in order to establish a temporal relationship between these two entities. **Grade C.**

**I) Hormonal or Endocrine**

The effect of androgens on desire/interest and sexual behavior is well established but few reports show direct end organ, corpora cavernosa, dependency on androgens, except the early growth and development of the male reproductive tract. [248-250] Carani et al [251] did show increased rigidity as measured by rigi-scan in eugonadal men treated with androgens but no change in frequency of NPT associated events nor duration of circumference change, suggesting an enhancement of corpora cavernosal function in response to androgens. In a study by Becker et al, [252] systemic and cavernous plasma levels of testosterone were found to be elevated during erection and with flaccidity and detumescence states, cavernous levels were significantly lower than systemic levels suggesting corporeal binding of testosterone in the cavernous spaces.

Primary or secondary hypogonadism is often associated with erectile failure but not always. This may be due to a low threshold of androgens necessary for cavernosal tissue function, perhaps even at levels that can be maintained by the adrenal androgens in the face of lack of testicular androgens. [253, 254] Hormonal dependency for erection seems to vary for erections produced by different situations,
during rapid eye movement sleep, with visual sex stimulation, or fantasy or sexual situation induced erections. [255-257] Severe low levels are necessary to suppress sleep-related erections, with moderate low levels affecting sexual situation with partner erections, and erections induced by visual sex stimulation not showing much androgen dependency. An article that demonstrates this last point and also the variation in androgen dependency for different types of erection was that by Greenstein et al in 1995. [258] Four, all who had surgical castration, of sixteen men who were surgically or medically castrated, had erection produced by a visual sexually stimulated film, and none were able to have erectile activity in a partner sexually induced situation. These four men had significantly, but yet still at castrate levels, higher levels of testosterone than the men unable to respond to the visual stimulation. Similarly Bancroft and Wu [259] had shown that androgen replacement in hypogonadal men improved erectile response to fantasy (as well as reported sexual acts per week at home) but erections in response to erotic films were not significantly different from normal controls either before or after androgen treatment. Another study showed the futility of using testosterone therapy in those patients with testosterone in the low range of normal to improve erectile function and suggests that testosterone has to be at extremely low levels to effect sexually related erections or nocturnal sleep erections. [260]

As far as epidemiological studies go, the MMAS study constitutes the largest male endocrine database available, by including reliable measurement of 17 hormones. Interestingly, testosterone (total, free, or albumin bound) or dihydrotestosterone (DHT) levels did not significantly correlate with erectile dysfunction. Of the 17 hormones measured, none, with the exception of dehydroepiandrosterone sulfate (DHEAS), correlated with erectile dysfunction. DHEAS levels of 0.5 mgm/ml were associated with a high probability of complete ED (16%) compared to DHEAS levels of 5 and 10 mgm/ml (6.5% and 3.4% respectively). [26, 254] However probabilities of complete impotence increased as DHEAS levels decreased while the overall and moderate ED probabilities remained unchanged. Such patterns support the hypothesis that minimally impotent men may become completely impotent if their DHEAS levels decrease from 10 to 0.5 mgm/ml level. Despite this evidence, Placebo controlled, randomized double blind studies have shown that DHEA administration is not useful for improving sexual dysfunction in men. [261, 262]

The weak relationship between low T and ED is supported by results from both human and animal studies. [263, 264] Rhoden et al [265] on a consecutive large series of almost 1000 elderly subjects, with or without ED, have documented a lack of association between T and International Index of Erectile Function (IIEF-5).

Severe hyperprolactinemia (PRL > 735 mU/L or 35 ng/mL) but nor milder form has a negative impact on sexual function, impairing sexual desire - as well as erectile function - and testosterone production. [266-268] In particular, it has been reported that in subjects with sexual dysfunction, a severely reduced libido is associated with a 10-fold increase in the prevalence of severe hyperprolactinemia. [270] A PRL-induced hypogonadism could explain, only partially, this association [266-268] since PRL plays also a direct role in the control of male sexual desire. Accordingly in hypogonadal subjects with hyperprolactinemia, prolactin-lowering drugs are able to restore both testosterone levels and libido [268], while testosterone replacement therapy is not as effective. [270] The relationship between hyperprolactinemia and erectile function is under debate. Some Authors have suggested a possible pathogenetic link between severe erectile dysfunction (ED) and severe hyperprolactinemia [271] although even negative associations have been reported. [269, 272] In addition, controlled studies evaluating the effect of dopamine agonists on ED subjects with hyperprolactinemia were inconclusive. [268]

g) Urinary tract diseases and Lower Urinary Tract Symptoms (LUTS)

Chronic renal failure is a risk factor for ED. [273] There were two high Prins score studies that looked at ED in patients seen in dialysis clinics and rates for ED were high for all ages almost all above 50% however stratified. [274, 275] In the USA general urinary tract symptoms predicted ED (odds ratio: 3.1), but not other investigated parameters (desire, ejaculation) of male sexual function. [20] These findings principally agree with those of Blanker et al from the Netherlands. [79] The latter also, in their sample of 50-78 year old men identified lower urinary tract symptoms (LUTS) as concurrent with ejaculatory dysfunction – defined as no ejaculation or significantly reduced ejaculatory volume - The odds ratios for the likelihood of moderate and severe LUTS as compared with no such symptoms to concur with ejaculatory dysfunction being as high as 3.8 and 7.8, respectively.

A number of studies from clinical and community populations have shown that the prevalence of ED and reduced sexual desire along with other types of sexual dysfunction is greater in men with LUTS. [276-282] Most of these studies have also shown that the presence of LUTS is an independent risk factor for sexual dysfunction. Moreover there is a positive correlation between severity of LUTS and severity of ED. [276, 277, 279, 281] Decreased sexual satisfaction as well as sexual activity are associated with increasing severity of LUTS. [276, 277] Recently there was a report in the literature
of the first multinational population-based study to evaluate the relationship among those with overactive bladder (OAB) and ED, and also sexual quality of life. [283] 502 cases of OAB were matched with 502 controls. Reduced sexual activity was 14% in cases versus 4% in controls. Those with OAB were significantly more likely to have ED than were controls (OR 1.5). Significantly more of those with OAB (15%) reported decreased enjoyment of sexual activity because of urinary symptoms relative to controls (2%). The perceived impact of OAB on the frequency of sexual activity, sexual enjoyment, and satisfaction appeared most pronounced in cases with urinary incontinence.

An excellent epidemiological study from Finland established the bothersomeness of LUTS symptoms and the prevalence of ED. [284] The target population were samples from Tampere and surrounding municipalities in Finland in 1999. Cohorts of men born in 1924, 1934, and 1944 comprised those studied. Adjusted odds ratios of ED were 2.6 for men with LUTS total scores of 11-19 compared to those without LUTS and 4.4 for those with scores of 20 or more comparing the two groups. For bother scores even low bother were significantly associated with ED.

**h) Other Chronic Diseases**

Polyneuropathy, which commonly involves autonomous dysfunction is another source of sexual dysfunction, particularly ED and ejaculatory dysfunction [285]. Thus, Vardi et al reported a 38% coincidence of polyneuropathy and ED in diabetics and a 10% coincidence of the two in non-diabetics. [286] Among other neurological conditions which may lead to male sexual dysfunctions are Parkinson’s disease. In these patients, decreased sexual desire and ED are common for still unknown reasons. [287-289] However, treatment with dopaminergic substance have been observed to increase level of interest/desire. Even the pathogenesis of the often reported ED is to date unclear. There is good clinical evidence that other chronic neurological disorders may affect sexual function. Thus, in seizure free periods, epilepsy can be associated with reduced sexual interest/desire and with ED. [285, 289] In a review article of genitourinary conditions associated with patients with multiple sclerosis the incidence of ED was reported to be 40-80%, usually occurring a half decade to a decade after onset of the progressive disorder. [290] In multiple sclerosis, ejaculatory dysfunction may, according to clinical reports, prevail in about 50% as the disorder progresses. [289]

In the USA Monga et al [291] In a retrospective study found a three fold increased prevalence of low sexual desire after stroke. Others have identified clearly smaller post-stroke changes in sexual interest/desire. [292, 293] In some contrast there appears throughout the clinical literature to be consensus that between half and two thirds of male stroke patients develop ED. Both early and delayed ejaculation have been described to emerge after stroke; but within in a very wide latitude. [291, 292] To which extent the profound sexual dysfunctions in these patients mainly are results of poor coping or are mainly somatogenic still remains to be elucidated.

Erectile dysfunction occurs in 90% of patients with multiple system atrophy, being the first symptom in 37% of the cases. [294] Other diseases and chronic disorders reported to have a risk for ED include sleep apnea, chronic obstructive lung disease [295], scleroderma [296], and Peyronie’s disease. [297] In a recent epidemiologic study of 70 patients who were candidates for a liver transplantation 52 (74%) had ED using IIEF-5 criteria. [298] This article is a good review of previous studies of this same link and discussion of the possible etiologic reasons for this association along with a review of effect of coexistent other medical conditions and social factors effecting this association.

Fitzgerald and others [299] remind all of the need to be aware of the effect of chronic disease on all urologic disorders including LUTS and ED. In bivariate analyses, most urologic and sexual symptoms were associated with type II diabetes, cardiac disease, hypertension, and depression. However, in multivariate models adjusting for all four illnesses, gender, race/ethnicity, age, alcohol intake, smoking, physical activity, and body mass index there were fewer significant associations. It was found that all urologic symptoms were significantly related to at least one illness, with depression increasing the odds of all urologic and sexual symptoms studied. Urinary tract specialists and sexual health professionals should consider factors outside the urinary tract that may be contributing to urologic symptoms. It remains unknown whether treatment of medical and psychological illnesses can result in meaningful improvement in urologic symptoms, or conversely, whether urinary tract symptoms can provide valuable insight into an individual’s overall health status.

**i) Surgery and Trauma**

Spinal cord injury patients are obviously at an increased risk for erectile and ejaculatory (anejaculation) dysfunctions with central induced erectile activity possible in those with lower spinal cord injury and reflexogenic erection possible in those with upper cord injury. Besides leading to fertility problems (the incidence of male spinal cord injury peaks at ages 15-30) these dysfunctions are among the most pronounced problems for the future quality of life in the quadriplegic or paraplegic men (for an overview see reference [285]). There is – to some extent anecdotal – data showing that both
men and women with complete spinal cord injury rostrally to peripheral genital innervation levels can experience orgasm elicited by stimulation of non-genital body areas and the majority of the men seem to have only minor dysfunction, if at all, concerning sexual interest/desire. Surgery or trauma affecting any level of neurologic control of erection or that interfering with the arterial supply of the corpora cavernosal tissue are unquestionably risk factors for erectile dysfunction. DePalma has reviewed the impact of vascular surgery on ED.\[300\]

From clinical experience, it is well established that ED and anejaculation are common after prostatectomy. There is, however, astonishingly little epidemiological data on this subject. Some four years ago Stanford et al \[301\] reported a high incidence (about 60\%) of post radical prostatectomy ED; whether or not the surgical intervention had been nerve-sparing. Other reports show higher retention of erectile activity after bilateral nerve sparing surgery in the younger male and in those with strong erectile activity before the surgery \[302, 303\]. Radiation therapy to the pelvis also is a source of damage to nerves involved in erectile and ejaculatory functions \[304\] while sexual functions remain stable after treatment for benign prostatic hyperplasia. \[305\].

Schrader et al in 2 studies showed a weak association between some parameters of erectile function and bike riding. \[306, 307\] In the first study 17 bicyclist men were compared to 5 non-cycling controls with nocturnal penile tumescence studies (NPT). The only difference between the groups was a statistical difference in the percentage of sleep time erections, 27.1 ± 9.7\% vs 42.8 ± 17.56 (p=.008). \[306\] Although traditional seats seem to clearly produce sensory deficits from prolonged bicycle riding, ED defects are weakly supported by evidenced based data. In the second study from Schrader et al, data regarding erectile function was available for 64 to 70 of 90 men who were studied at baseline, at which time traditional bicycle seats were used compared to using a no- nose saddle. This was a non-group controlled study with each man serving as his own control over the six months of the study. IIEF-5 was statistically better after 6 months (score of 29.12 vs 29.61 p= 0.015) – 72.7\% of officers scored a perfect 30 at baseline compared to 84.9\% at 6 months. No changes were noted in NPT data. \[307\]

\textbf{j) Psychiatric/psychological risk factors}

It is well established that disorders of the psyche may concur with male sexual dysfunction. There is valid epidemiological data on this subject. In the USA \[20\] emotional problems or stress were significant predictors of low level of desire (odds ratios 3.2), ED (odds ratios 3.6) and early ejaculation (odds ratios 2.3). The association of ED with depression is well established. \[26\] Using the Hospital Anxiety and Depression Scale (HAD) \[308\] Dunn et al \[119\] found that anxiety, but not depression, significantly predicted early ejaculation. Suppression and expression of anger indicate higher probabilities of moderate and complete ED \[26\]. Independently of medication, Araujo et al \[142\] demonstrated that depression is closely associated (odds ratios 2.0) with ED and as discussed elsewhere in this chapter many antidepressants may lead to sexual dysfunctions. This is particularly true for SSRIs, which are nowadays used for delaying early ejaculation.

\textbf{k) Medications and Recreational Drugs}

Erectile dysfunction due to prescription medications is sometimes difficult to prove and is probably often under-reported. In the MMAS, a statistically significant correlation between ED and vasodilators, anti-hypertensives, cardiac and hypoglycemic agents was noted. \[26\] However when the second analysis of the population was made in 1995-97, adjustments for comorbidities and health behaviors attenuated some medication associations with ED with only nonthiazide diuretics and benzodiazepines remaining statistically significant for association with prevalent ED. \[309\] Meinhardt and his co-authors have reviewed the influence of medication of erectile dysfunction in some detail. \[310\] Major classes of prescription drugs commonly reported to be associated with ED are histamine-2 receptor antagonists, hormones, anticholinergics, psychotropics and certain cytotoxic medications. Whether one type of anti-hypertensive agent is less likely to be associated with ED than another is difficult to pin down since the prevalence of ED is often an association with the hypertension condition as well. This debate is well discussed in two articles. \[311-312\] In an experimental rodent animal model of hypertension, data suggested that renin-angiotension system inhibition by enalapril, an angiotension converting enzyme inhibitor, may at least partially normalize penile vascular structure. \[313\] Calcium channel blockers and alpha adrenergic blocker theoretically may be the best alternatives, along with the angio-tension converting enzyme inhibitors, in attempting to reverse ED when associated with other anti-hypertensive agents. Rosen and others review sexual dysfunction problems with the selective serotonin reuptake inhibitors (SSRIs). \[314\] Trazadone is one antidepressant that is unlikely to be associated with ED and in fact has a risk of associated priapism. \[317\] In general, it is suggested that antipsychotics with strong alpha-1 receptor affinity properties be considered as substitutes for other prescription psychotropic drugs associated with ED. Life style related risk factors for ED include chronic alcoholism and chronic use of marijuana, codeine, meperidine, methadone and heroin. \[315\]

There are three recent reviews of the effects of psychiatric drugs on sexual function \[316-318\]
Tricyclic antidepressant and mono-amine oxidase inhibitors have been shown to be associated with delayed ejaculation in double-blind studies [319, 320]. Similarly, studies have shown that selective serotonin reuptake inhibitors (SSRIs) as well as venlafaxine are associated with anorgasmia and decreased libido. There is some evidence that a small number of men may experience erectile dysfunction as the result of SSRI therapy. [321, 322] Duloxetine [323], bupropion [324] and nefazodone [325] have low rates of sexual dysfunction. Most studies are consistent in finding that traditional antipsychotic drugs (for example, haloperidol, thioridazine) are associated with high rates of ejaculatory delay, decreased libido and/or erectile difficulties. [326] Risperidone also has a high rate of sexual dysfunction. [327] Quetiapine and olanzapine, appear to have lower rates of sexual side effects. [328] Most of the antipsychotic drugs and some antidepressants have been reported to be associated with priapism in isolated cases. The largest number of case reports concern thioridazine and trazodone. [329]

Corona et al. recently explored the relationship between the use of selective serotonin reuptake inhibitors (SSRIs), non-SSRIs antidepressants and benzodiazepines (BDZ), hormonal parameters and reported sexual dysfunction on consecutive series of 2040 attending their unit for sexual dysfunction [330]. The current use of SSRIs was associated with a 1.7 fold risk for any degree of hypoactive sexual desire (HSD), while the risk increased to two-fold when moderate/severe HSD was considered. Patients reporting the use of SSRIs showed lower frequency of intercourse and higher sense of guilt with masturbation. In addition, the use of SSRIs was associated with a significant impairment of erectile function and 3.4 fold risk of delayed ejaculation. Conversely, a lack of significant association was observed among BDZ or non-SSRI antidepressant users and all the aforementioned life-stressors and relational parameters.

I) The effects of modification of risk factors

Using data from the reassessment (1995-97) of a portion of the population without ED at baseline in the original MMAS study population (1987-89), an attempt was made to assess the effect of modification of certain risk factors associated with ED as decreasing the incidence of ED in this population. [331] Other chronic disease states were not present in this population at baseline, including men treated for heart disease or diabetes, history of prostate cancer, or those with incomplete data regarding chronic disease risk factors. The results of this analysis showed that a change in smoking status or change in heavy alcohol consumption did not decrease the incidence of ED. The average age at baseline in this population was 52 years of age and changes in tissue may not have been possible to reverse by middle age changes. Men originally obese at baseline seemed to have a higher incidence of ED regardless of the follow-up status. Sedentary behavior status was associated with developing ED with the highest risk of dysfunction for those who had maintained a sedentary life-style. The lowest level of risk for ED, for all factors analyzed, was in those subjects who initiated physical activity after qualifying as sedentary at baseline. Increasing physical activity, even in these men in their 40’s and 50’s, is effective for reversing other cardiovascular disease risk associations and this study seems to demonstrate a similar benefit for decreasing the chance of developing ED. Another lesson to be taken from this study is that modifiable risk factors may require earlier intervention than middle age.

There a very few data that support the notion that treatment of lifestyle risk factors may improve ED. Esposito et al [332], in 2009 published a prospective behavior modification study in which 209 subjects were randomly assigned to one of two treatment groups. 104 men randomly assigned to the intervention program received detailed advice about how to reduce body weight, improve quality of diet and increase physical activity. The control group of 105 subjects was given general information about healthy food choices and general guidance on increasing their level of physical activity. IIEF-5 scores were similar for both groups at the onset of the study. At baseline 35% of the subjects and 38% of the control group had normal erectile function. After two years these figures were 58 subjects in the intervention group and 40 subjects in the control group showing a significantly (P=0.015) improvement in erectile function. The conclusion of this study was that it was possible to achieve and improve erectile function in men at risk by means of non-pharmacological intervention aiming at weight loss and increasing physical activity.

A. INTRODUCTION

To most individuals, it seems obvious that psychological and interpersonal factors play a major role in both the etiology and maintenance of sexual problems. The ways in which love and affection are expressed in one’s family of origin, the unique and sometimes traumatic sexual experiences one has growing up, the religious, cultural and societal messages one receives about sex from peers, teachers, relatives and the ever-increasing impact of the media on one’s beliefs and behavior clearly play a role in shaping attitudes and promoting sexual health or dysfunction. More significantly, individual vulnerability to sexual disruption stems from personality and constitutional/biological dispositions to psychiatric and medical illness, medication, surgery as well as the inability to develop and sustain intimate relationships.

This chapter will review the most significant psychological and interpersonal dimensions contributing to sexual health. Other chapters will provide more of a focus on the biological aspects of sexual function and dysfunction. We will consider the predisposing, precipitating, maintaining and contextual factors involved in sexual dysfunction as well as the success of conventional and newer techniques of psychological treatment in the alleviation of these disorders. Finally, we will recommend a treatment model that offers a greater likelihood of success- an integrated biopsychosocial model that fully acknowledges the dynamic interplay between our mind and bodies.

There is a dearth of high level evidence-based studies in this area. The observations concerning developmental factors impeding or facilitating sexual health are primarily theoretical, clinical and anecdotal- with the emphasis on accounting for dysfunctional rather than healthy sexuality. Finally, there is a paucity of well-controlled, large-scale outcome research documenting the efficacy of sex therapy.

I. THE INHERENT TENSION BETWEEN EVIDENCED-BASED RESEARCH AND PSYCHOTHERAPY

It must be noted at the outset that there is an inherent tension between evidence-based medicine and the art and science of psychotherapy/sex therapy. Psychotherapy, as it is generally practiced, is more relational, symbolic and dynamic than other fields of medicine or therapy. The relationship style and personality of both the practitioner and the patient contribute significantly to treatment outcome as well as the therapeutic process itself. Other factors that cannot readily be quantified or manualized and contribute to positive outcomes [1] include such things as the placebo factors that enhance hope and expectancy [2], extra-therapeutic factors such as client motivation and chance events (e.g., meeting a new partner), relationship comfort between the client and therapist and finally, the degree to which the model and structure of therapy conform to the client’s expectations.

Laboratory research is important, but does not easily translate into clearly prescribed clinical interventions that enhance sexual life. Having an array of evidence-based behavioral interventions that enhance sexual function and facilitating sexual health are primarily theoretical, clinical and anecdotal- with the emphasis on accounting for
Sexual dysfunction is typically influenced by a variety of predisposing, precipitating, maintaining and contextual factors [3] (See Table 1). Predisposing factors include both constitutional and prior life experiences that contribute to a person’s vulnerability for dysfunction. Predisposing factors are quite varied and may include a history of childhood or adult sexual abuse or violence, anatomical deformity, chronic illness, etc. However, these factors alone are rarely sufficient to create sexual dysfunction [4].

Precipitating factors include those more immediate factors that can propel a person from adequate response to dysfunctional response. They include such things as separation or divorce, a humiliating sexual experience, a mutilating surgery and biological events such as illnesses, or medications or surgeries with sexual side effects.

Maintaining factors such as relationship conflict, loss of sexual confidence, performance anxiety, and lack of privacy or medications that negatively affect sexual function may prolong and exacerbate problems, irrespective of the original predisposing or precipitating conditions.

Contextual factors encompass the present day stresses and demands that impinge on the individual or couple. These include such diverse issues as serious financial struggles, unemployment, fatigue from childrearing, or the burdens of caretaking for a sick parent, child or partner, etc. They also include environmental factors such as partners working different shifts and not having sufficient privacy. The contextual issues are usually fleeting but can become chronic and do impact on sexual function. Each of these domains contributes to both the individual’s and the couples’ ability to sustain an active and satisfying sexual life or to develop and maintain sexual dysfunction.

1. PREDISPOSING FACTORS - CONSTITUTIONAL FACTORS

Constitutional factors are inborn biological and psychological traits that influence sexual interest levels and response tendencies. They may be created by genomically-based anatomical, hormonal, vascular and neurological characteristics. How constitutional factors lead to variations in desire, arousal, orgasm and pleasure from sex is not known with any precision, yet research suggests that each of these factors can either enhance or impede later sexual performance and satisfaction. For example, intersex children who are born with ambiguous genitalia are likely to experience more sexual problems in later life than those children born with normal genitalia [5].

2. PREDISPOSING FACTORS - DEVELOPMENTAL AND FAMILY OF ORIGIN CONTRIBUTIONS

Psychological development is an on-going process...
that begins before birth and continues throughout life. Over time, individuals either develop or fail to develop numerous sexual and interpersonal capacities, including the ability to love. The developmental processes that organize healthy sexuality, while not clearly understood, do not appear to be sexual per se. The quality of attachments to parents, and the ability of caretakers to identify and satisfy the child’s needs interact with constitutional and temperamental forces to foster sexual comfort and identity [6]. In fact, our understanding of sexual development is conceptual and descriptive and is largely devoid of sophisticated evidence-based studies.

**a) Gender identity development**

Each child develops a gender identity—that is, a sense of self as either a boy or a girl and an increasing preference for play, dress, and peer companionship that is perceived by adults as typical or atypical for a child of that gender. Gender conformity throughout childhood is an early developmental marker for adolescent heterosexuality [7]. Childhood gender nonconformity predicts adolescent and adult homosexuality with greater accuracy in boys than it does in girls [8]. Erotic fantasy often appears in the 10th year of life in both genders [9]. These fantasies reflect the formation of the child’s gender identity, sexual orientation and their preferred sexual “script” e.g., what the individual wants to do with another and what they want done to them [10]. Sexually atypical adolescents may become gay or lesbian and in extreme instances may be diagnosed as having a gender identity disorder (transsexualism) or a paraphilia (such as voyeurism, exhibitionism, fetishism, sadism, masochism, pedophilia) [11]. Although there is much speculation about the specific developmental factors that organize children’s gender identity, orientation, and sexual

scripts, research has been unable to clarify these developmental processes precisely [12].

b) Trauma- Event and process based trauma

Two types of developmental factors are thought to increase the likelihood of sexual dysfunction: event-based trauma (single episode) and process-based trauma (ongoing interactions or behaviors) with caregivers [13]. It is reasonable to assume that the remote influences that create sexual dysfunction during the adult years do so by triggering old trauma/ or anxiety-laden memories, which in the present, are experienced as sexual anxiety.

What follows are two examples of developmental experiences that influence sexual behavior; the first is an example of an event-based trauma, the second of a process based, conflict.

If a 12-year-old girl is raped by a stranger, a decade later when she participates in an entirely consensual sexual intimacy, she may be too frightened to enjoy her sexual experience. We label her childhood victimization as a traumatic developmental factor contributing to, or causing her adult sexual dysfunction. The terror she experienced during the rape may not have been sufficiently processed, understood or resolved. She is not free to enjoy present-day desired sexual experiences because of remnants from the past trauma.

A man avoids sexual intercourse with his wife because he prefers the “safety” of masturbation. Growing up, he experienced his mother as intrusive and over-bearing. He recognizes the hostility he bears toward his mother, but is unable to appreciate that his avoidance of his wife is related to his inability to psychologically separate his wife from his critical mother.

Most predisposing factors to sexual dysfunction are not event-based. Rather, they are process-based, typically involving the ongoing relationship with one’s caretakers. For instance, growing up with parents who express no warmth, do not touch their child affectionately, and refuse to acknowledge his/her feelings can inhibit healthy intimate relationships as an adult as well as undermine the child’s self-respect. Negative relationships in childhood may delay or inhibit healthy adult sexual development.

Clinicians elucidate the developmental factors that predispose a patient to current sexual dysfunction on a case-by-case basis. Our ideas tend to be based on retrospective patient self-reports [14] and are not “evidence based”. Nonetheless they seem helpful in illuminating both the patient’s and clinician’s understanding of the problem. Event and process based trauma may explain what enables one person who has suffered adverse circumstances such as unemployment, marital conflict, or an affair, to become dysfunctional while others under similar circumstances do not.

c) Puberty

Despite the long-held assumption that puberty provides the crucial trigger for the onset of sexual feelings, more recent research suggests that it is the maturation of the adrenal glands and secretion of adrenal hormones around age 10 that appear to be associated with the development of sexual attraction, thoughts and emotions which get shaped by cultural expectations of sexuality [12]. For both girls and boys, there is a positive correlation between plasma testosterone levels and increased interest in sex, although this association is more dramatic in boys than in girls [15].

As their bodies are changing during adolescence, boys and girls receive multiple cultural messages about how men and women do (or should) express, experience and manage their sexual feelings. Notions of men as “naturally” sexually aggressive and women as “naturally” passive may be socially reinforced with the consequence that both boys and girls follow prescribed sociosexual scripts, i.e. men are sexual initiators and women are sexual gatekeepers [16]. Social pressures appear to have a more significant influence in determining the sexual behavior of young women than young men. In fact, women are considered to be more “erotically plastic” than men and hence to be more amenable to gender and sexual cultural prohibitions and expectations [17]. This may help explain why women tend to have a higher incidence of sexual problems as adults than do men [18].

d. Impact and initiation of first intercourse

Although age of first intercourse and the emotional aspect of the experience are thought to contribute to later sexual functioning, research to date on how the sexual debut relates to adult sexual functioning has been limited and contradictory. Woo and Brotto [19] studied Euro-Canadian and Asian-Canadian university students. In the overall sample, older age of first intercourse was associated with more sexual problems as an adult, including more sexual infrequency, sexual avoidance, and non-sensuality. Among the women, Asian-Canadians reported higher scores on the Vaginismus and Anorgasmia measures, whereas the ethnic groups did not differ on the male-specific measures of sexual complaints.

Udry and Billy [20] sampled 1400 Caucasian adolescent virgins and studied which hormonal and social variables predicted the initiation of adolescents’ sexual activity. They found that for males, free testosterone level rather than social variables was correlated with the initiation of first coitus, while for females, hormones had no direct effect but most of the social variables did. These included their friends’ sexual activity, grades, deviance, religiosity, sexual permissiveness, parents’ educational level and locus of control.
In a qualitative study of adolescent girls' first intercourse, Thompson [21] found that the majority of girls in her research remembered their first coital experience as painful and unpleasant. In response, many girls decided to postpone further intercourse for one or more years. The girls who remembered and interpreted the experience positively had mothers who had talked to them about their sexuality in positive ways, had encouraged them to pay attention to their own desire (or lack of it) and had socialized them to expect satisfying sexual experiences. While the relationship of negative first experiences to the development of later sexual problems has not been well researched, it is an area that merits attention. Clinically, it is often reported that traumatic or humiliating sexual initiation and coitus may be associated with later sexual anxiety, aversion and difficulties.

3. SEXUAL ABUSE AND SEXUAL DYSFUNCTION

Childhood sexual abuse, a significant contributing factor to sexual dysfunction, may even be more difficult to discuss with patients than a current sexual problem. It is important to ask about sexual abuse because of its impact not only on gynecologic complaints but also on adult mental health symptoms.

Recent studies have demonstrated child sexual abuse survivors report a lifetime history of multiple exposures to various trauma and higher levels of mental health symptoms. Sexual violence is associated with increased risk of posttraumatic stress disorder and depression [22]. The influence of early sexual abuse on later adult sexual functioning has been found to pertain in particular to problems in sexual desire, arousal, orgasm and sexual pain.

Meston et al. [23] showed that the relationship between child sexual abuse and negative sexual affect was independent from symptoms of depression and anxiety, suggesting that the impact of child sexual abuse on sexual self-schemas may be independent from the impact that the abuse may have in other areas of the survivor's life. In a review article on factors predisposing women to chronic pelvic pain, sexual abuse was associated with dyspareunia and also to non-cyclical pelvic pain [24].

Rellini [25] attempted to create a theoretical model of understanding the sexual problems of women who experienced childhood sexual abuse (CSA). When exposed to sexual stimuli, CSA survivors experienced more inhibitory responses and less excitatory responses than women in a control group. Conversely, in situations when sexual stimuli were not present, CSA survivors showed a greater excitation of sexual responses than women in the non-CSA group. Additionally, CSA survivors showed a potential difficulty inhibiting intrusive sexual thoughts.

One of the major problems in studying CSA is the lack of agreement on the definition and description of sexual abuse. Definitions of sexual abuse vary considerably across countries, cultures and research articles. Without understanding the “meaning” of the behavior to the individuals involved, its putative impact on later sexual function and dysfunction cannot be fully appreciated. For instance, sibling “incest” may or may not be considered normative, depending on the cultural context.

In a well-conducted epidemiological study of sexual well-being in sexually abused Swedish women, Oberg, Fugl-Meyer and Fugl-Meyer [26] defined abuse as forced situations or acts that were perceived as sexual and 11 different abusive acts, ranging from forced exhibition of one's genitals to vaginal intercourse. The national representative sample consisted of 1,335 Swedish women aged 18-74. Twelve percent of Swedish women reported being abused at least once during their lifetime, with the most common types of abuse being vaginal penetration and genital manipulation by the perpetrator. About half of the abused women had been abused more than once. Nearly all types of sexual abuse were significantly associated with orgasmic problems, and the women who had experienced forced vaginal penetration, genital manipulation, cunnilingus or being forced to perform fellatio also had a lower level of sexual interest than non-victims of abuse. Fellatio and genital manipulation were significantly associated with a higher prevalence of vaginismus. Those who had been sexually victimized more than once had significantly lower levels of sexual interest and anorgasmia than women who had been abused only once. Moreover, 81% of the women who had been abused more than once reported one dysfunction. Finally, sexually abused women had lower levels of sexual well-being than non-abused women.

In a recent follow-up study of the long-term impact of CSA, 77 sexually abused and 89 comparison women (mean age = 20.41, SD = 3.38) were assessed 10 years after disclosure in a longitudinal, prospective study [27]. These investigators found that abused women were more preoccupied with sex, younger at first voluntary intercourse, more likely to have been teen mothers, and endorsed lower birth control efficacy than comparison participants.

The impact of sexual trauma on male sexual function has received relatively little attention, and there is some inconsistency in the studies reported to date. Although studies comparing the impact of victimization in men and women show a greater effect in women [28, 29], negative consequences have been found in men as well. In a questionnaire study of 301 men in a nonclinical sample, sexual victimization, sexual abuse and dysfunctional family background were predictive of premature ejaculation and sexual desire disorder. However, long lasting
adverse familial relationships had a greater impact on these disorders than sexual abuse per se [30]. Methodological factors that may affect outcome in these studies have included the definition of sexual abuse [31], whether or not an age discrepancy between offender and victim is required in defining childhood abuse [32], and whether sexual abuse has occurred as a single incident or as repeated victimization [33].

Sexual abuse is considered a salient risk factor for later adult sexual dysfunction, increased prevalence of high-risk sexual behavior and increased adult psychopathology [34, 35]. For instance, a recent study [36] of 1490 women revealed that one-third were survivors of sexual abuse involving penetration. Overall, regression analysis indicated a significant relationship between early sexual abuse and later participation in risky sexual behavior as an adult. The earlier that the abuse occurred, the greater impact it had on the likelihood of engaging in adult risk-taking sexual behaviors. Since child and adolescent sexual abuse is a global phenomenon with equal incidence reported in such diverse countries as Brazil, Chile, Mexico, Israel, Palestine, Sierra Leone, South Africa, Sweden and Switzerland, it is important to screen for its presence during the initial evaluation of both men and women [35, 37-41]. Observing or being the recipient of physical violence during childhood is another risk factor for sexual dysfunction. It has been related to a heightened neurophysiological response to perceived threat (startle response), disruption of trust, and impairment in self-esteem and personal autonomy [42]. Not only do many young people live with violence in intimate relationships, but youth everywhere are exposed to media images of violent situations in which people abuse power and control. These early experiences may predispose individuals to later difficulties with intimate relationships [43].

Chronic and troubling dyspareunia was reported by 37% of a sample of 409 women with a past history of sexual coercion and physical partner abuse and 75% reported various sexual dysfunctions [44]. Notably, only a small number of women had ever discussed these concerns with their physician [45].

4. BODY IMAGE AND SEXUAL FUNCTION

Body image appears to be an important factor contributing to sexual self-confidence for both men and women. It may function as a predisposing, precipitating or even maintaining factor for the development of sexual difficulties since it impacts both early experiences, (e.g., of being teased), and later sexual experiences with partners.

Men tend to worry about penis size, while women tend to worry about body shape and weight. Many women are sexually self-conscious and many avoid sex when they feel overweight or physically undesirable. Often, these feelings are not based on objective fact, but rather rigid (Western) standards, culturally imposed, about the importance of being young, thin and beautiful. There is little empirical research examining the degree to which an excessive focus on body image interferes with, or contributes to sexual dysfunction, per se, but clinical observations suggest that these preoccupations serve as a distraction during sexual exchange.

Changes in the appearance of one's body have also been linked to changes in sexual response. For example, female patients who have undergone treatments involving body – altering surgeries (e.g. for cancer) show a decrease in sexual arousal and interest post-surgery. Women who have undergone psychotherapy for eating disorders that include body – altering components (e.g. weight loss) show enhanced sexual responses following treatment[46].

Faith and Schare [47] examined the relationship between excessive self-focus on bodily appearance and sexual function. They found that negative body image was related to lower levels of sexual experience when sexual attitudes and knowledge as well as global psychological adjustment were held constant. This was an observational study using measures of general body image and sexual experience rather than a well-controlled study.

It should be noted that cultural standards of female beauty and desirability vary considerably cross-culturally. While thinness is socially valued in Western countries, more full-bodied women are considered sexually desirable in other regions of the world. Comfort and self-acceptance with one's body, irrespective of the degree to which it mirrors cultural stereotypes, is believed to be a salient contributory factor to overall sexual health and function.

5. VULNERABILITY AND RISK FACTORS INFLUENCING SEXUAL HEALTH & DYSFUNCTION

Space does not permit a thorough inventory of all of the many constitutional and developmental factors that may predispose an individual to later sexual problems. Suffice it to say that an individual's vulnerability to later sexual dysfunction is determined by the ratio of risk vs. protective factors as well as their personal resiliency. In general, one's vulnerability to sexual dysfunction is increased by having more risk factors lasting for longer periods accompanied by greater coercisiveness than a single negative or traumatic episode [48].

Resiliency is a psychological attribute that describes the individual's ability to cope with significant adversity or stress in ways that are not only effective, but result in their enhanced ability to confront and master future adversity [49]. When stress factors are greater than the individual's protective factors, then even resilient individuals may be overwhelmed and develop sexual problems.
Recent advances in immunology and neuroscience are elucidating the links between emotions and disease, between the brain and the immune system and the mind and body. “With sophisticated new genetic and mathematical modeling techniques, we can determine what part of our stress responsiveness we are born with, and how much is under environmental control. These sorts of theories will help us understand not only the reasons for individual differences in stress responsiveness, but will also point the way to develop new behavioral strategies that can change the set point of different individual’s stress responses [50].”

6. SUMMARY OF IMPACT OF PREDISPOSING CONDITIONS ON SEXUAL DYSFUNCTION

Negative developmental experiences such as problematic attachments, neglectful or critical parents, restrictive upbringing, sexual and physical abuse and violence, traumatic early sexual experiences as well as a variety of constitutional vulnerabilities are associated with a greater prevalence of sexual dysfunctions and difficulties in adult life. While some individuals appear less vulnerable and more resilient in the face of stressors, others are more susceptible. More research is needed on factors that increase personal resiliency and contribute to the development of healthy sexuality.

C. PRECIPITATING FACTORS

Precipitating factors are those that trigger sexual problems. For any single individual, it is impossible to predict which factors under what circumstances may impair sexual desire or performance. Nonetheless, an individual’s vulnerability to a particular set of circumstances can precipitate sexual dysfunction. For instance, suffering humiliation from one’s spouse may cause one man to lose his erection while another man may be unaffected. Similarly, in response to the discovery of a partner’s infidelity, one woman may lose sexual desire while another may become more sexually driven. While initially a precipitating event may be problematic and distressing, it need not necessarily lead to a diagnosable dysfunction long term. However, repetitive problematic sexual experiences damage self-confidence and ultimately are pathogenic for sexual dysfunction, even in reasonably resilient individuals. Often, there is not a clear distinction between either predisposing and precipitating factors or precipitating and maintaining factors. As a predisposing factor, anxiety can increase an individual’s vulnerability to sexual dysfunction. It can also serve as a maintaining factor leading to sexual avoidance or arousal inhibition.

Partners’ physical, emotional and sexual health can affect the sexual and emotional health of the other partner. Therefore, partner issues function as precipitating and maintaining factors. The following section explores this topic in detail and also provides a review of the relationships between anxiety, depression, sexual confidence and sexual dysfunction.

I. ROLE OF THE PARTNER

Studies have begun to clarify the dynamic and reciprocal relationship of one partner’s sexual function, sexual satisfaction, physical and mental health to the other partner’s sexual health and satisfaction. The partner’s role as a precipitating or maintaining factor has been overshadowed by focusing on individual medical or psychological factors or the impact of the quality of the relationship upon sexual function. This section will review the findings on partner issues as precipitating and maintaining factors in male and female sexual dysfunction. Two caveats: 1) we recognize that not all sexual behavior occurs in relationships and 2) the data are derived solely from studies with heterosexual couples. Clearly, more research is needed with gay/lesbian couples to characterize the influence of the each partner on the other’s sexual function and satisfaction.

1. SEXUAL FUNCTION AND SATISFACTION IN PARTNERS OF MEN AND WOMEN WITH SEXUAL DYSFUNCTION

a) Erectile dysfunction (ED)

Several randomized, placebo-controlled trials of men with ED who are treated with phosphodiesterase type 5 inhibitors (PDE5i’s) have evaluated the sexual function of female partners at baseline and end of treatment (see Table 2) [51-53]. Fisher et al. studied 293 women whose male partners had ED and were receiving either vardenafil or placebo [54]. Following the onset of ED 36% of women reported a decrease in sexual desire; 31% noted that their ability to experience orgasm declined; 46% had decreased sexual satisfaction and; the frequency of lovemaking also significantly decreased. Greenstein et al. [55] evaluated 113 female partners of men with ED attending a sexual dysfunction clinic. Fifty-five percent of these partners reported having some form of sexual disorder, mostly orgasmic problems and decreased sexual desire.

Shabsigh et al. [56] investigated the prevalence of female sexual dysfunction (FSD), urinary symptoms, and depressive symptoms in female partners of men presenting with ED. Women completed the Brief Index of Sexual Function for Women, Centers for Epidemiologic Studies-Depression, (CES-D), a demographics questionnaire and general medical questionnaire. Of the 50 women who completed the questionnaires, sexual dysfunction symptoms included: anxiety/inhibition (26%), hypoactive sexual

</table>
desire (20%), arousal/lubrication difficulty (30%), orgasmic difficulty (24%), dyspareunia (18%), and sexual dissatisfaction (34%). Urinary symptoms of frequency and urgency were reported by 36%. Depressive symptoms were present in 44%.

Goldstein et al. [57] reported that after men received 12 weeks of treatment with vardenafil, the female partners demonstrated significant improvements in total Female Sexual Function Index (FSFI) score as well as sexual desire, subjective arousal, lubrication, orgasm and satisfaction sub-domain scores. Chevret-Measson et al. [53] reported significantly improved scores on the Life Satisfaction Scale for women whose male partners were receiving sildenafil. Similar improvements in female partners sexual function, treatment satisfaction and sexual satisfaction following the man’s treatment with PDE5is are described by others [58-60]. Chevret-Measson [53] suggested that studies much closer to “real life” and clinical practice with a broader population than men and their partners in clinical trials are necessary to assess the global therapeutic approach in a context close to normal practice.

b) Premature ejaculation

The impact of premature ejaculation (PE) upon partners was documented by Riley and Riley in a retrospective audit of their medical records [61]. Approximately 50% of female patients with sexual problems, such as ‘not enjoying sex’ or anorgasmia, had partners with PE either at the onset of their problem or at some time in the relationship. Hartmann et al. [62] reported that 27% of dysfunctional men, including those with PE, were unsure of the capacity and frequency of their partners’ orgasm, compared to 4% of functional men. In contrast to Riley and Riley and Hartmann studies, Byers [63] and Revicki [64] found less impact of PE on female partners sexual function although all studies found women had diminished sexual satisfaction.

c) Female sexual dysfunction

Witting and colleagues [65] investigated the association between female sexual dysfunction, distress and partner compatibility. The two main complaints of women were “too little foreplay” (42%) and “partner is more interested in sex than you” (35%). The women experiencing distress on the Female Sexual Distress Scale (FSDS) or having a sexual dysfunction as determined by the FSFI reported more incompatibility with their partner compared with functional women.

Jodoin[66] asked 46 male partners of women with provoked vulvodynia to complete the Attributional Style Questionnaire-Partner Version, Brief Symptom Inventory, Dyadic Adjustment Scale, Sexual History Form and Global Measure of Sexual Satisfaction. The men’s global and stable negative attributions were related to lower sexual satisfaction whereas, higher levels of internal and global attribution were associated with men’s poorer dyadic adjustment. Additionally, all 4 negative attribution dimensions and higher levels of women’s pain intensity predicted increased levels of psychological distress in men.

Speckens et al. [67, 68] investigated female partners of men with ED where no organic cause could be found and partners of men with organically based ED. They compared the partner’s views on the relationships, sexual function, sexual attitudes, and psychological adjustment. Vaginismus and dyspareunia which preceded the onset of ED were more common in the partners of men with nonorganic ED as were relationship problems. The authors concluded that female sexual dysfunction, high sexual interest and relationship problems contribute to the onset, exacerbation and maintenance of non-organic ED.

The associations between desire discrepancies and sexual and relationship satisfaction in heterosexual dating couples (N = 72) were examined by Davies et al. [68]. Women whose sexual desire level was lower than their partners’ endorsed lower levels of relationship adjustment relative to women whose desire was either greater than or similar to their partners’.

d) Impact of illness on partner sexual function

Chronic Prostatitis/Chronic Pelvic Pain Syndrome (CP/CPPS) is a common condition in men involving pelvic pain and sexual dysfunction. Smith et al. [69] sought to identify potential predictors of sexual and relationship function among couples with CP/CPPS, and to examine associations among pain, sexual, and relationship variables. Men completed the International Index of Erectile Function (IIEF) and a subscale of the Multidimensional Pain Inventory. Female partners were administered to the FSFI, and all participants received the Golombok-Rust Inventory of Sexual Satisfaction and the Dyadic Adjustment Scale. Couples’ sexual function, sexual satisfaction, and relationship adjustment were all significantly associated. Patient sexual function was predicted by patient sexual satisfaction and female sexual function, whereas female sexual function was predicted by female sexual satisfaction and patient relationship adjustment. Pain severity significantly predicted sexual and relationship functioning among couples. However, multiple regression models revealed that sexual and relationship variables were the strongest predictors of patient and partner functioning, over and above pain severity.

Harden et al. [70] sought to examine how quality of life, self-efficacy and appraisal of the illness experience vary among men with prostate cancer and their partners according to age. They divided the sample into three categories: middle age (50-64); young-old (65-74); and old-old (75-84). Middle aged spouses reported the most distress related to sexual changes in their husbands. Spouses in both
the middle age and old-old group had more bother related to hormone therapy than the young-old spouses. Couper et al. [71] performed a review of the literature from 1994-2005 regarding psychosocial factors impacting the patient and partner. They found that partners report more distress than patients, yet believe that patients are the more distressed. The focus of concern of patients is on their sexual function which not shared to an equal degree by their partners.

McCabe et al. [72] examined the impact of multiple sclerosis (MS) on sexuality and relationships among 111 males and females with MS. The results indicated that MS had a negative impact on sexual functioning among men and women: only 35.4% of men and 20.4% of women were not experiencing any form of sexual dysfunction. The most common dysfunction for men was ED, and for women was hypoactive sexual desire. Surprisingly, the majority of men and women did not express concern about their sexual problems. Perhaps they accept these problems to be an inevitable consequence of developing MS. McCabe [73] examined the difference in sexual dysfunction between 381 people with MS and 291 people from the general population. Males with MS demonstrated higher levels of sexual dysfunction than males in the general population; however the only difference between females with MS and those from the general population was that MS females reported higher levels of numbness in their genital area.

These studies consistently demonstrate the interdependence of sexual function between partners. Specifically, they suggest that dysfunction in one partner tends to cause problems for the other and that improvement in function in one partner tends to have a positive effect on the other. The data strongly argue that clinicians take a biopsychosocial approach to the treatment of sexual dysfunctions and include evaluation of the partner if possible.

II. THE ROLE OF ANXIETY IN SEXUAL FUNCTION AND DYSFUNCTION

Anxiety played a significant role in early psychodynamic formulations of sexual dysfunction and later became the foundation for the etiological concepts of sex therapy established by Masters and Johnson [74] and Helen Kaplan [75]. Kaplan believed that sexually related anxiety became the final common pathway through which multiple psychopathogens led to sexual dysfunction.

1. RESEARCH STUDIES ON ANXIETY AND SEXUAL FUNCTION

The role of anxiety as a key etiological agent in the genesis of sexual disorders has been examined in several clinical studies as shown in Table 3. A review by Norton & Jehu [76] reported high levels of anxiety in sexually dysfunctional individuals [77-84], which varied in amount and quality. Some studies found higher levels of sexually related anxiety, but no differences in social or general anxiety [81, 82, 85, 86].

a) Anxiety and female sexual dysfunction

The relationship between anxiety levels and female sexual dysfunction has not been extensively studied. While most of the existing research has focused on anxiety in women with diagnosed sexual dysfunction, other research has studied the incidence of sexual difficulties in women with anxiety disorders compared to non-anxious women.

Murphy and Sullivan [87] compared sexually aversive women to sexually functional women and found that the aversive group experienced heightened levels of ‘acute’ anxiety related both to sexual and non-sexual spheres. In addition, the sexually aversive women reported difficulty with identity, self-acceptance and feelings of inadequacy in most psychosocial areas. Leiblum et al. [88] found that women with persistent genital arousal (PGA) were more likely than non-PGA women to experience a range of anxiety symptoms (e.g., panic attacks, obsessive compulsive disorder).

Kaplan [89, 90] believed that performance anxiety was the critical element in sexual avoidance, which reached panic proportions for some individuals. She reported that a significant number of ‘sexaphobic’ patients had a dual diagnosis of sexual and panic disorder. In fact, women with panic disorder have been found to have lower sexual desire than healthy controls [91].

Campillo et al. [92] compared anxiety and depression levels in women with and without sexual disorders and found higher levels of trait anxiety and depression in the sexually dysfunctional women. Trudel et al. [93] examined the role of anxiety, depression and marital adjustment in 20 couples with low desire in one or both partners. The results indicated that the sexually dysfunctional subjects had low levels of depressive mood but moderate levels of anxiety.

b) Anxiety and male sexual dysfunction

Feil and Richter-Appelt[86] compared beliefs and anxiety in ED patients and sexually functional men and found that men with ED reported a significantly higher degree of sexual anxiety but no difference in general or social anxiety. In addition, the subjective feeling of efficacy and personal competency was lower in the ED group.

In another study [94], 41 ED-patients completed the State-Trait-Anxiety-Index (STAI) and the International

Index of Erectile Functioning (IIEF). The majority of men had high levels of state anxiety as well as trait anxiety, but only trait anxiety correlated statistically with the severity of the erectile disorder. The authors concluded that anxiety as a personality factor could act either as an etiological substrate of ED or as a precipitant for this dysfunction.

With the same questionnaire, Mas et al. [95] examined the influence of personality factors on the erectile response to intracavernosal injections in 78 patients. When controlling for the severity of the ED through IIEF-scores, trait anxiety proved to be a highly significant predictor of injection efficacy. A number of recent studies have supported these associations between ED and anxiety [96-99]. There have been few recent articles that have examined the relationship between anxiety and other types of male sexual dysfunction. However, Althof and Rosen [100] concluded in their review article that the evidence that was available suggested a relationship, not necessarily causal, between anxiety and PE.

c) Summary: Anxiety in sexually dysfunctional men and women

From these results it can be concluded that the majority of sexually dysfunctional individuals exhibit heightened levels of anxiety suggesting a central role of anxiety in the subjective experience and maintenance of sexual disorders. Correlational evidence exists for the relationship between ED and anxiety. However this does not imply causality. It is also not clear if it is generalized anxiety, or anxiety that is more closely related to the sexual content that is more strongly related to sexual dysfunction in men and women.

2. THEORETICAL EXPLANATIONS OF HOW ANXIETY INTERFERES WITH SEXUAL PERFORMANCE

The central role of anxiety reported by sex therapists has been challenged by a number of sophisticated laboratory studies aimed at unraveling the sequence of cognitive-affective processes during sexual arousal in dysfunctional and functional men and, to a lesser extent, women. In these studies, anxiety is induced either by shock threat or by performance demand, sometimes combined with a special distraction condition. Sexual arousal is assessed with psychophysiological (penile tumescence or vaginal photoplethysmography) and subjective (lever, questionnaires, rating scales) measures. Special attention is paid to differences between sexually functional and dysfunctional subjects. Subsequent studies also examined the role of sympathetic activation (SNS activation) such as exercise or other conditions.

Laboratory data indicate that the sexual arousal process operates differently in sexually functional and dysfunctional subjects [101]. Contrary to the findings from clinical studies that indicate an inhibition effect of anxiety, the laboratory evidence has indicated that anxiety (as induced in the lab setting) either facilitates or does not affect sexual arousal in functional subjects. The evidence for sexually dysfunctional subjects is mixed.

Barlow [102] has offered a theoretical model explaining why anxiety may operate differentially in functional vs. dysfunctional individuals. His model emphasizes the role of cognitive interference in male sexual dysfunction. In general, what appears to distinguish functional from dysfunctional responding is a difference in selective attention and distractibility. What sex therapists consider performance demand, fear of inadequacy or spectatoring are all forms of situation-specific, task-irrelevant, cognitive activities which distract dysfunctional individuals from task-relevant processing of stimuli in a sexual context [103].

In summary, the cognitive-information processing models of sexual anxiety assert that sexual arousal is dependent upon ‘task-relevant’ processing of a sexual stimulus. In sexually dysfunctional subjects, sexual stimuli induce a performance demand, which in turn leads to a shift of attentional focus away from the sexual content of a situation, inhibiting arousal.

Lab studies show that subjective and physiological sexual responses are influenced by different mechanisms. Anxiety influences genital responses, but not subjective responses. Attentional focus seems influential in cognitive processing [104].

a) The laboratory evidence for women

For women, the relationship between anxiety and sexual performance has received limited research attention. However, the literature that is available suggests that activation of the sympathetic nervous system (including anxiety provoking stimuli) facilitates genital sexual arousal in sexually functional women and in women with low sexual desire (but not in women with orgasmic disorder) [105-110]. Overall, the evidence for the role of anxiety in sexually dysfunctional women is mixed, with the suggestion that it is more negative than facilitory [111].

Table 3 summarizes the significant clinical implications of anxiety as it relates to sexual behavior.

3. IMPLICATIONS

The laboratory studies on the relationship between anxiety, distraction, general sympathetic activation and sexual response have convincingly shown that anxiety is not universally disruptive to sexual functioning. In addition, results indicate that the anxiety – sexual response relationship is complex and that the term ‘anxiety’ is too broad for
comprehensively describing the variety of factors that can disrupt sexual arousal and functioning. The available evidence indicates that the level and the nature of anxiety and its history are important determinants. Whereas moderate levels and relatively ‘safe’ settings may catalyze sexual arousal, higher levels, less feelings of personal control or a longer history of anxiety very likely impair sexual functioning [91].

III. DEPRESSION AND SEXUAL FUNCTION

The relationship between depression and sexual functioning is of considerable interest to clinicians and researchers since both affective and sexual disorders are highly prevalent, are believed to exhibit a marked co-morbidity and might even share a common etiology [112, 113]. It is generally agreed that the relationship between depressive mood and sexual dysfunction is bi-directional and further complicated by the sexual side effects of antidepressants [114]. Depression has a powerful impact on all aspects of male and female sexual response: desire, arousal and orgasm. Examining sexual function in 134 depressed men and women who were not taking antidepressant medication, researchers reported that 42% of the men reported a decrease in sexual drive; a similar percentage had a decrease in interest in sexually explicit material, sexual fantasies and masturbation. Twenty-six percent of the men were not sexually active in the month prior to assessment. Of those who were sexually active, 34% stated that their erection was less vigorous, 46% were unable to sustain an erection, 12% reported PE and 23% reported delayed ejaculation [115].

1. DEPRESSION AND SEXUAL FUNCTION IN MEN AND WOMEN

The most common sexual pattern associated with depression is loss or reduction of sexual interest and/or sexual arousal. Beck [116] found low sexual interest in 61% of severe depressives compared with 27% of non-depressed controls. Both Derogatis et al. [117] and Schreiner-Engel and Schiavi [118] examined the prevalence of acute psychiatric symptoms and lifetime psychopathology in men and women with different sexual dysfunctions. Derogatis conducted a psychiatric interview and administered the Symptom Checklist 90 Revised (SCL-90R) to a sample of 325 patients (199 men and 126 women). Men with ED had specific elevations on the depression dimension of the SCL-90R. Similarly, anorgasmic women and women with sexual pain disorders also had major elevations of the SCL-90R depression scale reflecting dysthymia and feelings of self-deprecation.

Schreiner-Engel and Schiavi [118] studied the lifetime history of psychopathology in patients presenting with desire disorders. Forty-six subjects (22 men and 24 women) were compared to 36 matched controls, utilizing clinical interviews, SCL-90-R and an instrument assessing lifetime affective and schizophrenic disorders. Although none of the patients manifested any clinical affective disorder at the time of assessment, the proportion of low desire patients with histories of major and intermittent depression was almost twice as high as that of control subjects. Moreover, in 88% of the men and 100% of the women, the initial depressive episode almost always preceded or coincided with the development of inhibited sexual desire. Hayes et al. [119] also found that depression was a strong predictor of arousal and orgasmic dysfunction among women. Interestingly, Lykins et al. [98] found that depression was more strongly associated with lower sexual desire in men than in women. Schreiner-Engel and Schiavi [118] suggested that a past history of depression may contribute to the pathogenesis of low desire or that both disorders result from the same underlying condition.

One of the most recent and intriguing studies looking at the relationship between depression and sexual function in women was that of Frohlich and Meston [120]. These researchers studied 47 college women with low Beck Depression Inventory (BDI) scores (non-depressed) and compared them to 47 women with clinically significant BDI scores. Results showed that the depressed group reported more desire for solitary sexual activity, e.g., masturbation than did the control group but there was no difference in the two depression groups in desire for sex with a partner. The depressed group reported a higher frequency of problems with arousal, orgasm and pain, less satisfaction, and less pleasure. The authors speculated that greater desire for masturbation in the depressed women’s group might reflect the wish for a reliable form of pleasure. It remains to be established whether similar results would be obtained with a population of male students.

Table 4 provides an overview of the studies that have been conducted looking at sexual dysfunction in men and women.

2. DEPRESSION AND ERECTILE DYSFUNCTION

Many of the recent studies have focused on the association between depression and ED. Data from the Massachusetts Male Aging Study [121] showed that depression and anger were highly correlated with ED. Nearly all men with symptoms of major depressive disorder (MDD) had some degree of ED[122]. Based on logistic regression analyses that controlled for other potential predictors of ED, moderate-to-complete ED was 1.82 times more likely in those who exhibited depressive symptoms compared to those who did not.

Assalian writes that men with ED may become depressed because of their sexual dysfunction and because of the secondary effects that ED may have on the relationship [123]. In men who present with one of these two problems it is crucial to ask about the other because of their frequent coexistence. The effective management of depressed men with ED often involves treating both conditions concurrently.

Shabsigh et al. [124] studied 120 men who presented to a urologic clinic with ED, benign prostatic hyperplasia (BPH), or both. Rates of depression in the ED group, the ED and BPH group, and the BPH group alone were respectively 54%, 56% and 21%. Patients with ED and depression were more likely to discontinue (intracavernosal injection or vacuum) treatment than ED patients without depressive symptoms. In a later review, Shabsigh et al. [125] stressed that ED and depression have a significant negative impact on the quality of life of patients and their partners.

Strand et al. [126] screened a cohort of 120 men who sought evaluation at a sexual behaviors clinic for depressive symptoms which were determined either categorically (DSM-IV diagnosis of depressive disorder: yes or no) or dimensionally as individual scores on the Brief Symptom Inventory (BSI). Utilizing DSM-IV criteria for depression, only a small, but by no means insignificant, subset of men (12%) qualified for a diagnosis of depressive disorder, but when distress was measured dimensionally the group demonstrated significantly elevated levels among all dimensions, including depression. These results indicate high levels of emotional distress in ED patients similar to those found by Derogatis et al. [117]. Sugimori et al. [99] found that among middle aged men (45-59 years) there was a strong association between ED and depression. Corona et al. [96] demonstrated that among men, depression was also related to low levels of sexual desire.

Seidman [127] suggested that ED and the accompanying psychosocial distress may stimulate the development of depressive illness in vulnerable individuals, or that depression might cause ED. It is likely that the relationship between depression and ED is bidirectional.

Finally, the results of a large-scale study of 4557 depressed patients in France found high rates of sexual dysfunction [128]. Patients with DSM-IV major depressive episodes but no previous diagnosis of sexual dysfunction were studied. Evaluation included both questionnaire (the Arizona Sexual Experience Scale) and physician observation. Overall, the researchers found that 35% of the participants spontaneously reported sexual problems and 69% indicated problems when asked by the physician. The frequency of sexual dysfunction was higher in patients treated with antidepressants than in untreated patients (71% and 65% respectively).

3. SUMMARY

In summary, the empirical evidence confirms a prominent role of depression in sexual dysfunction. While the exact direction of causality is difficult to ascertain, the data not only indicate a close correlational relationship between depression and sexual disorders but also support a functional significance of mood disorders in causing and maintaining sexual dysfunction. Compared to functional controls, sexually dysfunctional men and women exhibit both higher levels of acute depressive symptoms and a markedly higher lifetime prevalence of affective disorders. All of the studies reported have been at levels 3,4 and 5 of evidence and consequently, more randomized controlled research is needed.

Further, we recommend that assessment of anxiety and depression should be included as part of the initial evaluation in individuals presenting with sexual complaints and dysfunctions. An attempt should be made to ascertain whether the anxiety/depression is a consequence or a cause of the sexual complaint. If a pre-existing acute depression exists, it should be treated along with the sexual problem. Some research suggests that relief of the sexual problem is associated with relief of depression [129]. The role of anti-depressants and anti-anxiety medications as contributory factors to the sexual dysfunction should be evaluated and if implicated, a change in medication(s) may be indicated.

IV. OTHER PERSONALITY FACTORS AND SEXUAL FUNCTION/DYSFUNCTION

Hoyer et al. [130] reported on the relationship between patients seeking treatment for mental health concerns and sexual dysfunction at an outpatient clinic. Pre-treatment, of the 451 patients seeking psychotherapy, mostly for anxiety and depression, 68% of females and 54% of males reported at least one sexual complaint. Following treatment that did not focus on sexual dysfunction, those in remission, or those who had a positive response to therapy, demonstrated a 26% reduction in sexual symptoms. Patients who did not respond to therapy had a 4% reduction in sexual symptoms. The authors suggest that clinicians treating patients with anxiety and depression be aware of the high rate of sexual dysfunction and consider augmenting treatment by also treating their sexual dysfunction.

1. OBESSIVE-COMPULSIVE DISORDERS AND SEXUAL DYSFUNCTION

There are a few reports examining the association between obsessive-compulsive disorder (OCD) and sexual dysfunction. Independent studies [131-134]
suggest that approximately 50% of individuals with OCD report sexual problems and that 60% to 73% of OCD individuals are dissatisfied with their sexual lives.

While Van Minnen and Kampman [91] believe that OCD develops as a reaction to severe sexual conflicts within the patients or in their family of origin, Staebler et al. [134] did not find any differences in the sexual history of OCD patients or patients with panic or depressive disorders.

A variety of research studies suggest that OCD may be a specific risk factor for sexual difficulties. For instance, in a descriptive study of 44 OCD patients, Rasmussen and Tsuang [133] reported that 32% had sexual impulses that conflicted with their values. In a comparable study, 36% of the sample patients had sexual obsessions [131]. A recent study of women with persistent genital arousal disorder (PGAD) found that they were more likely than non-PGA women to evidence high levels of panic attacks and OCD [88]. Corona et al. [96], in contrast, found that high levels of OCD symptoms were associated with a lower prevalence of HSDD in men. Clearly, more research is needed to better understand the role of OCD in the development and maintenance of sexual dysfunction in men and women.

2. HISTRIONIC PERSONALITY DISORDERS AND SEXUAL DYSFUNCTION

There is a marked lack of research regarding the sexual attitudes, behavior, and relationships of patients with histrionic personality disorders. Apt and Hurlbert [135] compared a sample of women with histrionic personality disorder (HPD) with a matched sample of controls (aged 24-31 years). Women with HPD were found to have significantly lower sexual assertiveness, greater erotophobic attitudes toward sex, lower self-esteem, and greater marital dissatisfaction. They also had significantly greater sexual preoccupations, lower sexual desire, more sexual boredom, greater orgasmic dysfunction, and were more likely to enter into an extramarital affair. Apt and Hurlbert concluded that, although these patients are inordinately concerned with their physical attractiveness and sexual appeal, their sexual behavior varies widely and tends to run the gamut from unresponsive to promiscuous.

3. BORDERLINE PERSONALITY DISORDER AND SEXUAL DYSFUNCTION

Similar to the study above, Hurlbert [136] found that women with borderline personality disorder showed higher sexual self-esteem and sexual assertiveness compared to controls but also a greater likelihood of having extra-marital affairs. Sensation seeking, often associated with narcissistic personality disorders, has been associated with increased sexual desire and arousability but is not associated with marital/sexual satisfaction [135].

4. SUMMARY: SEXUAL DYSFUNCTION IN OBSESSIVE-COMPULSIVE, BORDERLINE AND HISTRIONIC PERSONALITY DISORDERS

It appears that personality disorders are often associated with difficulties in intimacy, sexual desire, and pair-bonding. However, the empirical evidence is too limited to draw conclusions regarding causal relationships between any specific personality disorder and sexual dysfunction. The available information consistently indicates higher levels of psychological distress and a substantial overlap with symptoms of mental disorders in sexually dysfunctional patient samples. The problems most often identified in sexually dysfunctional individuals are mood and anxiety disorders, and deficits in self-esteem and self-regulation, with some studies indicating that women are more affected by these factors than men.

However, conclusions based on the data currently available are seriously limited on methodological grounds. A wide array of heterogeneous instruments ranging from unvalidated global measures of psychopathology to more refined and validated instruments including interviews have been used to establish diagnostic criteria. In addition, in some studies, mixed diagnostic groups and small samples were used, while others did not employ matched control groups.

5. OTHER PRECIPITATING FACTORS FOR SEXUAL FUNCTION AND DYSFUNCTION

In addition to the disorders described above, there is a wide array of precipitating factors that may “tip the balance” from satisfactory sexual function to dysfunction. Among these factors (but by no means all) are life stage stressors such as childbirth, infertility, divorce or loss, unemployment, extra-relationship affairs, humiliating or traumatic sexual experiences, partner sexual inadequacy or clumsiness and most significantly, relationship discord. Space limitations preclude a discussion of all of these factors, so we will focus on the most important, namely interpersonal and relationship contributions.

6. ANGER ASSOCIATED WITH SEXUAL DYSFUNCTIONS

In assessing individuals and couples with sexual problems, clinicians often identify the presence of anger in the individuals and relationship. Kinsey
pointed out the striking similarities between the physiological responses during sex and the bodily reactions that accompany the experience of anger [137]. This similarity was also noted in primate studies where MacLean [138] showed that sexual and aggressive responses are in extremely close proximity to each other in the limbic system of the brain. Several clinicians speculated that sexual dysfunction may be a means of expressing anger at the partner [139, 140]. Additionally, Kaplan [75] stated that the partner rejection, power struggles and sexual sabotage create dysfunction rather than pleasure. Sex therapy cannot be conducted separately from an examination of the couple’s hostility. Exploration of anger must be pursued if treatment is to be successful in the longer term [141].

D. INTERPERSONAL DIMENSIONS OF SEXUAL FUNCTION AND DYSFUNCTION

Clinically, it has been observed that sexual problems are sometimes the cause and sometimes the result of dysfunctional or unsatisfactory relationships. These observations generally stem from clinical data rather than controlled research with community samples. Often it is difficult to determine which came first— a non-intimate and non-loving relationship, or low sexual desire and/or performance problems leading to partner avoidance and antipathy. The research literature is conflicting, and often difficult to interpret since couples begin therapy with varying degrees of relationship satisfaction or dissatisfaction. An early study found that sexual and relationship satisfaction were independent domains [142] (see Table 5). Heiman et. al. [142] reported that sexual satisfaction remained intact in a non-clinical sample of 110 couples even when a sexual dysfunction was present, although the majority of the research literature shows a correlation between sexual problems and relationship problems.

Most studies that have examined the impact of interpersonal issues on sexual function have used a correlational study design rather than randomized controls trials, limiting the extent to which causative statements and generalizations may be drawn.

I. RELATIONSHIP DYNAMICS AND SEXUAL DYSFUNCTION IN MEN AND WOMEN

McCabe and Cobain [143] found that global deficits in the current relationship were more likely to occur among sexually dysfunctional women than sexually functional women, but found no differences between the two groups in communication or number of arguments. These authors believe that women who are in poor relationships may express their lack of relationship satisfaction by avoiding sexual interactions and restricting their range of sexual experience and intimacy. Among men, however, relationship problems did not appear significantly related to sexual dysfunction, but the level of arguments did. Men with HSDD evidenced more difficulties than non-HSDD men in their level of relationship functioning by demonstrating increased arguments and lower sexual satisfaction. Donahue and Carroll [144] reported similar findings: female clients with HSDD demonstrated lower levels of relationship satisfaction than male clients with HSDD. Kelly et al. [145] also found that among couples where the female was experiencing orgasmic disorder, the couples experienced poorer communication than control couples who did not experience any sexual dysfunction. Roffe and Brit [146] found evidence for high levels of hostility among couples seeking sex therapy. They also found that lack of expressiveness and low levels of affection within the relationship contributed to sexual dysfunction. Although there has been limited research conducted on the relationship of men with PE, Rosen and Althof [100] found that PE impacted on both the men and their partners. The impact of sexual dysfunction on the relationship is well illustrated in a study conducted by Oberg and Fugl-Meyer [147], who found that the major predictors of female sexual dysfunction were dissatisfaction with the relationship and partner sexual dysfunction.

An interesting finding by Smith et al. [69, 148] was that the partners of men with Chronic Prostatitis/Chronic Pelvic Pain Syndrome also experienced low levels of sexual functioning and sexual satisfaction, as well as poor relationship functioning. In fact, male sexual functioning significantly predicted the sexual functioning of their female partner. Atwood et al. [149] also emphasized the importance of the couple relationship in both the development and maintenance of ED. Clinicians and researchers have noted that these relationship problems are often not well addressed in the resolution of sexual dysfunction in both men and women [150].

There are methodological problems associated with most of the research exploring the interaction between sexual and relationship function and satisfaction. Many of the studies consist of small, non-representative samples, lack a no-treatment control group, provide inadequate assessment of the specific sexual dysfunction(s) and fail to adequately assess the couple’s relationship. More significantly, it is difficult to determine to what extent the sexual complaints led to lower relationship satisfaction or the conflict in the relationship resulted in poorer sexual function and satisfaction. Finally, the reported association between relationship maladjustment and sexual dysfunction is confounded in studies of “clinical populations” rather than population-based studies.

II. RELATIONSHIP DYNAMICS AND HYPOACTIVE SEXUAL DESIRE

HSDD is one of the most perplexing, prevalent and etiologically complex of all the sexual dysfunctions. It is generally found to be more common in women than in men [151-153]. In men it is often confounded with arousal and erectile problems, making it difficult to determine the primary diagnosis. There is a considerable overlap between desire, arousal and orgasmic difficulties for both men and women.

Interpersonal factors are frequently cited as one of the causal determinants of low sexual desire. Social-developmental theories e.g., Scharff’s [154] object relations perspective; differentiation theories; (e.g., Schnarch [155]), and cognitive behavioral theories (e.g., Pridal & LoPiccolo [156]), address the role of relationship factors as either inhibiting or facilitating the experience of sexual desire.

Most theories describe HSDD as emerging from an interaction between individual and dyadic characteristics. Notable examples are Talmadge and Talmadge’s [157] relational model, and Rosen and Leblum’s [158] sexual scripting paradigm. Zilbergeld and Ellison[159] and others [155] have theorized that sexual dysfunction, particularly HSDD, serve as a “distance regulator” in a relationship. If a couple is fearful that too much intimacy will lead to fusion and lack of individual differentiation, one or both partners may attempt to create distance, often through sexual apathy. Even approaches that do not view relationship issues as central to sexual desire recognize the role of the current relationship in maintaining the individual determinants of the disorder [160].

It is generally agreed that, at the very least, the cooperation of the partner without HSDD is essential for the successful treatment of desire disorders [161]-[162]. In fact, 73% of surveyed physicians endorsed the belief that sex therapy or psychotherapy with both members of the couple is the best form of treatment for most cases of inhibited sexual desire[163]. Further, there is empirical evidence indicating that sex therapy with the couple is more efficacious than treating the HSDD patient alone [164], that combined marital and sex therapy approaches are more efficacious than sex therapy alone for couples with HSDD [165], and that women with HSDD show modest improvement in desire and other aspects of sexual functioning following brief marital therapy [166].

There is research supporting the observation that low sexual desire is associated with lower levels of relationship satisfaction and adjustment, both for individuals with low desire and their partners [167]. For example, couples with HSDD have poorer levels of dyadic adjustment than couples without HSDD [168]. Similarly, Trudel, Landry and Larose[93] found that compared to controls, couples in which one partner was diagnosed with HSDD obtained lower adjustment scores on the Marital Happiness Scale. Hurlbert et al. [169] found that the relationship between HSDD and relationship functioning was stronger for women than for men.

A large scale health and sexuality survey of 2,050 pre-, peri-, and postmenopausal women between the ages of 20-70 found that those women who reported lowered levels of sexual desire also reported more relationship dissatisfaction, lower frequencies of sexual activity, fewer orgasms and more distress [170].

McCabe [171] observed that individuals with HSDD reported lower levels of intimacy and lower satisfaction with the quality of the intimacy in their lives than controls. Davies et al. [172] examined discrepancies between partners’ levels of sexual desire, and found that for both husbands and wives, individuals who felt that there was a discrepancy between their own and their partner’s desire reported lower relationship satisfaction.

In stable long-term relationships, sexual frequency declines over time, although satisfaction may continue to remain high. Even among young adults, sexual frequency declines over time. Klusmann [173], for example, reported changes in sexual interest in students between 19 and 32 years of age who were in “steady partnerships.” He found that both sexual activity and sexual satisfaction declined over time but that desire decreased only in women. Desire for tenderness decreased in men but increased in women over that period.

III. THE IMPACT OF RELATIONSHIP THERAPY ON SEXUAL DYSFUNCTION

Wiederman [174] suggests that treatment focused solely on the sexual dysfunction is likely to fail if the underlying relationship dynamics are ignored. He maintained that without treating the problematic relationship, enhanced sexual function is likely to be temporary or that other psychological symptoms in one or both partners will develop in order to maintain homeostasis. At present, there is limited empirical research to either support or refute this view.

In a comprehensive review of treatments for sexual dysfunction, Besharat [175] highlighted the importance of communication and conflict resolution strategies as well as resolution of systemic issues in the relationship. While there are conflicting findings, the preponderance of evidence suggests that therapy, which specifically addresses relationship
issues, will be more successful than therapy that only focuses on the resolution of the sexual dysfunction. The existing research supports the observation that the quality of the relationship plays an important role in the outcome of sex therapy [176].

Stravynski et al. [177] conducted a study to determine if treatment outcome for sexually dysfunctional men differed depending upon whether therapy focused on sexual problems, interpersonal issues, or a combination of both. The results demonstrated that a focus on the interpersonal issues was more effective than the other two treatments. Although the combined treatment was more effective at post-therapy and at six months follow-up than the interpersonal therapy, by the one-year follow-up there were no differences between the levels of sexual dysfunction for these two groups. This finding would suggest that, in the long-term, the most important focus of therapy for sexual dysfunction is on developing interpersonal skills and resolving relationship problems. In a subsequent study of sexually dysfunctional women, Stravynski et al. [177] found that treatment focusing on the resolution of sexual problems or relationship problems were equally effective compared to a control condition in resolving sexual problems at both post-treatment and 12 month follow-up. Kilmann et al. [178] also found that relationship adjustment was the strongest predictor of successful treatment outcome among men with erectile dysfunction. Similar findings were obtained among sexually dysfunctional women [179].

In contrast to the above findings, Hawton, Catalan, and Fagg [180] found that the quality of the couples' relationship was not related to successful treatment outcome for women presenting with low sexual desire. The most important predictor of success was the male partner's motivation to obtain a successful outcome at the beginning of therapy.

The role of the partner in the treatment outcome of sexually dysfunctional couples is clearly illustrated in a study by Hirst and Watson [181]. These authors found that good outcomes following treatment were obtained for dysfunctional individuals without partners, or for those individuals whose partners agreed to participate in therapy, whereas substantially poorer outcomes were obtained for those individuals whose partners did not participate in treatment. Consistent with the importance of the partner in treatment outcomes, Sand et al. [182] found that men with ED rated their relationship with their partner higher than many other aspects of their lives (e.g., employment, material possessions). These findings highlight the importance of interpersonal relationships in managing ED.

In a series of case studies, Leiblum [183] and Althof [184] both found that although oral medication (e.g., sildenafil citrate) may assist a man in obtaining an erection, the use of this intervention was unlikely to lead to a satisfying sexual relationship unless relationship issues were also addressed. These issues include feelings of insecurity that develop as a result of the sexual dysfunction, as well as anger and disappointment. Returning to an active sexual life after an extended period of sexual abstinence requires more than medication alone. Leiblum and Althof [184] highlighted the importance of obtaining a thorough assessment and treatment of both the interpersonal and sexual relationship as well as including the partner, where possible, in the therapy process.

While the evidence is not conclusive and the studies cited are not randomized controlled trials but primarily Level 3, 4 and 5 research, the findings demonstrate a significant relationship between sexual and relationship functioning. While it is impossible to determine cause and effect relationships with any certainty, the literature suggests better long-term outcome when relationship issues are treated and resolved.

Whether the relationship problems preceded the development of the sexual dysfunction, or vice versa, it would appear that the most effective form of intervention is to treat both the relationship and sexual difficulties. If this does not occur, the problem that is not addressed may continue to influence the other area that is the focus of treatment, and so eventually undermine the treatment process. Clearly, more rigorous controlled studies need to be conducted to determine the validity of this argument more conclusively.

E. LOVE AND INTIMACY

It would be neglectful to discuss psychological and interpersonal contributions to sexual function and dysfunction without including some references to the importance of love and intimacy. While cultures vary enormously in the degree to which they consider love important for marriage, or even, the importance of love at all in interpersonal committed relationships, most individuals in Western countries believe that emotional intimacy and feelings of love enhance and sustain sexual satisfaction and pleasure.

There is little or no empirical research on this topic, so the comments that follow are based on clinical observation rather than scientific data.

It is clear that love implies different meanings to different individuals [6]. Some of the meanings include the following:

- Love is a label for the transient emotions that bring together various degrees of pleasure and interest between two individuals.
- Love is an idealized ambition e.g. To have mutual respect, reliability, fidelity,
intimacy, sexual pleasure, and a comfortable balance of individuality.

- Love is a commitment. Typically, love involves the commitment of two people to honor and cherish each other throughout life’s vicissitudes.
- Love is an idealized internal representation of the partner. When a person falls in love and continues to be happy with a partner, an internal image of the beloved is created and reinforced. This internal idealized image enables an individual to deal with a partner when he or she is behaving badly or when disappointments ensue.
- Love is a “deal” with a person who possesses desired and desirable assets.
- Endearing words of love are often expressed when a person wants to have sex.

While not typically discussed in scientific discourse or evidence-based research, love is a vital ingredient for many individuals in fostering and maintaining strong and satisfying interpersonal and sexual intimacy. Mechanistically treating sexual problems without considering or discussing the quality of caring and love between partners is usually unsuccessful, if not immediately, then over time.

### F. MAINTAINING FACTORS FOR SEXUAL DYSFUNCTION

While the predisposing and precipitating factors that have been reviewed are important to assess, they may not be responsible for the chronic nature of a sexual problem. It is the maintaining factors that are responsible for transforming disappointing or episodic sexual failures into chronic dysfunction. Examples of maintaining factors include the following: performance anxiety, loss of sexual confidence, guilt, inadequate sexual information or stimulation, psychiatric disorders, relationship discord, loss of sexual chemistry, fear of intimacy, impaired self-image or self-esteem, restricted foreplay, and poor communication. The factors that maintain sexual dysfunction may not be the ones that initially predisposed or precipitated the initial sexual failure. However, by the time individuals present for treatment, the maintaining factors may be more disruptive to therapeutic outcome than those that initially predisposed the person to develop the sexual dysfunction. A case illustration may illuminate this point:

A 34-year-old woman complains of an inability to become both physically and subjectively aroused during sexual intercourse with her male partner of two years. Assessment reveals an early history of father-daughter incest, which, however, appeared to have been satisfactorily resolved during her late adolescent years. She enjoyed good sexual response during early courtship with both her present partner and previous partners. However, her current partner is often demeaning and critical of her body shape and weight and so, she has become quite self-conscious during love-making. This has led to distraction during sex, which further interferes with her sexual response, which then becomes a point of contention between them. Anticipation of critical comments from her partner leads to performance anxiety and further inhibits her response creating a downward spiraling negative cycle.

### I. PERFORMANCE ANXIETY

Early etiological theories [74] regarded performance anxiety as the crucial pathogenic factor for maintaining sexual difficulties. Performance anxiety is the fear of future sexual failure based on previous failures- a common maintaining contribution for almost all male and female sexual dysfunctions. Many theorists consider performance anxiety to be the central causal factor interfering with sexual arousal since it serves as a distraction from sensual feelings, undermines sexual self-confidence and ultimately, contributes to sexual avoidance.

### II. SEXUAL CONFIDENCE

An important aspect of the psychological response to sexual dysfunction is the extent to which the man or woman lost, or in some cases never achieved confidence in both their capacity to function sexually, as well as the extent to which they perceive themselves to be a sexual being. This is given the umbrella term of "sexual confidence", and the limited literature that has evaluated this important concept is outlined below.

Althof [185,186] described one of the goals for psychotherapy for both men with ED and PE to be the enhancement of his sexual confidence. He suggested that although there are now medical treatments for PE, it is important to address the psychological factors associated with this condition, one of which is the level of the man’s diminished sexual confidence. Perelman [187] also noted the reduction in sexual confidence that is associated with PE, and emphasized the importance of addressing the man’s confidence in his sexual functioning in therapy.

Men receiving sildenafil or tadalafil for the treatment of ED reported significantly improved sexual confidence following treatment [188-191]. Additionally, Phelps, Jain, and Monga [192] found that a combination
treatment with sildenafil and a psychoeducational intervention was more likely than sildenafil alone to increase the man’s sexual confidence as well as his satisfaction.

The above findings demonstrate the importance of considering sexual confidence in the treatment of both ED and PE among men. It is possible that medical treatments may increase the level of a man’s sexual confidence, but it would appear that psychological interventions may be necessary for many men to restore their confidence in their sexual functioning.

No studies were located on the association between female sexual dysfunction and the levels of sexual confidence. However, it is highly likely that sexual dysfunction is strongly associated with a reduction in a woman’s level of sexual confidence, and so this dimension of psychological functioning should be targeted in therapy.

### III. OTHER MAINTAINING FACTORS

Space precludes a discussion of all the maintaining factors that may be responsible for turning an acute problem into a chronic one. Suffice it to say that maintaining factors include those present conditions that enhance or impede sexual comfort and intimacy. In particular, anxiety, depression and confidence, as well as problems in the relationship, which are factors that have been discussed elsewhere in the chapter, are likely to be responsible for maintaining sexual dysfunction in both men and women. Maintaining factors include immediate contextual factors that influence sexual spontaneity, as well as partner-related factors such as sexual technique and absence of sexual dysfunction. It is obvious that there is reciprocity in partner-related sexual activities such that a problem in one partner may trigger problems in the partner and vice versa. It is therefore essential to assess how sexual partners mirror each other in terms of desire, arousal and satisfaction.

### G. HOW SUCCESSFUL ARE WE IN CHANGING DYSFUNCTIONAL SEXUAL BEHAVIOR?

### I. THE CHALLENGE OF OUTCOME RESEARCH IN SEX THERAPY

Sex therapy outcome studies are notoriously difficult to design and conduct. The challenge facing researchers is not only to design studies that meet the highest level of evidence-based medicine but to also demonstrate regard for the complexity of sexual life. A narrow mechanistic focus on genital function/dysfunction or successful performance fails to encompass the broader variables that constitute patient and partner sexual satisfaction and dysfunction and disease-specific quality of life (QoL) [184, 193]. As such, in some newer models of sexual response [194], psychological and relational components play a more significant role than previously was the case. For these reasons the use of validated tools such as the IIEF and the FSFI in the measurement of any changes during sex therapy is likely to have only limited value due to the narrow focus and specific items measured by the instruments. An example of incorporation of a psychological construct of perceived control over ejaculation has recently been determined as central to measuring benefit in men treated with a new compound dapoxetine for rapid ejaculation [195]. A recent systematic review of published self-report outcome measures of sexual function concluded that of the 23 self-report measures identified, only 14 could be judged reliable and valid measures, of which only two met ‘superior’ psychometric standards [196]. The use of target symptoms identified by the individual at the onset of sex therapy may likewise restrict the capacity for the researcher to identify the change processes which may occur during therapy.

Understanding and measuring changes in the flexibility of cognitive and behavioral coping processes which may be facilitated within sex therapy may be more appropriate outcome measures [197]. Additionally, QoL variables encompass relational, self efficacy/confidence, emotional and sexual satisfaction and pleasure. Thus, outcomes conceived solely in terms of women’s facility in achieving coital orgasm, men’s prowess at delaying ejaculation, the buckling force of an erection, blood flow through the clitoris and vagina, or the frequency with which partners bring their bodies together are far too restrictive outcome criteria. Sexuality outcome studies must assess the complex interplay between the biological, emotional, psychological and relational components of individual’s and couples’ lives [198].

For example, intracavernosal injection of vasoactive substances is an efficacious treatment in terms of inducing erection. However, the high-dropout rate, up to 60%, suggests a lack of treatment satisfaction [184]. Which clinical endpoint(s) should be used to assess treatment outcome? Should it be continued use of the treatment, efficacy in achieving or maintaining firm erections, sexual or relational satisfaction or partner sexual or QoL variables?

Chronic illnesses can disrupt QoL through adverse effects on sexual function which may long term or irreversible. As such, pharmacological treatments may have limited effectiveness for some chronic illnesses (e.g. diabetes).
There is also disagreement as to what defines a good treatment outcome even when function-oriented criteria are employed. For instance, in treating female anorgasmia, what defines success—achieving orgasm once, achieving orgasm from manual or oral stimulation some specified percentage of occasions, achieving coital orgasm with or without clitoral stimulation, etc? And, what constitutes success in treating erectile dysfunction—the ability to consummate intercourse (which is a distinctly heterosexual goal but which ignores a wide segment of the population, namely gay and auto sexual men) or the degree of penile rigidity?

The CORE Outcome Measure (CORE-OM) [199] is a 34-item questionnaire designed to measure a pan-theoretical ‘core’ of clients’ global distress, including subjective well-being, commonly experienced problems or symptoms, and life/social functioning. The main purpose of the tool is to offer a global level of distress which is expressed as the average mean score of the 34-items that can be compared with clinical thresholds before and after therapy to help determine clinical and reliable change. A recent study concluded that the psychometric properties of the CORE-OM are reproducible in a psychosexual population [200]. Finally, the emphasis on frequency counts of various sexual acts or initiations as a primary outcome measure is also questionable since it ignores both positive changes in sexual satisfaction and physical and emotional intimacy.

II. WHY IS THERE A PAUCITY OF WELL-CONTROLLED SEX THERAPY OUTCOME STUDIES?

Fundamentally, it appears that there are two primary explanations for the dearth of well-controlled sex therapy outcome studies. The first is that they are labor intensive and unfortunately, are not considered a priority by governmental granting agencies. Moreover, because there is no incentive for pharmaceutical companies to fund purely psychological treatments, this source of funding has been unavailable. The second reason is that the incredible success of Masters and Johnson’s [74] original treatment program made it seem as though we had found the “holy grail.” Never before or since has such a large-scale study reported such a highly successful post-treatment and five year follow-up of 792 men and women been achieved (with an overall reported failure rate of only 15%). For several decades, the field relied primarily on their treatment approach and few innovations were forthcoming [201]. Unfortunately, no other clinical study or center has been able to replicate Masters and Johnson’s impressive success either short- or long-term.

III. METHODOLOGICAL PROBLEMS IN SEX THERAPY OUTCOME STUDIES

Outcome studies in psychotherapy are lacking [202] and those in sex therapy pose some unique challenges. Spence [203] criticizes sex therapy outcome studies because often they: 1) employ small sample sizes; 2) do not use experimental control groups (waiting list, no treatment, attention placebo controls); 3) lack random allocation to conditions; 4) fail to offer clear cut definitions of diagnostic criteria to permit replication; 5) generally do not include assessments of long-term outcome; and 6) do not adequately describe the therapy method utilized.

Heiman and Meston [204] further criticize sex therapy studies for failing to utilize treatment manuals, which are considered prerequisites for designating a treatment as “well-established” using the American Psychological Association (APA) standards. This failure to describe a standardized manualization of interventions remains problematic because of the difficulty of reproducing interventions in subsequent investigations [205] and especially in sub-populations. Additionally, the effectiveness to the patient of any intervention may depend on the skills of the clinician delivering the intervention which is in turn influenced by previous training and on-going supervision of the individual sex therapist.

Psychometrically sound measurement instruments has, until recently, been lacking in the majority of outcome studies, thereby raising questions about the validity of the reported results. Many studies employ self-report instruments or patient diaries that lack validation or clinical judgments made by un-blinded clinicians.

The few studies that have reported long-term follow-up suffer from serious problems of sample attrition. Thus, the generalizations stemming from these studies may represent a biased subset of the total population.

Changes to the delivery of care will also influence the need for both improvement and choice of outcome measure. For example, studying the use of bibliotherapy [206, 207, 208] Hunot and Wylie [208] carefully designed evidence-based self-help tools [209] and internet delivery of sex therapy [210-213]. Finally, the overlap between different sexual dysfunction diagnoses can make comparisons across studies and treatment interventions difficult.

In past research, patients were often diagnosed with one dysfunction based on the belief that sexual dysfunctions were discrete disturbances in the sexual response cycle. There is currently recognition of the fact that there is considerable overlap among sexual...
disorders [153, 214]. There also remains an absence of clear consensus concerning core definitions [215]. This lack of clarity and overlap between diagnostic categories must be methodologically or statistically controlled in order to assess the impact of any intervention on the disorder under study.

Despite all of these shortcomings and difficulties, there is suggestive data indicating that sex therapy can be quite helpful in ameliorating male and female sexual dysfunctions. Further, there is no evidence against the efficacy of psychotherapy when applied to appropriate clinical populations [216].

H. PSYCHOLOGICAL TREATMENT OF SEXUAL DYSFUNCTIONS-GENERAL FORMULATIONS

Masters and Johnson’s groundbreaking contributions recounted in Human Sexual Inadequacy [74] described their innovative format of employing mixed-sex co-therapy teams working with couples in a quasi residential setting with daily individual and conjoint treatment sessions. Basic treatment elements included an emphasis on sensate focus exercises and the elimination of performance anxiety. Masters and Johnson recommended beginning with non-sexual touching and then, in a desensitization paradigm, moving on to more genitally focused caressing. By emphasizing the non-demand nature of the sensual exchange, Masters and Johnson sought to eliminate performance pressure.

Masters and Johnson’s treatment method was an expensive, therapist intensive, impractical model to reproduce. Therefore modifications of their treatment format were investigated to ascertain if similar results could be achieved with more conservative, conventional outpatient treatment models. Clinicians examined the impact of single therapist versus co-therapy teams, weekly versus daily treatment sessions and group formats versus individual/couple sessions. The results indicated that couples did as well when seen on a weekly basis and by a single therapist [217-219]. Two studies examined whether matching the gender of the therapist with the gender of the symptom bearer would result in improved outcome; no differences were found [217, 220].

Researchers also examined the efficacy of individual versus group treatment formats. Group formats were advantageous because they were less costly in terms of therapist time, provided patients with the knowledge that they were not alone in their suffering, offered peer support, and allowed patients to learn from the experiences of others. Additionally, competition within the group motivated patients to change behaviors and desensitized them to discussions of their private sexual lives [203]. However, the use of groups in sex therapy has been limited because of organizing and scheduling difficulties as well as finding enough patients with the same disorder available for treatment at the same time. One recent Cochrane Database systematic review to evaluate the effectiveness of psychological interventions for the treatment of ED found 11 RCT's and evidence that group therapy improved ED [221, 222]. Further a combination of sildenafil and psychotherapy together showed significant improvement in erectile function and decreased discontinuation from treatment. Drop out from therapy and lack of end of treatment therapy measures, regardless of whichever measure is used will further distort the reporting of change – beneficial or otherwise from sex therapy.

More recent approaches to sex therapy have included cognitive-behavioral interventions focused on challenging or correcting maladaptive cognitions, behavioral techniques such as desensitization and assertiveness exercises, family of origin and psychodynamic explorations exploring the role of past developmental experiences on present behavior and systemic and couples therapy.

The following sections will review the outcome of psychological and sex therapy on female and male sexual dysfunction.

I. TREATMENT OUTCOME FOR FEMALE SEXUAL DYSFUNCTIONS

In this section, treatment outcome will be described for both the recognized DSM-IV-TR and recommended new diagnostic categories of female sexual disorders, namely, hypoactive sexual desire disorders, female sexual arousal disorder (which includes genital arousal disorder, subjective arousal disorder, combined genital-subjective arousal disorder and persistent genital arousal disorder), orgasmic disorder and sexual pain disorders. Each of these dysfunctions can be further categorized into acquired and lifelong specifying whether they began after a period of normal function (acquired type) or have been present throughout the woman’s sexual life (lifelong). Heiman [223] and Heiman and Meston [204] have published comprehensive reviews of much of the evidence-based research looking at the prevalence, etiological factors and treatment outcome for the various female dysfunctions. In the last edition of this volume, Althof, Leiblum, et. al. [224] provided a more current update and evaluation of the literature on female sexual dysfunctions. This section will summarize the treatment outcome studies for female sexual dysfunction that have been conducted both in the past and most recently.
I. SEXUAL DESIRE DISORDERS

There is a dearth of efficacy data on the psychological treatment of sexual desire disorders, despite the fact that hypoactive sexual desire is the most common female sexual complaint [225]. There is no shortage of published descriptions of psychological treatments [155, 226], but most however, do not meet contemporary standards for evidence based research. Consequently, most of the studies reviewed here are of Levels 3, 4 and 5 evidence.

Sexual desire is difficult to define and difficult to measure. Does one count sexual frequencies of various sexual behaviors or attempt to assess the degree of internal motivation to engage in sexual activity? Do we tally sexual fantasies or frequency of various sexual behaviors as a proxy measure of desire or interest? And, perhaps more importantly, what should be considered indicative of a successful treatment outcome? Greater frequency of sexual behavior? More pleasurable activity? Partner or self satisfaction with the degree, intensity and frequency of sexual exchange? Less subjective distress about the level of desire? Changes on a validated assessment instrument?

Basson [227] and others [228, 229] have argued that many women never report spontaneous desire yet can become readily aroused with effective stimulation or the wish to be intimate with a partner. Basson believes that lack of responsive desire is more likely to be a marker of HSDD than spontaneous desire. She [227] postulated that many women in established relationships engage in sex from an initial stance of sexual neutrality and then, with increasing amounts of arousal, begin to experience desire. Often, desire is triggered by a variety of internal motivations or external reinforcements rather than intrinsic physical tension although for women in new relationships, desire may be experienced more spontaneously. It must be acknowledged that the motivations or incentives to either initiate or respond to a sexual request or overtire are extremely varied. In an interesting research study conducted by Meston and Buss [230] with 1,549 undergraduates, the researchers and their students identified hundreds of reasons for engaging in sex, but were able to categorize them into four main factors and 13 subfactors. The four main factors were Physical, Goal Attainment, Emotional and Insecurity. The Physical subfactors encompassed stress reduction, pleasure, physical desirability and experience seeking. The Goal Attainment subfactors included resources, social status, revenge and utilitarian. Emotional subfactors included love and commitment and expression. And finally the three Insecurity subfactors were self-esteem boost, duty/pressure and mate guarding. Obviously, knowing that a sexual experience has occurred tells us nothing about either the desire accompanying it, or the diverse and not necessarily sexual motives for engaging in it!

There is little agreement about what constitutes normal desire in women of various ages given the hormonal variations accompanying different life stages. Consequently, there is little agreement as to what constitutes a sexual desire disorder as opposed to normative changes in sexual interest over the female life-cycle [229]. While situational and acquired loss of desire is characteristic of many life stages, e.g., pregnancy and child-rearing, generalized and chronic lack of desire is more resistant to intervention and suggests a different etiology.

Hawton and his colleagues [231] conducted a prospective, non-controlled study of a community sample of couples who underwent a modified Masters and Johnson treatment program. Sexual desire problems seemed to be alleviated largely or completely in 56% of the couples following treatment. However, in follow-up, 1 to 6 years after treatment termination, 75% of the sample had relapsed. In a subsequent review of the efficacy of sex therapy for sexual dysfunctions, Hawton [218] noted the variable outcome that is often found across studies. He observed that outcome is worse when the male partner is the identified HSDD patient and has low motivation to engage in treatment than when the female partner is the target of treatment.

Hurlbert [232] investigated the viability of orgasm consistency training for the treatment of female HSDD. Women were randomly assigned to group treatment with either standard sex therapy interventions or the addition of orgasm consistency training (directed masturbation) in addition to sensuality exercises, communication training and education. Post-treatment and follow-up at 3 months suggested that there was greater improvement in the orgasm consistency group although both groups demonstrated greater sexual arousal and assertiveness as well as greater sexual satisfaction.

The efficacy of cognitive-behavioral therapy for women with HSDD has been reported in two studies. McCabe [233] found that of the 43% of women complaining of HSDD who underwent 10 sessions of CBT, 54% had the same complaint following treatment. Treatment in this case consisted of 10 sessions of a cognitive behavioral therapy. The program included interventions designed to enhance communication between partners, increase sexual skills and reduce sexual and performance anxiety. Overall, improvement was noted for 44% of the women. The findings are limited, however, in that many of the women had multiple sexual dysfunctions and there was no control group.

In a study by Trudel et. al. [234] comparing cognitive behavioral interventions specifically developed to address desire disorders with a control condition, 74%...
of the low desire women no longer met diagnostic criteria for HSDD after 12 weeks of group therapy and these effects were said to be maintained at a 1-year follow-up assessment. Compared to the control group, CBT resulted in significant improvement in quality of sexual and marital life, sexual satisfaction, perception of sexual arousal, sexual self-esteem and less depression and anxiety.

The most recent and promising group treatment for women with sexual desire complaints is employs a three session mindfulness-based psychoeducational intervention [235, 236]. “Mindfulness” is described as “relaxed wakefulness” or “non-judgmental, present-moment awareness” and is derived from Buddhist meditation [237]. In a small study of 26 women with complaints of either desire or arousal problems, Broto, Basson and Luria [235] reported significant improvement in sexual desire on the Female Sexual Function Index (FSFI) and a reduction in sexual distress with just three 90 minute psychoeducational sessions spaced two weeks apart. The psychoeducational intervention consisted of a variety of cognitive-behavioral exercises targeted to sexual arousal and desire complaints (e.g., body image distortion, maladaptive beliefs about sexuality, relationship distress, etc.) but most importantly, mindfulness exercises along with homework assignments involving reading, self-observation, behavioral exercises and couple communication. The most positive changes were noted in the 8 women with a prior history of sexual abuse. These authors suggest that mindfulness techniques might be especially helpful in altering the activity of the middle prefrontal cortex which consists of brain areas which are activated when a reflective state is achieved and prior expectations, automatic thoughts and emotional reactions are reduced.

At this time, most of the large-scale funded research seeking to enhance female sexual desire have focused on pharmacological interventions, eg., bupropion or libanserin [238, 239] or hormonal treatments such as androgen supplementation delivered via gels, creams, patches, pills or injections [240-242]. Recently there have been randomized, double-blind, placebo-controlled studies investigating the long-term treatment of a testosterone patch on women’s sexual desire and arousal. Several of these studies have found small changes in the number of satisfying sexual events, improved sexual satisfaction, and diminished distress with androgen treatment [240, 243]. A review of this research is beyond the focus of this chapter and may be found later in this volume. Unfortunately, there are no studies comparing hormonal supplementation with other pharmaceutical compounds, sex therapy or couples’ therapy and none looking at the impact of combined treatment. Combination therapy with both medical and psychological interventions has the potential to address the multiply-determined biopsychosocial issues that contribute to the development and maintenance of HSDD. This is an area that warrants well-controlled research with different populations of women, both pre- and post-menopausal.

### I. SEXUAL AROUSAL DISORDERS

To date, there are only a few published outcome studies specifically focusing on the psychological treatment of female arousal disorders. This is partly attributable to the historical lack of attention paid to arousal disorders per se as well as to the described co-morbidity of female sexual disorders. Recently, there has been considerable interest in female sexual arousal disorder because of the success of vasoactive agents in the treatment of male erectile disorder [244-246].

Although not officially adopted at this time, a recent consensus conference composed of experts in women’s’ sexuality proposed a new nomenclature for diagnosing women’s sexual disorders generally, and arousal disorders in particular. Four sub-types of arousal disorders in women were identified: genital sexual arousal disorder, subjective sexual arousal disorder and combined genital and subjective arousal disorder. Additionally, a disorder involving excessive and persistent genital arousal was identified, persistent genital arousal disorder (PGAD), which is characterized by insistent feelings of genital vasocongestion and throbbing in the absence of conscious desire, genital arousal unrelieved with orgasm, genital arousal unrelated to sexual desire, genital arousal which is intrusive or unwanted, and genital arousal which is at least moderately distressing [247-249]. To date, most of the treatment of PGAD has consisted of single case reports involving either discontinuation of medications that appeared to be associated with the onset of symptoms, mindfulness and distraction based interventions, pelvic floor therapy, or surgery for anomalous blood flow conditions [250, 251].

While most of the treatment studies involving complaints about sexual arousal have focused on the use of hormonal supplementation, e.g. estrogen or androgen replacement for deficient lubrication or sensation, there are a few recent studies exploring the use of psychological treatments for increasing subjective sexual arousal. For example, the psychoeducational group treatment model used to treat women with sexual desire complaints (described above) was also found to be effective for the treatment of arousal difficulties in women with gynecological cancer [236, 252]. In this small group intervention, three sessions focusing on cognitive and behavioral therapy with education and mindfulness training was employed. Women completed questionnaires and had a physiological measurement of genital arousal both at the start
and end of the therapy. The investigators reported a positive effect on sexual desire, arousal, orgasm, satisfaction, sexual distress, depression and overall well-being and a trend towards significantly improved physiological arousal.

III. ORGASMIC DISORDERS

According to the DSM-IV, female orgasmic disorder is defined as the “…delay in, or absence of, orgasm following a normal excitement phase….” although what constitutes a normal excitement phase is uncertain [253]. Summarizing several studies, Haavio-Mannila and Kontula [254] reported that women experience orgasm only 40 – 80% of the time, regardless of the method of stimulation. The absence of orgasms during intercourse does not constitute a genuine sexual dysfunction [255, 256]. The overlap between desire, arousal, and orgasm difficulties in women further complicate differential diagnoses.

No single factor has been shown to be strongly related to orgasmic response and dysfunction in women [257]. In general, women with orgasm difficulties tend to experience more sex guilt [258, 259], tend to be less sexually assertive [260, 261], and endorse more negative attitudes towards sexual activity and masturbation [143, 145]. Women with orgasmic difficulties have been found to be less aware of physiological signs of arousal and orgasm [255, 262]. Heiman and Grafton-Becker [257] noted that anorgasmic women often fear loss of control during orgasm.

As with other sexual dysfunctions, female orgasmic disorder can be divided into lifelong and acquired subtypes. Different treatment approaches have been shown to be effective for the two subtypes. Directed masturbation training is most efficacious for lifelong and generalized orgasmic problems [204]. This treatment involves self-stimulation in which the woman becomes more aware of the type of stimulation needed to increase her arousal and pleasure and subsequently generalizing this to partner sexual situations. Heiman and Meston [204] noted that across all studies involving nearly 600 women seen for between 6-14 treatment sessions, directed masturbation alone was superior to systematic desensitization and directed masturbation with sensate focus was more effective than sensate focus alone [263-273]. Women with acquired and situational female orgasmic disorder tend to be more distressed about and less satisfied with their overall relationship [178, 274, 279]. Consequently, treatment often includes some combination of education, sexual skill training, couples’ therapy, masturbation and non-demand touching exercises, as well as interventions to address body image concerns and negative sexual attitudes.

Many investigations highlighted the importance of couples’ treatment along with sex therapy for the resolution of these problems. Women with acquired and situational female orgasmic disorder tend to be more distressed about and less satisfied with their overall relationship [178, 274, 279]. Consequently, treatment often includes some combination of education, sexual skill training, couples’ therapy, non-demand touching exercises as well as interventions to address body image concerns and negative sexual attitudes.

In the McCabe [233] study cited above, of the 36 women (67% of the initial sample of 54 women) presenting with anorgasmia who completed treatment, successful outcome was achieved with 89%. Heiman [223] notes that “treatments for primary anorgasmia appear to fulfill the criteria of “well-established” whereas situational anorgasmia studies fall into the “probably efficacious” group.

It should be noted that the relative failure of reported treatments of coital anorgasmia may be due to misdiagnosis. A major difficulty with past definitions of orgasmic disorder was that women who were
diagnosed with female orgasmic disorder may well have been more accurately diagnosed with a sexual arousal disorder, that is, a lack of sufficient physical or subjective arousal which obviously impeded orgasmic attainment. In fact, the more accurate diagnosis for many of the women in earlier research would be female sexual arousal disorder rather than orgasmic dysfunction [280].

IV. SEXUAL PAIN DISORDERS: DYSPAREUNIA AND VAGINISMUS

The sexual pain disorders tend to be quite prevalent, although they often go unreported since some women tolerate uncomfortable sexual exchange for months or even years without seeking assistance. Coital pain has been estimated to affect about 15% of American women according to the recent large-scale survey of sexual health [151].

The definition of dyspareunia recommended by the consensus conference on women's sexual disorders (2001) is "persistent or recurrent pain with attempted or complete vaginal entry and/or penile vaginal intercourse". Although included as a sexual dysfunction in the DSM-IV, Binik and his collaborators have long argued that dyspareunia should be classified as a pain disorder rather than a sexual dysfunction since pain is the most salient aspect of the syndrome [281].

Etiologically, a host of psychological factors have been associated with the complaint of dyspareunia but it is difficult to determine which is the cause and which is the effect of living with a chronic pain disorder [282]. Among the psychological concomitants that have been researched are: childhood sexual trauma, phobias, hostility, and in particular, reports of anxiety and depression. Even depression scores are associated with greater pain complaints. Relationship discord is frequently reported. There are also a large number of organic conditions that can either cause or maintain sexual pain: physical factors such as infection, hymenal scarring, STD's, pelvic inflammatory disease and most especially, neural and pelvic floor contraction are often instrumental in the genesis of the problem. Pelvic floor massage with an experienced massage therapist in addition to cognitive education, relaxation training, self-insertion exercises and sensuality training are included in treatment programs. The repeated experience of pain with sexual intercourse typically leads to increased genital muscle tension which further exacerbates existing pain by adding muscle pain to the original pain interfering with penetration and reducing genital blood flow[283]. Catastrophizing thoughts and hypervigilance as well as performance anxiety only make matters worse.

Treatment of dyspareunia ideally requires a multidisciplinary approach involving a physician, a pelvic massage therapist, and a psychotherapist. Treatment focuses on learning techniques for reducing or coping with the pain as well as dealing with catastrophic thoughts, anticipation of pain and avoidance of all sexual exchange. Biofeedback, vaginal and/or pelvic massage, tricyclic anti-depressants, Xylocaine before intercourse, sensuality exercises, avoidance of perfumed or irritating products, a low oxalate diet and relaxation techniques have all been tried, with varying degrees of success. Education about vulvodynia in general, and vulvar vestibulitis in particular, has been found helpful as well as cognitive restructuring and sex therapy with both partners.

The most well controlled study of women with vulvar vestibulitis was reported by Bergeron et. al. [284], who compared biofeedback, cognitive-behavioral therapy and vestibulectomy in a randomized series of 78 patients. While all three groups reported improvement in symptomatology post-treatment and at 6 month follow-up, vestibulectomy resulted in approximately twice the pain reduction as compared with the other two treatments. The authors concluded that vestibulectomy was superior to the two psychological interventions, although it did not significantly change the frequency of intercourse or other psychosocial variables. In a 2.5 year follow-up study of these women [285], 51 of the 78 women from the original study were reassessed. The investigators completed a gynecological exam, a structured interview and validated pain and sexual functioning measures. There were less pain complaints at the 2.5 year follow-up than at the 6 month follow-up and there were no differences on the sexual measures at 6 months or at 2.5 years follow-up. Of significance, higher pre-treatment pain intensity was associated with poorer treatment outcome at the 2.5 year follow-up for all interventions- vestibulectomy, biofeedback, and cognitive-behavioral therapy.

Vaginismus has been diagnosed as persistent or recurrent difficulties to allow vaginal entry of the penis, a finger, and/or any object, despite the woman's expressed wish to do so. There is variable (phobic) avoidance and anticipation/fear of pain [280] associated with this disorder. It is usually treated through a combination of relaxation exercises and in vivo graduated self-insertion of dilators of increasing size [286]. Typically, education about the female anatomy as well as Kegel and puboccygeal exercises are part of treatment along with more psychodynamic exploration of the genesis and meaning to the woman of vaginal penetration. While Masters and Johnson [41] reported a 100% success rate in their treatment of 29 women, more recent investigators have noted somewhat less positive outcome, although most studies concur in finding behavioral desensitization ultimately successful with motivated women [287].

A recent study reported considerable efficacy with the use of cognitive-behavioral therapy on women with life-long vaginismus [288]. In this Dutch study, women with primary vaginismus were allocated at random to a 3 month CBT (N=81) or a waiting list control condition (N=36). The primary outcome measure was full vaginal penetration by the partner. A reduction in scores on a fear of coitus and non-coital penetrative behavior instrument were also assessed. Treatment resulted in an increase in intercourse, a decrease in fear of coitus and an enhancement of successful non-coital penetration behavior compared to the no treatment condition. No particular treatment predictors were identified but the authors concluded that behavioral techniques such as gradual exposure, aimed at decreasing avoidance behavior and penetration fear, were effective interventions in resolving lifelong vaginismus. Chapter 25 in this volume provides a comprehensive overview of the etiology and treatment of sexual pain disorders.

V. PSYCHOLOGICAL TREATMENT WITH MIXED FEMALE SEXUAL DYSFUNCTIONS

In what was described as a “field trial” of the effectiveness of behavioral treatment for sexual dysfunctions, Sarwer and Durlak [289] reported the outcome with 365 married couples presenting to an outpatient sexual therapy clinic with a variety of sexual dysfunctions. Interventions included sexual education, communication skill training and body-touching exercises over a period of seven weeks. Treatment outcome was evaluated by the clinician as being either successful or unsuccessful-successful if the primary sexual complaint had abated by the end of treatment with no new problems developing and the couple had engaged in intercourse once in the last 3 weeks of therapy. Given the loose definition of success and the methodological shortcomings in both problem definition and outcome, it is still encouraging to find that the authors reported overall success for 65% of the couples with few dropouts. Moreover, outcome did not vary significantly as a function of diagnosis, gender or even history of sexual abuse. Surprisingly, the best predictor of successful outcome was the amount of sensate focus exercises completed in the last week of treatment rather than the nature of the dysfunction or the prior history of sexual abuse.

A more recent study investigated the impact of a psychoeducational group on women with varying sexual concerns [290]. In this study, 25 women between the ages of 25-70 completed a demographic and baseline FSFI questionnaire indicative of sexual dysfunction. Significant improvement was found in one or more FSFI domains and in the total FSFI score at the conclusion of the group intervention.

Based on clinical observation and experience as well as some empirical research, Hawton [219] and others [152] have identified a variety of factors that appear to be related to more positive outcome with psychological treatment interventions: the motivation for success of both partners, relationship satisfaction and compliance with homework assignments. Conversely, four variables have been identified with treatment dropout: 1) lower socio-economic status, 2) the male partner’s lower or lack of motivation for treatment, 3) a conflicted partner relationship and 4) poor progress by the third treatment session.

Overall, psychological interventions utilizing sensate focus exercises, directed masturbation and cognitive-behavioral interventions have been highly successful in treating primary orgasmic dysfunction and somewhat less effective in treating coital anorgasmia. Treatment outcome with desire and arousal disorders and sexual pain complaints is more variable since these problems can co-occur and a variety of contextual factors can interfere with outcome. However, several recent studies utilizing a small psychoeducational group treatment format consisting of mindfulness and cognitive behavioral interventions have been promising for women with sexual desire and arousal disorders. Treating the contextual and relationship issues that inevitably accompany these problems is crucial, however, for long-term improvement.

**J. PSYCHOLOGICAL TREATMENT OF MALE SEXUAL DYSFUNCTION**

This section will review the existing psychological research on male sexual dysfunction. While the majority of current research tends to focus on pharmacological interventions, this is no way obviates the critical importance of psychological and interpersonal interventions. In fact, the future will hopefully focus on combined and/or integrated treatments. These ideas will be discussed in the following sections.

**I. SEXUAL DESIRE DISORDER**

There are no reports solely on the psychological treatment of men presenting with HSDD [291]. Some men with HSDD are included in studies of men and women presenting with mixed sexual dysfunctions but the small numbers of these men does not lend itself to a careful outcome analysis. In medical practice, HSDD is often misinterpreted as ED, and treated as such. The lack of public education on sexual health issues, the myth that men are always motivated to be sexual, the insufficient sexological knowledge of health-care providers, and the lack of tools to comprehensively assess male HSDD, comprise causative factors of this misconception, which may partly explain the high proportion of failures of treatments for symptomatic ED.

It is likely that the etiology of HSDD is multifactorial. Hormonal, medication side effects, mood and interpersonal issues may all play a role in the development and maintenance of this problem. For the therapeutic management of HSDD, either pharmacological or psychological treatments have been tested, but factorial designs to investigate the differential contributions and interactions of both approaches have not been reported [291]. Moreover, there is a paucity of evidence-based interventions for psychogenic hypoactive sexual desire disorder in either sex [292].

**II. PSYCHOTHERAPY OF ERECTILE DYSFUNCTION**

The prevalence of ED ranges between 10% [293] and 52% [294] and has a significant impact on the man, couple and relationship. Different age distributions and concomitant medical conditions, as well as methodological differences, may explain much of the variance in reported prevalence rates. The biopsychosocial model is helpful in understanding the etiology of ED which can be due to multiple organic causes such as illness, medication and surgery (e.g., diabetes, hypertensive medication, and post-radical prostatectomy) in combination with psychological and relational issues (performance anxiety, depression, and relationship concerns). Etiological factors may change with time, disease processes can improve or worsen, damaged nerves may heal, medications can be started or discontinued and psychological and interpersonal issues can wax and wane leading to different etiological configurations of ED over time.

Psycho-sexological literature has made an important contribution in ED description, etiology and diagnosis, but it lacks large, randomized and controlled studies demonstrating the efficacy of the psychotherapeutic treatment (see Table 7) [295, 296]. As noted by The National Institutes of Health Consensus Conference on ED [297], “outcome data of psychological and behavioural therapy have not been quantified, and the evaluation of success of these treatments is poorly documented”.

Psychological treatment of ED consists of a variety of interventions including: psychodynamic interpretations regarding transference or anxiety, systemic desensitization, sensate focus, couples therapy, behavioral assignments, sex education, communication and sexual skills training, and masturbation exercises. However, it is not clear which

of these interventions in combination or alone has the greatest efficacy. Clinical experience highlights that these interventions help the patient and/or couple to improve their relationship and sexual life. Men with acquired ED demonstrated more gains than men with life-long ED [186].

Hedon [298] offers three recommendations regarding anxiety and the treatment of ED: 1) to fully explain ED to patients to reduce worry related to lack of knowledge; 2) to reassure the patients that their problems are not unique and that they can be overcome; and 3) to propose positive action to assist the patient and his partner in resolving the ED.

The paper by Althof and Wieder [299] describes the four goals of psychotherapy for ED: 1) seeking to reduce or eliminate performance anxiety; 2) understanding the context in which men/couples make love; 3) implementing psycho-education and modification of sexual scripts; and 4) to identify and reduce the resistances to premature discontinuation of pharmacotherapy.

Sex therapists play an important role in assessing and treating the emotional, cognitive and interpersonal components that are associated with erection difficulties, whether these be causes of the condition, consequences of the condition, or both [300]. In a recent study [301] alexithymia levels were found to be correlated with the severity of erectile dysfunction, as measured by the International Index of Erectile Function (IIEF). These data confirm the importance of the emotive dimension in human sexuality, in particular of the individual capacity to feel and communicate emotions. The limited imaginative activity of alexithymic subjects can also be reflected in a lack of sexual fantasies, considered central to human sexuality.

Masters and Johnson [74] reported initial failure rates of 41% and 26% for lifelong (primary) and acquired (secondary) ED, respectively. Their two to five year follow-up of this cohort indicated sustained gains. In a review of studies of the treatment for ED, Mohr and Beutler [302] wrote that the component parts of these treatments typically included behavioral, cognitive, systemic and interpersonal communication interventions. Averaging across studies, it appears that approximately two-thirds of the men suffering from erectile failure will be satisfied with their improvement at follow-up ranging from months to six years. These studies utilized either a couples or a group format. The duration of couple’s therapy ranged from 4 to 20 weekly meetings. Group therapies met weekly for 10 to 20 sessions. All forms of intervention except biofeedback, pelvic muscle floor exercises and hypnosis were equally effective in producing sustained change.

Wylie [303] reported on a prospective study of 23 couples where the man presented with ED. Utilizing a combination of modified sex therapy and behavioral system couple therapy, 87% of men demonstrated improvement in their sexual symptom within six sessions of treatment. Moreover, the improvements were found in men’s sexual confidence and frequency of sexual activity and pleasure derived from sexual activity. The gains were sustained at the six-month follow-up. Wylie [304] has also provided a non-systematic review considering different published studies regarding various types of sex therapies. These data can be characterized as uncontrolled, unblinded trials. The conclusions from this review are consistent with the findings outlined above.

There are few controlled reports on individual therapy for single men, except for that of Reynolds [305] who highlighted the difficulties of treating men without partners. All studies with long-term follow-up have found a tendency for men to relapse. Hawton [231] noted that recurrence of or continuing difficulty with the presenting sexual problem was commonly reported by 75% of couples; this caused little to no concern for 34%. Patients indicated that they discussed the difficulty with the partner, practiced the techniques learned during therapy, accepted that difficulties were likely to recur, and read books about sexuality.

Melnick et al [221] conducted a meta-analysis of the effectiveness of psychological interventions for ED compared to oral drugs, intracavernosal injections and vacuum pumps. Only 11 randomized or quasi-randomized trials involving treatment of 398 men could be found in the literature. These 11 trials employed multiple psychological techniques. The authors concluded that group therapy significantly improved erectile function and demonstrated greater efficacy than men in a control group. Men randomized to receive psychotherapy plus sildenail showed significant improvement of ED and were less likely than those receiving only sildenail to discontinue treatment. No differences were found between psychological intervention and men receiving either injection or vacuum pump therapy.

More recent research has shown that ED has a significant negative impact on both the man and his partner. Loss of penile rigidity can have a profoundly adverse effect on a man’s psychological well-being and may be associated with behavioural changes such as the avoidance of intimacy that can impair their general relationship [306]. Couples who have been sexually abstinent for several years often adapt to life without sex. The Index of Sexual Life (ISL) developed by Chevret et al. [52] indicated that the partners of men with ED reported a significantly decreased sexual drive and sexual satisfaction, compared with partners of men without ED. Fisher et al. [54] in the Female Experience of Men’s Attitudes to Life Events and Sexuality (FEMALES) study reported a decline in sexual desire, arousal,
orgasm frequency and satisfaction among female partners of men with ED, compared with their sexual functioning before their partner developed ED. Studies have shown that the participation of the partner supports the adherence to therapy, and her involvement facilitates successful long term ED therapy. These studies suggest that women should be included in ED treatment if possible [307, 308]. Moreover, the presence of the couple ensures not only the restoration of erectile function but improves the sexual quality of life of both partners [308].

1. RELAPSE PREVENTION

The concept of relapse prevention has generally not been incorporated into sex therapy. In the past, the patient and therapist reached a mutual decision about when to terminate, worked toward that goal and ended treatment on a set date. Patients could, of course, re-contact their therapist for additional treatment if problems returned.

To prevent relapse, McCarthy [309] has suggested that therapists schedule periodic “booster or maintenance” sessions following termination. Follow-up sessions have been recommended in order to resolve “glitches” that have interfered with progress.

III. PSYCHOTHERAPY WITH PREMATURE EJACULATION

The Global Study of Sexual Attitudes and Behaviors suggest a global prevalence of PE of approximately 30% across all age groups [293] and which, according to some authors, has a greater impact on QoL and sexual enjoyment than ED [100, 185, 310].

Researchers have described the different forms, pathogenesis and diagnosis of PE as well as its treatment, especially pharmaceutical. A recent report by the International Society for Sexual Medicine (ISSM) established a contemporary, evidence-based definition of lifelong PE [311]. The Committee proposed that lifelong PE should be defined as a male sexual dysfunction characterized by ejaculation which always or nearly always occurs prior to or within about one minute of vaginal penetration, and the inability to delay ejaculation on all or nearly all vaginal penetrations, and negative personal consequences, such as distress, bother, frustration and/or the avoidance of sexual intimacy.” The panel of ISSM researchers concluded that there are still insufficient published objective data to propose an evidence-based definition of acquired PE [311]. This definition identifies the areas to assess, namely, short intravaginal ejaculation latency time (IELT), lack of control and distress for both partners [312, 313]. McMahon et al. [311] suggested that acquired PE might point to a psychogenic etiology, while lifelong PE might have an organic etiology, although further evidence remains to be gathered to support this assumption.

Althof [314] has reviewed the different psychotherapies for PE, from the pioneering “stop-start” techniques of Semans [315] to the “squeeze technique” of Masters and Johnson. After such initial approaches, successive sex therapies have focused mainly on subjective aspects of the life of both the patient and his partner, as well as on their relationship.

Present day psychotherapy for rapid ejaculation is an integration of psychodynamic, systems, behavioural, and cognitive approaches within a short-term psychotherapy model. The guiding principles of treatment are to learn to control ejaculation while understanding the meaning of the symptom and the context in which it occurs [316, 317].

Thus, besides teaching self-control techniques to delay ejaculation, modern psycho-sexual therapies try to achieve the following aims: 1) to help the patient recover his self-confidence and confidence in his sexual performance; 2) to reduce performance anxiety; 3) to increase communication between the partners; and 4) to resolve interpersonal issues that precipitate and maintain the dysfunction. In addition, psychotherapists seek to modify rigid sexual repertoires, and help the couple remove barriers to intimacy.

The majority of psychotherapy treatment outcome studies can be characterized as uncontrolled, unblinded trials; none meet the requirements for high level evidence-based studies. The literature is comprised of reports on small to moderately sized cohorts of subjects who received different forms of psychological interventions with limited or no follow-up. In most studies, active treatment was not compared to placebo, control or wait list groups [316].

The biopsychosocial perspective has introduced a non-linear epistemological model. It is necessary to view the individual as a multidimensional (biological, psychological and social) unique being and definitely overcome the mechanical-medical and linear approach which, referring to an eighteenth-century metaphor, sees the body as a machine.

Since the early 1970s, an array of individual, conjoint, and group therapy approaches employing behavioural strategies such as stop-start [315] have been used to treat rapid ejaculation [75, 309, 318-320]. Table 8 summarizes the initial and long-term efficacy of psychological interventions for rapid ejaculation.

Masters and Johnson reported on 432 men who were seen in their quasi-residential model utilizing multiple treatment techniques including the squeeze technique in combination with sensate focus and interpersonal therapy. Failure rates of 2.2% immediately after treatment and 2.7% at the five year
follow-up were documented [74]. Other researchers have been unable to replicate Masters and Johnson’s success rates. For instance, only 64% of men in Hawton’s study were characterized as successful in overcoming their premature ejaculation [3].

Cognitive behavioral therapy [321] as well as multimodal psychodynamic and behavioural treatments [13, 322] are described in review papers; however, there are no documented carefully controlled outcome studies that examine the efficacy of these methods. Minimal therapist contact, defined as between 4 to 15 brief weekly telephone contacts, with bibliotherapy has also been found to lead to successful outcomes [323]. This finding may not hold for more complex situations that involve relationship and communication difficulties (see Table 8).

Psychosexual-behavioral therapy for PE can also be delivered in group format or through bibliotherapy [324]. Although initial rates of success of psychosexual-behavioral therapy have been very high, more recent rates are more modest and range between 60% and 90% [325]. Further, these rates are not sustainable and may fall to 25% three years after therapy [325]. Such observations are not surprising since many of the studies have pooled patients with different PE categories (lifelong and acquired), age groups, levels of general and sexual anxiety, sexual experiences and somatic vulnerabilities (such as tactile and/or CNS hypersensitivities) [325].

In a recent study by De Carufel and Trudel [326] the aim was to compare the efficacy of a new functional-sexological treatment for PE with a behavioral treatment (squeeze and stop-start techniques). They also compared the two treatments against a wait list condition. The results showed that there was a significant change between pre-treatment and post-treatment and between pre treatment and follow-up in the two treatment groups. For the wait list control group, changes were not significant (see Table 8). Additionally, hypnosis has been utilized in the treatment of PE. This treatment approach focuses not only on the symptom, but has a more holistic focus [327].

When utilizing pharmacotherapy for PE, clinicians may also utilize brief, targeted psycho-educational interventions, called coaching [185, 187, 328, 329]. Coaching can help clinicians treat that component of PE not addressed by pharmacotherapy by targeting obstacles to affective sexual activity including: restrictive sexual patterns, avoidance of sexual activity and an unwillingness to discuss sex with a partner. The goals of coaching are to identify and resolve the patient’s resistance to medical therapy, reduce or eliminate his performance anxiety, help him gain or regain sexual confidence and modify his maladaptive sexual “scripts”. Coaching can be conducted by a non-mental health professional but it requires time, interest, some training in sex therapy and sensitivity; in addition, they should compile a list of appropriate therapist referrals.

Psycho-dynamically oriented therapists view the dysfunction as a metaphor in which the man/couple is trying to simultaneously conceal and express conflicting aspects of themselves or the relationship. In symbolic terms, the dysfunction contains a compromised solution to one’s life dilemmas. Alternatively, behavior therapists understand the dysfunction as a conditioned response or a maladaptive response to interpersonal or environmental occurrences [316].

Donahuey and Miller [1] reported that regardless of the therapeutic modality (individual, couple or group therapy), or the specific therapeutic goals, there are several common factors that make psychotherapy effective: 1) empowering the patients to experience themselves as having the ability to create change and impact contextual factors; 2) the patient/therapist relationship is critical to successful therapeutic outcome. The therapist must be able to assess and accommodate to the patient’s readiness for change and provide a safe and empathic environment where the patient can explore obstacles, choices and meanings of his psychological and behavioural dilemmas; 3) the role of hopefulness and realistic expectancy should be provided in psychotherapy [316].

Therapy should be tailored for each patient, as one treatment does not fit all. Each treatment option should be discussed with the PE patient including the success rate and possible adverse effects such that the patient participates in the decision-making. This will improve compliance and success of therapy [312].

Taylor and Simonelli [330, 331] report on alexithymic patients who had “coexisting” PE. Generally it was the partner who asked them to seek professional help. This situation may result in a lack of the man’s intrinsic motivation which leads to his adopting a passive role in the therapeutic process, limiting the effectiveness of treatment. The man’s passivity in the clinical relationship and the therapist’s emotional reactions (feelings of impotence, discouragement, anger) evoked by the alexithymic relationship style may reproduce what happens in the dynamics of the couple and in this sense it may be a valuable starting point for the psychotherapist [330, 331].

**IV. DELAYED EJACULATION**

Delayed Ejaculation (DE), alternately known as retarded or inhibited ejaculation has a relatively low prevalence rate rarely exceeding 3% [151, 332, 333]. Recently however, there has been greater interest in

this dysfunction with suggestions that the prevalence may be higher than initially reported [151, 332]. The dysfunction appears moderately and positively related to age. The etiology and pathophysiology are incompletely understood and there are no evidence based treatments reported for this dysfunction [334, 335].

In terms of the psychological underpinnings of DE, there are three very different perspectives. The first posits that delayed ejaculation is due to the man’s not receiving sufficient physical stimulation. An alternative perspective is that the man is insufficiently mentally aroused even though he has an adequate erection. Finally, the third perspective focus on the stimulation the man has become accustomed to receiving through his idiosyncratic masturbatory practices and that these sensations are not reproducible when engaged in partner sexual behaviour.

The available literature concerning the psychological treatment of DE is almost entirely anecdotal with small numbers of patients in each report[336]. Men suffering from delayed ejaculation may benefit from different psychological approaches including: sex education, reduction of goal oriented anxiety, increased and more genital focused stimulation and sex therapy. Richardson reviews the following treatment techniques for DE [337]: viewing erotic films, sex play, erotic fantasies, sexually stimulating literature or magazines, and masturbatory exercises [338, 339]; meditative relaxation therapy or hypnosis combined with psychotherapy [338].

In a meta-analysis, Munjack and Kanno report the success rate for sex therapy of DE ranges between 42% and 82% [340]. A distinguishing characteristic of men with DE and one that has implications for treatment is that they usually have little or no difficulty attaining or keeping their erections: in fact they are often able to maintain erections for prolonged periods of time. Yet, despite their good erections, they report low levels of subjective sexual arousal and pleasure, at least compared with sexually functional men [341]. Similar to men with other types of sexual dysfunction, men with DE demonstrate high levels of relationship.
distress, sexual dissatisfaction, anxiety about their sexual performance, and general health issues significantly higher than sexually functional men. Along with other sexually dysfunctional counterparts, men with DE typically report lower frequencies of coital activity [342].

Bancroft perceives men with DE as having inadequate physical stimulation and recommends the use of, 'vigorous stimulation using a lubricating jelly or cream to overcome the block' [343]. Men are first stimulated to ejaculate extra-vaginally with gradual introduction of intercourse and vaginal ejaculation.

Perelman focuses on the men’s idiosyncratic masturbatory practices and seeks to instruct these men in more conventional masturbation that more closely mimics sensations derived from intercourse [329, 332, 342, 344]. As characterized by Perelman, masturbation serves as a “dress rehearsal” for sex with a partner. By informing the patient that his difficulty is merely a reflection of “not rehearsing the part he intended to play,” the stigma associated with this problem can be minimized and cooperation of both the patient and partner can be evoked. The goal of most current therapeutic techniques for DE (either primary or secondary) is not merely to provide more intense stimulation, but rather to stimulate higher levels of psychosexual arousal and, eventually, orgasm within the framework of a satisfying experience.

Hawton discusses that during masturbatory exercises with the partner, the man must be trained to concentrate on genital stimulation [339]. He also recommends the male-superior position as he postulates that this often facilitates ejaculation. Hawton, Bancroft and Winzce recommend the use of vibrator to increase sexual arousal [256, 339, 343].

Self-stimulation techniques incorporating fantasy can be used to achieve incremental increases in arousal. Fantasy can help block inhibiting thoughts, often a significant step that might otherwise result in interference with the progression of sexual arousal. Additionally, an important component in the treatment of any type of DE is the removal of “demand” or “performance” anxiety [256].

Jannini perceives the delay in ejaculation as mirroring the men’s over controlled personality organization [345]. That is in life these men show little emotion and seem over controlled. They also discuss the role of men’s fear of impregnating his partner or contracting sexually transmitted diseases as interfering with arousal and ejaculation. If the clinician suspects the patient’s DE is related to fear of conception, he may inquire about the patient’s ability to experience a coital ejaculation with contraception (including condoms) but not during “unprotected” sex. Such a “test” can serve as a powerful diagnostic indicator: Resolving this issue typically requires individual consultations with the man and occasionally with the partner [334].

Whether related to fertility or not, the man’s anger (expressed/unexpressed) toward his partner may be an important intermediate causational factor and must be ameliorated through individual and/or conjoint consultation. Anger acts as a powerful anti-aphrodisiac, and while some men avoid sexual contact entirely when angry at a partner, others attempt to perform, only to find themselves only modestly aroused and unable to maintain an erection/and or reach orgasm [334].

As treatment progresses, interventions may be experienced as mechanistic and insensitive to the partner’s needs and goals. In particular, many women respond negatively to the impression that the man is essentially masturbating himself with her various body parts, as opposed to engaging in the type of connected lovemaking she may prefer [334]. Therefore, the formation of a strong therapeutic alliance where the aims are clearly discussed and shared within the couple is fundamental to avoid poorer treatment prognosis.

The biopsychosocial model is helpful in understanding the etiology of male and female sexual dysfunctions and provides a useful paradigm for developing comprehensive treatment interventions. There is a dearth of knowledge concerning male HSDD and delayed ejaculation and there is an enormous need for controlled trials in these areas. The psychological literature has made important contributions in ED description, etiology and diagnosis and development of validated clinical outcome measures. The uncontrolled trials regarding psychotherapy for ED demonstrate modest to good success; however, large, randomized controlled studies demonstrating the efficacy of the psychotherapeutic treatment need to be undertaken. Similarly, several uncontrolled trials support psychological intervention as helpful for PE yet there remains a need for large, controlled trials using validated outcome measures.

### K. INTEGRATING MEDICAL AND PSYCHOLOGICAL TREATMENTS FOR SEXUAL DYSPNFUNCTION

Combination or integrated therapy is an exciting concept that has the potential to significantly advance the manner in which men, women and couples receive treatment for sexual dysfunctions [328, 346-349]. Combining medical and psychological interventions harnesses the power of both treatments to enhance efficacy, increase treatment and relational satisfaction, and decrease patient discontinuation. Previously, combination therapy, alternatively called coaching or integrated therapy has been successfully employed in the treatment of
depression, childhood anxiety, schizophrenia, and posttraumatic stress disorder [350-352]. It is also an important aspect of treatment for diabetes and breast cancer because psychosocial support is a crucial component of care giving.

Combination or integrated treatment is the logical extension of the biopsychosocial model. It addresses the relevant biological/medical as well as psychosocial issues that predispose, precipitate and maintain sexual dysfunction. Too often, medical treatments for sexual dysfunction, those approved and those off-label, are narrowly or mechanistically directed at sexual function alone and fail to address the salient psychosocial issues (see Table 9). Likewise, psychological intervention alone may be time consuming, costly and fail to yield rapid symptom amelioration. For example, PDE5is for ED are generally efficacious in 70% of men with ED; yet, 60%-70% of individuals fail to continue treatment. In response to this surprisingly high discontinuation rate, clinicians developed medical and educational strategies to “optimize” PDE5i treatment which focused on patient education, dose optimization, need for sexual stimulation, and follow-up [353-355]. However, none of these “treatment optimization” proposals addressed any of the crucial psychosocial issues such as: restarting a sexual life after an extended period of abstinence, partner resistance, partner concerns or dysfunction, lack of confidence and performance anxiety, depression, relationship issues, men with unconventional sexual scripts and unrealistic expectations. These factors are likely to be present in men, even if the ED was initially due to organic causes because of the number of years that men generally take to seek treatment for their ED. Combination therapy would include all the medical optimization recommendations while simultaneously addressing the psychosocial barriers that hinder treatment efficacy, satisfaction and compliance. These psychosocial interventions are also well placed to address partner issues that may impede that treatment process.

Combined or integrated treatment paradigms challenge traditional sex therapy practices. They provide a venue where the psychosocial factors that precipitate or maintain sexual dysfunction can be identified, acknowledged and addressed while the patient simultaneously makes use of and has success with a variety of efficacious medical treatments for sexual dysfunction.

An emerging body of evidence strongly supports the value of combination treatment. There are however, several important questions that require further clarification as regards combination therapy: 1. What is the best theoretical model for combination therapy? 2. Who delivers the care (nurse, social worker, psychologist, or, physician)? 3. Where is the intervention performed (medical clinic vs. mental health office)? And, 4. Are the medical and psychological treatments concomitant or stepwise [328]?

From experience, we know the traditional referral of patients from a primary care, urological, or gynecological specialist to a sex therapist is fraught with difficulties. For a variety of reasons (stigma, cost, insurance issues, lack of motivation, etc.) patients rarely follow through. The rule of thumb is that only 10% of referrals present for a first visit with a sexual counselor. Additionally, sex therapists are a rare commodity. Many patients are not willing to pay for these services and/or cannot commit to treatment over a period of several months.

One solution to the problem of resource availability, time, and money would be to offer the initial services at the site of the primary care or specialty physician. Onsite intervention would allow more individuals to have access to sexual health education and intervention. In a “one-stop shopping” model, patients could see the physician and the person designated to do the psychosocial intervention (this may or may not be one and the same person). This eases the time and financial burden on the patient and might serve as an additional income stream for the practitioner. To take a lesson from the behavioral medicine interventions, this would require sexual experts to train physicians and other health care workers in assessment, education, and rudimentary psychological intervention. The conceptual model would guide these caregivers to recognize when more intensive psychological treatment is required and to appropriately refer. Or, in the future we may witness the establishment of comprehensive sexual health centers that include specialists (urologist, gynecologist, cardiologist, internist/family practice specialist, endocrinologist, mental health clinicians) from multiple disciplines working together as teams under one roof offering a more integrated level of care.

I. REVIEW OF COMBINED THERAPY TREATMENT EFFORTS

This section will review studies describing combined medical and psychological treatments for men with ED. While there are articles on combination therapy for PE they are not evidenced based. Additionally, medical treatments for FSD have lagged behind those for men and thus there is scant literature on combination therapy for women with low desire, arousal or orgasmic dysfunction. Given the multiply determined nature of FSD it is likely combination medical and psychological therapy will ultimately be of significant benefit to women as well. There are descriptions of combination therapy of female pain disorders; however, this will be discussed in Chapter 25.

</table>
Abdo et al. and Melnick et al. [221, 356, 357] together and independently, have a series of articles that compare combination sildenafil and group counseling to group therapy or sildenafil treatment alone. Abdo et al. [356] randomly assigned 120 men with psychogenic ED to one of three experimental conditions: in Group 1, participants received 3 months of weekly group psychotherapy plus sildenafil; in Group 2, they received only sildenafil; and in Group 3, they received only weekly group counseling. The initial dose of sildenafil was 50 mg; however, it could be increased to 100 mg. At the end of 3 months, compared to baseline, all three groups demonstrated significant improvement in post-treatment Sexual Health Inventory for Male (SHIM) scores. The combined therapy group had the highest post-therapy scores on the SHIM and the Male Sexual Quotient measure compared to the other two groups.

Melnik and Abdo [357] randomly assigned men with psychogenic ED to one of three experimental groups. In Group 1, participants received 6 months of theme-based psychotherapy plus sildenafil 50mg; in Group 2, they received only 50 mg of sildenafil; in Group 3, they received only theme-based sexual counseling. At the end of 6 months, compared to baseline, all three groups demonstrated significant improvement in post-treatment International Index of Erectile Function (IIEF) scores. However, utilizing the criterion of normalization of IIEF scores (EF domain ≥26), only the combined and psychotherapy only groups demonstrated statistically significant improvement.

The authors explained the results in terms of psychotherapy encouraging patients to understand the emotional component of their condition, helping them to strengthen their commitment to the change process, to become more deeply involved, and to benefit from treatment. Psychotherapy also promoted more realistic and positive sexual expectations instead of expecting automatic, autonomous erections.

Aubin et al [358] reported on 44 couples who were randomly assigned to receive sildenafil alone or sildenafil plus 8 sessions of couples’ therapy. Sexual and couple outcome variables included: the IIEF and FSFI, four sexual cognition scales, Dyadic Adjustment Scale, and two emotional and sexual intimacy scales of the Personal Assessment of Intimacy in Relationship questionnaire (PAIR). The main study hypothesis of greater treatment gains for the combined vs. drug-only treatment in all domains of sexual function, cognition, and couple relationship was partially supported. The couples plus sildenafil group had a greater number of improved and maintained sexual function and cognition domains for both partners from pre- to post-treatment than the sildenafil only group. Regardless of treatment condition, men obtained improvements in five out of six domains of sexual function. However, during the follow-up phase, men in the sildenafil only group showed decreased sexual function in four out of six domains, whereas men in the combined treatment group maintained treatment gains in all sexual function domains. Women in the combined group obtained a greater number of improved sexual function and cognition domains than women in the sildenafil only group. There were comparable gains in sexual intimacy for women in either group.

Phelps, Jain, and Monga [192] highlighted the value of combined therapy in a study where the psychological intervention consisted of a one-session psychoeducational meeting. The authors compared two groups of men: The first received combined treatment with one 90 minute session psychoeducational intervention and sildenafil, and the second received only sildenafil. The initial dose of sildenafil was 50mg with titration allowed to 25mg or 100mg. The psychoeducational group included information about sexual function, clarified their treatment expectations, suggested communication exercises and provided references for self-help books. After 24 weeks of treatment, there were no differences in the IIEF scores between the two groups: Both demonstrated significant improvement. However, the EDITS treatment satisfaction total score for the psychoeducational intervention group was significantly higher than the sildenafil-only group.

Banner and Anderson [359] randomized 53 men with psychogenic ED and their partners into 2 groups: 1) combined sildenafil and cognitive behavioral sex therapy (CBST) and, 2) sildenafil only. After 4 weeks, CBST was added to the sildenafil only group. The authors fashioned criteria for success that included the IIEF erectile function and sexual satisfaction domain scores >19 and ≥6 respectively. At 4 weeks, 48% and 66% of combined therapy (CBST) group vs. 29% and 38% of sildenafil only group met success criterion. At 8 weeks, 66% and 75% of original CBST group and 58% and 45% of the new combined group met success criterion for EF and sexual satisfaction respectively.

Bach et al. [360] examined the effect of supplementing sildenafil treatment with a range of different strategies in men where the sildenafil was effective in creating erection, but the men and their partners were not satisfied with their sexual lives. There were several unique aspects to this study including: an assessment of the impact of combination therapy on partners; minimal contact with the therapist, and the use of a treatment manual. The treatment manual consisted of: 1) psychoeducation regarding sexual dysfunction and normative sexual functioning, 2) information on various factors affecting sexual arousal, 3) discussion of typical reactions to sexual problems, 4)
recommendations for optimizing conditions in which sexual activity occurs, 5) strategies for improving communication, and 6) instructions on the use of behavioral strategies such as sensate focus. Each week participants were asked to read assigned chapters from the manual and to complete the corresponding exercises. They would have weekly telephone contact with the therapist.

Five of six men evidenced increases in sexual satisfaction and the frequency of intercourse after adding the manualized treatment with minimal therapist contact to the use of sildenafil. They maintained these gains at an average of 6 months post-treatment.

Three articles have addressed combined treatment with intracavernosal injection therapy (ICI). Lottman, Hendricks, Vruggnik, and Meuleman [361] compared a small group of men receiving ICI plus three sessions of counseling at weeks 0, 6, and 12, with a larger cohort of men receiving ICI without counseling. During the trial dosing phase, there were no differences in discontinuation patterns. From the trial dosing phase forward until the 6-month follow up, no additional patients discontinued treatment in the combined therapy group. In contrast, the discontinuation rate after the trial dosing phase in the ICI-only group was 60%. Patients reported that counseling increased their knowledge about factors contributing to erectile dysfunction and improved their ability to communicate about their sexual interest and desires. Through counseling they felt more comfortable talking about feelings and thoughts concerning sexual problems.

Hartmann and Langer [362] described an integrated treatment program involving injection therapy and sex counseling. They concluded that a combined approach was more beneficial to men with primarily psychogenic ED and that improvement could occur only in the absence of partner problems or premature ejaculation.

In a more recent study, Titta et al. [363] reported on a group of non-nerve sparring radical retropubic prostatectomy and cystectomy patients receiving ICI who were randomized into two groups. The first group received ICI plus sexual counseling, while the second group received only ICI. Patients were followed for 18 months after initiating ICI. Over the course of the 18 months, all men also received a trial of sildenafil. In these patients, there were no differences between the groups on baseline IIEF or postsurgery scores. At the 3-month and 18-month follow-up, compared to the ICI only group, the counseling plus ICI group achieved significantly higher erectile function, desire, orgasm, and satisfaction scores. Additionally, the counseling plus ICI group manifested a lower discontinuation rate and were able to achieve good quality erections with lower doses of medication. Finally, more men in the sexual counseling group responded to sildenafil than men in the ICI-only group.

Combined treatment utilizing vacuum tumescence therapy and counseling was reported by Wylie et al. [364] who randomized 45 patients with primarily psychogenic ED into two groups. The first group participated only in couples therapy, whereas the second was instructed in the use of a vacuum device while simultaneously receiving couples therapy. Improvement was reported by 84% of the combined group, but by only 60% of the therapy-only group. The authors suggested that early combination treatment of couples therapy and a physical treatment, such as a vacuum device, may lead to a more beneficial response than psychotherapy alone. They also highlighted the importance of demonstrating potential benefits from a physical intervention early in therapy and suggested that delaying the demonstration of such benefits to the patient may have a negative impact on treatment outcome.

Whether using oral medication, intracavernosal injection or vacuum pump therapy for ED, these studies all suggest that combining medical and psychological treatments for ED improves the efficacy of the medical treatment and promotes greater treatment satisfaction and decreased discontinuation rates than medical treatment groups alone. The benefits of the psychological intervention appear to be educational, motivational and help men/couples to sort through some of the psychosocial obstacles that impede successful and satisfying treatment outcomes.

L. SEXUAL COUNSELING ON THE INTERNET

Sex therapy on the Internet is a controversial notion. There are several ethical and professional challenges to be overcome; nonetheless use of the Internet poses several advantages for patients that include: easy accessibility, anonymity, practicality, and reducing embarrassment or humiliation in obtaining treatment. It additionally removes the barrier of geographical isolation and therapist’s availability during business hours. Internet psychotherapy has been successfully used to treat panic disorder, social phobia, depression and recurrent headache [365-368]. Therapists may find that lack of visual contact and physical proximity to the patient may result in not detecting the subtle and not so subtle visual and auditory cues. There are also professional issues including liability, consent and conducting treatment in states or countries where the clinician is not licensed. From a physician’s perspective there are also multiple concerns regarding prescribing medication over the Internet without physically examining the patient or gathering a detailed and accurate medical history.
There are six papers that examine the benefits of providing Internet treatment to individuals with sexual problems [369-372]. All are exploratory in nature, and report on small samples of patients. Three of the six focus on treatment of men with ED; the other three include men with PE and women with sexual dysfunctions.

In a pilot study with 8 subjects, Hall examined online sex therapy for men and women with a diverse range of sexual dysfunctions including: anorgasmia, vaginismus, dysparuenia, premature ejaculation, delayed ejaculation and erectile dysfunction [369]. The number of email sessions ranged between 2 to 23. Online therapy began with patients completing the Problem Evaluation Form which solicited sexual history and information about the specific dysfunction. Based on the patient's responses to the form the online therapist devised a treatment plan. At the conclusion of treatment patients completed an online evaluation form.

Online therapy improved sexual function significantly, much, slightly in 2, 3 and 2 patients respectively. Two patient's sexual function remained the same. All 8 patients reported an improved self awareness and 6/8 said their sexual knowledge improved. Obviously, this was an uncontrolled study using unvalidated questionnaires with a very small number of patients. However, it was designed as a pilot study and suggests that Internet sex therapy may benefit some patients.

Leusink and Aarts [370] investigated the effectiveness of electronic consultations to 219 men suffering from ED. Unlike the previous study after completing an online history form the authors provided prescriptions for PDE5i’s as well as suggestions for psychological interventions. The IIEF and General Assessment Question (GAQ) were given pre and post online therapy and response to both were compared. Eighty-one percent of men reported improved erectile function at the conclusion of their econsultation. This study did not include a comparison group, making it difficult to assess whether similar outcomes would have been achieved following face-to-face consultation, or might have been due to spontaneous recovery.

McCabe and Price [371] evaluated the effectiveness of an Internet-based treatment program for ED and compared a combined medical and psychological Internet intervention to only an psychological Internet intervention. Each arm of the study received the same psychological treatment intervention. Outcome measures included the International Index of Erectile Dysfunction, Self Esteem and Relationship Questionnaire, Kansas Marital Satisfaction Scale, Index of Sexual Satisfaction and World Health Organization Quality of Life BREF. The psychological intervention was a cognitive-behavioral intervention targeted to resolve psychological and relationship factors related to ED. The Internet program called Rekindle consisted of three treatment components: sensate focus, communication exercises and unlimited email contact with a therapist. Subjects and their partners were encouraged to spend approximately 2 weeks completing each of the five treatment modules. The entire Rekindle Internet program took 10 weeks to complete.

The purpose of email contact (unlimited) was to resolve any individual or relationship problems that the men experienced as a result of the sensate focus or communication exercises. Improvements in erectile function were significantly greater among men who completed the program compared to those who received no treatment. Rekindle was not associated with significant improvements in orgasmic function, sexual desire and overall satisfaction.

Both the combined therapy and psychological intervention only groups demonstrated improvements in sexual function from pretest to post-test. There were no significant differences between either treatment. Similarly, compared to baseline, at the end of treatment both groups demonstrated significant improvements in relationship satisfaction. The authors suggest that in cases where ED is more severe or has been established for a significant period of time, a more intensive Internet intervention may be necessary. Additionally, they point out that when other comorbid sexual dysfunctions are present, or when the level of discord within the general relationship is high, Rekindle may also need to be supplemented with additional treatment.

McCabe et. al. [372] completed another study where they compared the Rekindle program to a no treatment control group. After completion of the study subjects in the control arm could participate in the treatment arm. Men in the treatment arm reported improved erectile function and relationship satisfaction in contrast to men in the control group. The sexual gains of men in the Rekindle group remained stable for 3 months following the termination of treatment. While the second study employed a control group and utilized validated outcome measures the numbers of subjects enrolled in the study was relatively small (12 in Rekindle; 19 in the control arm) and there was no involvement or data from partners.

In a wait-list controlled, randomized study, van Diest and van Lankveld et. al. studied the impact of Internet counselling on men with ED and PE [373, 374]. Forty-nine men and 32 men with ED and PE respectively completed 3 months of treatment as well as two follow-up assessments at 3 and 6 months. The unique aspect to van Lankveld’s protocol was that patient’s were required to pay for treatment. The protocol employed validated measures to assess outcome including the IIEF, Golombok Russ
Inventory of Sexual Satisfaction (GRISS), Global Endpoint Question (GEQ) and the confidence scale of the Self Esteem and Relationship Questionnaire (SEAR). Internet treatment was modelled after Masters’ and Johnson techniques such as sensate focus and augmented by cognitive behavioral interventions. Additionally, when deemed appropriate PDE5i’s, clomipramine, SSRI’s or topical anaesthetic cream was prescribed.

In participants with ED, erectile functioning and overall sexual satisfaction improved significantly; however, the results of treatment for PE men was not superior to wait list controls. Treatments gains were maintained at follow-up.

The use of the Internet shows promise for offering therapeutic interventions to patients suffering from sexual dysfunctions. However more work remains to be done in terms of extending the Internet offerings to larger and more diverse populations of subjects and providing extended follow-up of the stability of the changes. Additionally, the aforementioned challenges of protecting patient’s privacy, consent and concerns with liability need to be addressed.

M. CONCLUSIONS AND RECOMMENDATIONS

Despite the numerous studies cited in this chapter, the predominant levels of evidence tend to fall between systematic reviews of cohort studies (level 2) to expert opinion without explicit critical appraisal (level 5). The complexity of sexuality, whether normal or dysfunctional, is created by the interaction of the forces of culture, individual development, individual psychology, interpersonal relationships and biology. There is no sexual behavior, solitary or partnered, that is not shaped in some way by each of these five influences.

Advances of medical and psychological therapies for sexual dysfunctions need to be perceived through this intricate biopsychosocial web. The biopsychosocial model provides a compelling reason for skepticism that any single intervention—i.e. a PDE5 inhibitor, supraphysiological doses of a hormone, processing of childhood victimization, marital therapy, pharmacotherapy of depression, etc. can by itself be sufficient for most patients or couple’s experiencing sexual dysfunction. This is especially true since sexual behavior most often occurs in a dyad with two individuals who bring their unique histories, inhibitions and motivation to the treatment.

The goal of treatment is the restoration of lasting and satisfying sexual function. Clinical work demands that the therapist works to understand all of the forces that caused the problem even as they are providing treatment. This requires the therapist to conceptually identify and separate the predisposing developmental factors from the precipitating factors from the contextual factors from the factors that maintain the symptom.

While the committee recognizes the reality that all physicians and mental health professionals do not have the same ability to work with biological, cultural, interpersonal, and individual psychological contributions to a given dysfunction, we urge all professionals to guard against simplistic thinking about the cause and treatment of any of these problems. We conclude this chapter by offering the following recommendations:

1. There is a vital need for collaboration between clinicians in the evaluation, treatment and education surrounding sexual dysfunction. Each discipline has something to contribute to patient care.
2. In many cases neither psychotherapy alone, nor medical intervention alone, is sufficient for the lasting improvement of sexual problems.
3. The adoption of the biopsychosocial model that includes predisposing, precipitating, maintaining and contextual factors. Such a model leads to a comprehensive understanding of the sexual problem and serves as a roadmap for thoughtful treatment.
4. More research is needed on factors that increase personal resiliency and contribute to the development of healthy sexuality.
5. Clinicians need to carefully assess patient’s presenting with sexual disorders for the presence of depression and design studies to determine if there is a causative link between depression and sexual dysfunction.
6. Population based studies of the interpersonal relationship dimension and sexual dysfunction are needed.
7. Large scale, randomized, controlled studies employing validated outcome measures and long-term follow-up for the psychological treatment of male and female sexual dysfunctions need to be conducted.
8. Research is needed to identify the best models for conducting combined and/or integrated treatments for sexual dysfunction.
9. Professional organizations need to develop guidelines for Internet treatment of sexual dysfunction.

FERNANDO UGARTE Y ROMANO (MEXICO)
INTRODUCTION TO THE CHAPTER

The Ethical, Socio-cultural and Educational Aspects of Sexual Medicine Committee will be comprised of three separate essays describing the elements listed in the Committee’s title. Because the topics Committee was assigned were diverse, the Committee members chose to submit the content as separate contributions, focusing on more specific points related to each of the three topics above.

The sections will include:

I. EDUCATIONAL ASPECTS OF SEXUAL MEDICINE

II. ETHICAL PERSPECTIVES IN SEXUAL MEDICINE

III. SOCIO-CULTURAL ASPECTS IN SEXUAL MEDICINE
I. EDUCATIONAL ASPECTS OF SEXUAL MEDICINE

S. Parish, J Dean

1. INTRODUCTION

In modern society there are many educational needs regarding sexuality and the clinical management of sexual concerns, problems, and disorders. This discussion will focus on the current state of sexual health education in physician undergraduate, graduate, and postgraduate medical education. We will also provide a summary of current standards for developing curricula and defining competencies in sexuality education.

a) Need for Improved Sexual Health Education

There has been an increasing awareness regarding sexual health in recent years, and more public attention has been focused on sexual problems, such as erectile dysfunction (ED). However, despite increased professional awareness and increasing demand from patients, ED remains under-diagnosed and under-treated by doctors across the world. This is also true for other male sexual dysfunctions, as well as dyspareunia and disorders of desire in women.[1] Only 25% of U.S. primary care physicians actually take a patient's sexual history, citing lack of training as the most common reason for not doing so.[2,3,4]

Both patient's and physician's acknowledge the lack of discussion of sexuality in clinical settings and thus under-diagnosis of sexual problems. Patients want to discuss sexual issues, but perceive significant barriers. For example, in one study, 71% of surveyed patients felt their physician didn't have time, 68% didn't want to embarrass physician, and 76% believed no treatment was available.[5] Patients report non-empathetic judgmental responses, physician discomfort, concerns regarding privacy, and a lack of cultural sensitivity. Many patients do not have confidence in their physician's skills in managing sexual problems and do not believe they would receive effective treatment. An international study of 27,500 men and women revealed that half of all sexually active participants had at least one sexual problem; but only 19% had sought medical care, and only 9% reported being asked about sexual health in the previous 3 years.[6] Most patients (over 90%) believe that it is a physician’s role to address sexual health concerns and are grateful when their doctor initiates the discussion.[7]

b) Physician Barriers

Physicians report numerous barriers to addressing sexual problems including: insufficient knowledge about the diagnosis of sexual function and dysfunction; inadequate training in communication skills; lack of information about treatment options; apprehension that their inquiries may offend the patient; low recognition that healthy sexual activity is important; time constraints; inadequate reimbursement, lack of privacy, cultural, and language barriers, and personal discomfort about sex including language, ageism; and the assumption that all people are married, heterosexuals, and monogamous.[8] Physicians may have difficulty remaining objective and separating their personal views from those of their patients.[9] Physicians in training may have limited sexual experience, unresolved issues regarding their own sexuality, or concern about developing sexual feelings toward patients.

In several studies physicians reported gender as a significant barrier to sexual history taking. In one survey of a multidisciplinary practice, male and female physicians reported significant discomfort interviewing patients of opposite sexes.[10] and in
a course on ED, dealing with communication and management strategies, female physicians report more perceived difficulty as compared to their male colleagues.[11]

c) Detection of Hypoactive Desire and Related Female Sexual Problems

Sexual problems in women are common. In the recently published study Prevalence of Female Sexual Problems Associated with Distress and Determinants of Treatment Seeking (PRESIDE), almost half (43.1% age adjusted estimate) of women had some sexual problem. Low desire, present in 37.7% (age adjusted estimate) of subjects, was the most common sexual problem observed. Sexually related personal distress was present in 22.8% of subjects, and a sexual problem with associated personal distress was present in 12.0% of women.[12] Despite this substantial prevalence, the majority of physicians rate their knowledge of FSD as only fair to poor; and their level of comfort parallels their self-assessed knowledge. In a systematic survey of an academic primary care clinic in which half of potential subjects responded, 90% of clinicians reported little confidence in making the diagnosis of Hypoactive Sexual Desire Disorder (HSDD). 90% of physicians had not screened a patient for HSDD. Faculty were more confident than residents.[13]

In a recent fax/ e mail study of a random sample of practicing physicians that used a case vignette-based survey, 21% of OB/GYNs and 38% of primary care physicians reported that they were not at all confident about treating HSDD. In multivariate analysis, low confidence was associated with perceived time constraints, the perceived lack of effective therapy, fewer years in practice and fewer patients who presented with distressing sexual problems per week. Female PCPs were less confident than males about their ability to treat HSDD, an observation not reported in OB/GYNs. Respondents also cited perceived time constraints and lack of therapeutic options as barriers to initiating discussions about sexual health. Respondents believed that medical and residency education provided inadequate training for sexual history taking, however participation in continuing medical education and practice experience were associated with greater confidence in the multivariate analysis.[14] The many significant barriers to providing effective care for women’s sexual health are poorly and variably addressed by existing curricula and educational programs.[15]

d) Screening and Detection of Sexual Problems

Clinicians infrequently screen for sexual problems, so detection rates are consequently low. If practitioners do take sexual histories, they most commonly focus on sexually transmitted disease risk assessment and prevention and/or contraception rather than sexual problems. Improving screening procedures does improve recognition. In a frequently cited study in which clinic physicians were trained to take a screening sexual history, 53% of the patients reported a sexual problem.[7 Most] (91%) of the patients said they considered questions about sexuality to be an appropriate part of the interview. Training in sexual health screening increases detection, which satisfies patients.

e) Physicians’ Desire for Sexual Health Education

In the ED course discussed above, physicians’ previous training in communication skills was reported as the strongest predictor for sexual history taking.[11] While physicians typically do not receive adequate training in sexual medicine and sexual history taking, they believe that they should address sexual problems and that they need more training. Practicing physicians can gain increased comfort and experience in managing sexual problems by incorporating routine sexual health questions into their practice, by addressing the barriers discussed above, by sharing cases with colleagues, and by exploring their own attitudes toward sexuality.[9]

As we will discuss, physician education, targeted at improving skills, increasing knowledge, and encouraging awareness of personal biases, is the key to minimizing obstacles that interfere with doctors optimally addressing sexual health.

2. CURRENT STATE OF UNDERGRADUATE SEXUAL HEALTH EDUCATION

The majority of medical students believe that sexual history taking will be an important part of their future clinical practice; however, between 42-62% of U.S. medical students feel that the training on sexuality they received in medical school is inadequate.[16] Studies assessing curricula at individual institutions have demonstrated that students receive a broad range of non-standardized training. More controversial topics in sexual health have even less favorable representation. For example, of the 82 U.S. medical schools that responded to a survey (65% of the 126 schools surveyed), 8 faculty reported that they had no teaching on gay and lesbian issues.[17] Cultural influences on sexual practices do not appear to be addressed in most sexuality curricula.

The most comprehensive recent information about the status of undergraduate sexual health education is reported in a recent survey on sexual health training in medical schools in the USA and Canada.[18] In this survey 141 medical schools were contacted, and 101 valid responses were returned. The survey asked about the type of educational experiences, whether they were mandatory or elective, whether they were designed by single or multiple disciplines, and the number of course hours dedicated to human
sexuality. The questionnaire also assessed specific content areas, as well as exposure to and training in clinical settings addressing sexual problems. Additionally, the survey assessed the availability of continuing medical education (CME) programs in sexual medicine and related topics.

A total of 84 respondents (83%) reported using a lecture format for sexuality education. Two thirds of the schools used a multi-disciplinary approach to teach sexual health, and three quarters of the schools reported Psychiatry as the most frequently involved discipline. The majority (54%) of the schools provided 3-10 h of education. The curricula of 96 respondents included causes of sexual dysfunction (94%), its treatment (85%) altered sexual identification (79%) and issues of sexuality in illness or disability (69%). Only 43 (42%) schools offered clinical training programs that focused on treating patients with sexual problems and dysfunctions; and 56 (55%) provided the students in their clerkship with supervision in dealing with sexual issues.

In a survey of 25 UK medical schools’ teaching on erectile dysfunction (ED) to undergraduates, only 9 indicated that the subject was covered in their curriculum; and only 5 reported providing significant exposure within an integrated program of teaching on sexuality. The others stated that ED is covered by a 30-60 minute lecture, either during urology or gynecology rotations.[19]

A global survey was conducted through a collaboration between ISSIR (Int. Soc. for Sexual and Impotence Research), WHO, and World Federation of Medical Education (WFME). The report concluded that approximately 30% of medical schools have no educational program in human sexuality or sexual medicine and that 50% have less than 10 hours teaching, mostly related to reproduction. The disciplines most involved in teaching are Gynecology, Psychiatry and Urology; and only 15% of schools have more than 20 hours of teaching with multidisciplinary involvement.[19]

**a) ISSR/ISSM Curriculum in International Undergraduate Sexual Health Education**

In response to the survey described above, the ISSIR educational committee (www.issir.org) recommended a globally applicable curriculum (www.med-sexedu.net) calling for an intensified global strategy in the future teaching of medical doctors in Sexual Medicine. In 2005 the International Society of Sexual Medicine (ISSM) chartered an education committee that was charged with reviewing curriculum at 1,700 medical schools worldwide. The committee then initiated the creation of a structured, multidisciplinary, medical school curriculum with modules pertaining to sexual medicine that could be adapted to suit different cultural needs. Although the curriculum is still under development, when available these modules could be distributed to medical schools for direct use or as a basis for independent curriculum development. In addition to the teaching materials, a 20-30 hour program (available electronically) is to planned to assist in faculty training and development.[20]

**b) New Developments in U.S. Undergraduate Medical Sexual Education**

A number of medical schools have made improvements to their sexual health education programs. Several models described below incorporate a multi-disciplinary approach to enhance trainees’ attitudes, knowledge, skills, and overall comfort in managing sexual health problems. Table 1 outlines the elements including attitudes, knowledge, and skills training that have been addressed in sexual health curricula. A variety of innovative teaching methods are described in the examples below.

Case Western Reserve University School of Medicine described the implementation of a “comprehensive, cross-disciplinary and innovative curriculum that is based on three primary objectives for teaching sexual health: attitude change, behavior change and knowledge acquisition.” [21] Attitude change is accomplished by promoting students’ awareness of their own attitudes toward sexuality and exposure to normal variations of sexuality. Behavior change is being addressed by enhancing communications skills “regarding all aspects of sexual functioning.” Knowledge acquisition involves a multi-disciplinary approach to all aspects of sexual health, including topics such as biology; sexual development; and sociologic issues such as the impact of ethnicity, race, culture, and economic status on sexual health. Strategies to incorporate the sexual health content include faculty development to enhance sexual communication skills; additional didactic sessions; case-based learning; standardized patient (SP) interviews; testing using multiple choice questions; assessment of students’ attitudes using the Sex Knowledge and Attitudes Test (SKAT); and the creation a sexual health website.

The enhanced curriculum at Case Western also employed Objective Structured Clinical Exams (OSCEs), including both sexual health content in existing stations and stand-alone stations. An OSCE is a timed, multi-station examination in which learners perform tasks such as interviews, physical exams, and counseling with SPs in realistic settings. At each station learner performance is evaluated with specific checklists or global rating scales, completed by faculty proctors and/or SPs.[15]

The University Of Massachusetts Medical School implemented curricular enhancements throughout the four years. These include an elective reflection session regarding students’ reactions to the dissection of the female pelvis during the first year anatomy course; an elective session on the
“Medical Risks of the Gay, Lesbian, Bisexual and Transgendered Community”; and a multi-disciplinary one-week elective women’s health course for fourth year students.[22]

Other educational initiatives in sexual medicine include student-initiated programs. Useful learning methods included discussions with fellow students, interactive presentations with faculty, patient panels, didactics, and teaching peers.

c) New Developments in International Undergraduate Sexual Medicine Education

Some innovative model curricula have emerged from medical schools in the United Kingdom (U.K). The University of Cambridge instituted role-playing mock clinic scenarios, which allows students to empathize with the patient, and discover and test beneficial behaviors.[23] The University of Cambridge also conducts a session dedicated to increasing awareness of homosexuality. During the session students explore internalized prejudice by brainstorming all the slang terms they know relating to homosexuality and then reflecting on them silently.

Another medical school in the UK, Leicester-Warwick Medical School, initiated a course designed to aid the students in recognizing their attitudes and values toward sexuality.[24] Methods include desensitization, problem solving and reflection. Students address their embarrassment with sexual topics, including becoming familiar with slang and medical terms in a safe environment in which they might rehearse their reactions and responses.

3. CURRENT STATE OF U.S. GRADUATE MEDICAL EDUCATION

Sexual health training in graduate medical education is understudied and largely unaddressed. According to Rosen et al, “Residency training in sexual medicine has been largely neglected, with little attention given to educational curriculum development or implementation; and few programs have training in sexual problem management across disciplines or subspecialties (e.g. family medicine, internal medicine, OB-GYN, urology, and psychiatry).[25]

a) Accreditation Standards for U.S. Undergraduate and Graduate Sexual Health Education

The Liaison Committee on Medical Education (www.lcme.org) determines accreditation standards for medical schools. The curricular requirements related to sexual health are general and include learning about: behavioral subjects; communication skills, medical consequences of common societal problems, such as abuse; diverse cultures and belief systems, and gender biases. The Accreditation Council for Graduate Medical Education has outlined residency program training requirements for all disciplines (www.acgme.org). Sexual medicine requirements are also very general. Internal Medicine residents should receive “instruction and clinical experience in the prevention, counselling, detection, diagnosis, and treatment of gender-specific diseases of men and women.” Family medicine guidelines call for the “teaching of human sexuality.” Pediatrics requirements mandate learning about sexual abuse, and male and female reproductive health including sexuality, pregnancy, contraception and STDs. Urology requirements include training in sexual dysfunction. OB-GYN residents should receive training in contraception, infertility, menopause, high-risk sexual behavior, as well as specific sexual medicine skills such as sexual history taking and psychosexual counseling. Psychiatry guidelines are vague, addressing issues of gender, race, ethnicity, socioeconomic status, religion/spirituality, and sexual orientation (knowledge and attitudes).[15]

Both the LCME and ACGME now require performance-based assessment to document the acquisition of competencies. They require direct observation of live patient encounters; SPs and OSCEs are the preferred or next best method for assessing many clinical skills. These principles of competency evaluation have not yet been directly applied to sexual medicine skills; in order to meet contemporary standards, the discipline of sexual medicine will need to incorporate these educational approaches into new curricular efforts.

b) New Developments in Residency Sexual Health Education

Few residency training programs have described innovations in sexual health education. The Robert Wood Johnson Medical School (RWJMS) has been an internationally recognized model for comprehensive sexual health education for medical students since 1973. Using a small group interactive format, the course seeks to provide a culturally diverse and patient-centered approach’ focusing on three components: (1) integration of didactic and attitudinal learning; (2) multidisciplinary approach to sexual problems; (3) clinical skills, including communication skills and sexual history taking (http://www2.umdmj/hspweb). A similar model was developed for residents, incorporating the three components into a half-day program for senior house staff from RWJMS-affiliated residency programs in multiple specialties, including 46 internal and family medicine, psychiatry, geriatrics, OB-GYN, urology, and pediatrics residents.[25] Methods included didactic presentations on sexual dysfunction, physician and patient panels, an audience response system with feedback, and interviewing skills practice.
4. CURRENT STATE OF POST-GRADUATE SEXUAL HEALTH EDUCATION AND CME PROGRAMS

Less than half (44.6%) of the North American medical schools who responded to the 2003 survey discussed above offered continuing medical education (CME) programs for professionals interested in sexuality related topics.

In response to the increasing demand and interest, some organizations, composed of practicing physicians in one or several disciplines, now offer lectures, workshops, and longer courses on the evaluation and treatment of sexual dysfunction. Organizations that have provided these courses include the American College of Physicians (ACP) (representing general internists and subspecialists), the American Academy of Family Physicians (AAFP), the American Psychiatric Association (APA), the North American Menopause Society (NAMS), and the American Urological Association (AUA). Academic societies, such as the Society for General Internal Medicine (SGIM), offer workshops geared toward clinician educators that address both clinical care and teaching strategies. In the last decade multidisciplinary, specialized organizations such as the International Society for the Study of Women’s Sexual Health (ISSWSH) have been sponsoring meetings that are dedicated to sexual health research and educational courses designed to enhance clinical care.[15] Other international organizations, such as the Latin American Society for Sexual Medicine (SLAMS), have also offered sexuality courses on the Internet. Also, post-graduate sexual education commonly occurs through the establishment of preceptorships, other formal arrangements and consultations, direct observation of sexual health specialists, and networking.

Industry sponsored CME programs consist of symposia at professional meetings, teleconferences, and internet-based training programs on sexual health problems. Teleconferences include interactions with live speakers in conjunction with slide presentations on clinical assessment and management. Web-based resources include case-based formats and video demonstrations of skills such as sexual history taking and communication, as well as ED management. The intervention employed an array of instructional methods including didactics, tutorials, video-based dramatization, group scripted role-play demonstration with participant discussion and decision-making and individual role-play practice. Standardized questionnaires demonstrated shifts in physicians’ attitudes toward patient-centeredness and less judgmental attitudes towards patients’ sexuality. Physicians’ self-assessed their knowledge acquisition and rated the efficacy of the course components; participants gave the highest ratings to the tutorial on ED management and the sexual history taking role-play.

Consistent with previously published studies, Athanasiadis and colleagues’ assert the effectiveness of scripted role-plays, combined with interactive small group formats using problem-based learning, for acquiring communication skills for sexual history taking and clinical management of sexual dysfunction.[26] It is important to note that their outcomes solely relied on self-reported changes attitudes, knowledge, and skills, and not on physician self-reported or objective changes in their clinical practice.

The most extensive post-graduate CME program to date was initiated by the European Society for Sexual Medicine (ESSM) in 2007. The ESSM launched the Oxford course, a 2-week residential program of 76 hours of teaching, discussion, and sexual health interviewing and counselling skills training, conducted by international experts, for 29 physicians of 21 nationalities from a wide spectrum of disciplines. This course, described as “an outstanding success,” was designed to be a first effort toward compliance with the “structured teaching requirements” anticipated for professional qualification as a sexual health specialist under the new European Division of Sexual Health.[27]

5. SUMMARY OF SEXUAL HEALTH EDUCATIONAL METHODS

In the examples above, an array of educational methods have been employed to meet the challenges of teaching sexual medicine at all levels of medical education. These and other methods and their benefits are summarized below:
Lectures on sexual health content: instruction by experts on complex biomedical issues

Case-based seminars: interactive, generate adult learning

Workshops and patient panels: exposure to multiple viewpoints

Training in interviewing couples: modelling of complex interaction

Discussion groups: exploration of feelings and self-reflection

Immersion/desensitization: exposure to alternative practices

Scripted Role-Play: observe expert demonstration of interviewing/counselling skills

Role-play (individual): practice eliciting sensitive information in a safe environment (open-ended questions and normalizing statements)

Standard patient scenarios: structured practice with immediate feedback

Observed structured clinical encounters (OSCEs): competency assessment and evaluation

Video review of live encounters: individualized feedback and self-reflection

Clinical and research electives: personalized in-depth exposure

Faculty development: enhance dissemination and multidisciplinary interaction

6. SUMMARY OF DEFICIENCIES IN CURRENT SEXUAL HEALTH TRAINING PROGRAMS

Numerous innovations have occurred in recent years in undergraduate, graduate, and post-graduate sexual health education. Emerging curricula have enhanced training in knowledge, skills and attitudes; and institutions and organizations have employed an array of educational methods. However, standards for curriculum development and the assessment of competencies, such as those developed in the U.S. by the ACGME, have not been adequately employed in sexual health education. Four specific deficiencies can be identified.

(1) Most curricula have consisted of set lectures or seminars. Few programs have employed learner-centered learning, which encourages individual learners’ to self-assess their needs, define personalized goals, and track their progress.

(2) The majority of program innovations have focused on the dissemination of clinical knowledge. Some programs have included skills training; however few have addressed the full spectrum of clinical skills including sexual history taking, physical exam, procedures, behavioral counseling, and medical recommendations. Individualized skills training, combined with immediate feedback, has not been substantially employed.

(3) Evaluation of the efficacy of educational programs has primarily relied upon trainees’ self-report of program efficacy and self-assessment of changes in knowledge, skills, and attitudes. Objective measurement of the performance of clinical skills has not been reported. Although some training programs have employed OSCEs to assess the acquisition of clinical skills, standardized competencies and performance parameters have not been well described.

(4) Objective measures of the impact of graduate and post-graduate physician training in sexual health on patient satisfaction and objective health outcomes are lacking. Follow-up questionnaires documenting changes in clinical practice after sexual health training have not been employed.

Future training programs at all levels of medical education should incorporate standardized measures of skill acquisition with objective patient outcomes into the design of the educational initiative. Objective evidence of the benefits of sexual health education on patient care is necessary to stimulate the development of the field and support the need for more widespread education and training.

7. BARRIERS TO THE IMPLEMENTATION OF SEXUAL HEALTH EDUCATIONAL PROGRAMS

While there have been some substantial advances in the delivery of sexual health education programs worldwide, significant barriers to their implementation still exist. These include:

- Lack of public awareness of the importance of sexual health as a priority
- Lack of governmental and other public funds dedicated to the development of sexual health education programs
- Deficiency of resources in educational settings, such as new textbooks and equipment
- Few hours of dedicated curricular time in medical schools and residency training programs
- Paucity of faculty development programs
- Few well qualified and trained professionals to carry out educational programs
• Lack of widespread access to educational programs

• Lack of attention to sexual health issues across ethnicities, religions, and races

8. MANDATE FOR A UNIVERSAL UNDERGRADUATE SEXUAL HEALTH CURRICULUM

This committee recommends an intensified global strategy in the future teaching of basic sexual health education, as an obligatory part of the learning requirements for physicians. As described above several international organizations have made recommendations through initiatives regarding the development of sexual health curriculum.

Recently, the ISSM Education Committee has initiated the process of recommending a universal curriculum for all medical schools. This committee has targeted three aims that include (i) defining competencies in relevant to sexual health education, including knowledge, skills and attitudes; (ii) creating an effective teaching and assessment process to ensure and demonstrate the acquisition of competencies and impact on patient outcomes; and (iii) designing an implementation strategy that includes dissemination to worldwide medical universities.

Core elements should include:

• Basic knowledge of human sexuality

• Awareness of personal attitudes towards one’s own and other people’s sexuality, which should include a respectful attitude towards persons with different sexual orientations and sexual practices

• Basic skills in identifying, diagnosing, managing and, if necessary, referring to the appropriate professional, sexual health problems

9. RECOMMENDED SEXUAL HEALTH TRAINING FOR POST-GRADUATE PHYSICIANS

This committee promotes the need for the establishment and support of continuing education for established health professionals. This committee also believes that there should be a requirement for physicians specializing in sexology and sexual medicine to undertake a specified training program appropriate to their discipline.

We recommend that the content for such curricula should be similar to undergraduate education, with the addition of issues relevant to the practicing physician (highlighted with an *). A core training program should be based on the best available evidence-based medicine and include:

Knowledge
Anatomy and physiology of the sexual response
Psychology
Biological basis of human sexuality
Sexual development
Sexual identity and orientation
Gender identity
Sexual behavior
Sexual dysfunction
Cross-cultural issues in sexual health
Sex and relationships
Sex and reproductive health
Sex and ageing
Sex and the effect of medical problems and their treatments
Therapeutic interventions for sexual dysfunction
  Medications
  Surgery
  *Office-based counseling
  Sexual psychotherapy
  *Medico-legal aspects of sexuality and sexual behavior
  *Ethical aspects of sexual medicine
  *Sexual research
  *History of sexual medicine

Skills
Communication
  With professionals
  With patients and partners
  *Education
  With professionals
  With patients and partners
Clinical assessment
Clinical management
Clinical governance
  *Administrative skills
  *Research skills
  *Advocacy skills
Such programs, whether at basic level or for
the specialist, should be properly validated and supervised by an appropriate academic authority. In conjunction with universal standards, we recommend the establishment of regional and international centralized infrastructures, which create standards for accreditation, and overseeing of the practice of sexual medicine.

10. CONCLUSIONS

Concordant with major advances in the evaluation and treatment of sexual dysfunction, society has become more willing to recognize sexual problems and discuss sexual health. However, many medical students, house staff, and practicing physicians continue to receive variable, non-standardized or inadequate training in sexual history taking and sexual dysfunction management. The efficacy of these interventions on the acquisition of clinical skills and patient outcomes has not been assessed. Hopefully, existing models have established a trend that will inspire all medical schools to offer mandatory, comprehensive curricula in sexual health education. Graduate medical sexual education is has just begun to address the need to give physician trainees uniform, standardized skills to meet the demands of current clinical practice. Continuing medical education programs are being offered in multiple disciplines and by specialty multidisciplinary organizations. The challenge is to create widely available programs that provide physicians across specialties with the skills needed to meet contemporary patients’ needs in sexual health care.[15]

II. ETHICAL PERSPECTIVES IN SEXUAL MEDICINE

Leonore Tiefer

1. PATIENT-PHYSICIAN ETHICS

In their classic text, Beauchamp and Childress[1] described a medical ethics framework for patient-physician relations based on four fundamental moral principles: respect for autonomy, nonmaleficence ("do no harm"), beneficence and justice. All the traditional aspects of modern professional medical practice can be seen to derive from one or another of these principles, e.g., mandatory informed consent for treatment and research participation, confidentiality, patient rights protection, access to care, and respect for human dignity. This approach is described in some detail in the ethics and education chapter in the previous edition of this Sexual Medicine text.[2]

The approach based on principles has been used in constructing the ethical codes of many professional medical organizations and has many important applications to the practice of sexual medicine. However, there are some important challenges and supplements to principilism that have particular relevance for sexual medicine.

Challenges to autonomy

It is often said that respect for autonomy is the keystone of contemporary medical ethics. Each patient is respected as a competent individual and given the right to make informed choices about their own health care. However, sexual activity presents certain dilemmas that are almost impossible to resolve using the conventional approach to autonomy and require that we expand our professional outlook.

First, sexuality is a subject about which many—perhaps most—people are very poorly informed due to the widespread absence of comprehensive sex education, the limits on sexual information provided to the public and the abundance of sexual myths.[3] Assuming that a patient needs only to be informed about the specific medical choices relevant to his specific problems ignores the larger context of misinformation and ignorance, and the almost inevitable presence of sexual embarrassment and even shame. Dodds [4] argues, for example, that a person’s “autonomy competency” is limited whenever they are uncomfortable, frightened, experiencing values conflicts, or otherwise compromised, a situation that seems to describe sexuality quite well.

Second, sexual activity usually involves another person and has substantial implications for the physical and psychological health and well-being of that other person. Thus considering only the patient’s autonomy and rights when it comes to sexual health is oversimplified.

Consider the common situation where a man with erectile dysfunction consults a physician but does not bring his wife, whom he says is his only sexual partner. The range of available treatments—sex therapy, medical devices, medications, and surgeries—will all have some impact on his wife. The patient needs information and education about his problem and the available treatments AND his wife needs information and education also. The sexuality knowledge base of both individuals is likely to be limited. Moreover, the wife may have important perspectives to contribute. She may have health issues that would limit her interest in vaginal intercourse. She might be so worried about the impact of the medication, device or surgery on her (often elderly) husband’s health that she is fearful about engaging in sexual relations with him. It is possible that she may feel a more important problem in the couple’s sexual life is being overlooked by the focus of this particular consultation. Research has shown that the information provided by the patient’s wife sometimes changes not only the treatment recommendation but the actual sexual dysfunction diagnosis.[5]

Given these information and relationship issues, the ethical physician will make every effort to involve the patient’s wife in order to educate her, involve her and consider her choices in the matter before a treatment decision is made.

2. ETHICS IN A MULTICULTURAL WORLD

We live in multicultural societies where sexual practices, attitudes and values vary widely, to say the obvious, from the very liberal to the very conservative. A small number of professionals will practice sexual medicine in homogeneous societies, but the rest need training to clarify their own values and learn how to handle the complexities posed by cultural diversity.[6] Professionals without suitable exposure and facility with the subject of human sexualities are likely to feel uncomfortable discussing sexual issues with patients, are likely to make assumptions based on cultural or age-related stereotypes, may take overly brief and medicalized histories, and may feel conflicted about the proper use of resources for patients such as educational books, videos, websites and erotic stores.

Sexual values clarification workshops and trainings are unlikely to be scheduled at medical conferences but sexology groups such as the American Association of Sex Educators, Counselors and Therapists (http://www.aasect.org) have decades-long experience offering workshops addressing professionals’ attitudes and values.

Sexual rights are an important component of
sexual values, and organizations such as the World Association for Sexual Health (WAS) http://www.worldsexology.org/ offer regional congresses that include professional training in sexual rights. WAS has developed documents such as the Declaration of Sexual Rights (approved in 1999) that is now available online in 18 languages (http://www.worldsexology.org/about_sexualrights.asp). Study of this document will enlarge the sexual medicine professional’s sense of the human rights and civil rights perspectives on sexual conduct. Finally, discussions of ethics are part of the trend in cultural competence in health-care delivery.[7] Cultural competence in sexual medicine embraces awareness of linguistic, inter-cultural, intra-cultural, and economic variations, and leads the provider to avoid making assumptions but rather to inquire closely about each patient’s and partner’s sexual beliefs and their origins. It will move the provider away from overly standardized and stereotyped approaches towards assessment and treatment that is truly respectful and patient-centered.

3. ETHICS AND RESEARCH, CONTINUING EDUCATION, PROFESSIONAL ORGANIZATIONS

The past decade has seen an explosion of interest in ethical dilemmas related to the new relationships between healthcare professions and the pharmaceutical industry. This evolving area is especially relevant to sexual medicine because of the strong interest of the pharmaceutical industry in potential markets for sexual dysfunction and dissatisfaction treatments.

A 2009 report by the highly respected U.S. Institute of Medicine (IOM) reviews this area of professional ethics and makes a number of recommendations for reform as regards the relationship between industry and clinical research, education and patient-care. (http://www.iom.edu/CMS/3740/47464.aspx) The IOM’s solution to “disentangling the relationships between doctors and drug companies” (p.1193) includes government-sponsored registries to monitor industry payments, greater disclosure of all professional-industry relationships, and setting limits on industry gifts and payments to health-care professionals.

Rothman and colleagues recently reviewed ethical issues that pertain to professional medical associations (PMAs).[9] PMAs have central roles in defining and advancing health care through conferences, continuing medical education, practice guidelines, codes of conduct, and public advocacy positions. PMAs have been very important in developing the new field of sexual medicine. Rothman and colleagues emphasize that any threats to the integrity of PMAs because of questionable financial links could harm public health and compromise the role of medical professionals.

During the past decade, the relationship between medicine and industry, specifically involving pharmaceutical and medical device companies, has come under intense scrutiny. The overriding concern is that industry ties create conflicts of interest both real and perceived….The problem has exceptional relevance for PMAs because industry funding of their activities, although varying in degrees, is pervasive (ibid, p.1367-8)

After reviewing many areas where industry makes important contributions to medical progress as well as many potential conflicts of interest, Rothman and colleagues conclude with 10 explicit recommendations for PMAs. First on the list is “a complete ban on pharmaceutical and medical device industry funding” for general PMA operational costs (including meetings, research or fellowship sponsorship, journals and practice guideline developments) except for clearly identified marketing opportunities such as journal advertising and exhibit hall fees (ibid., p. 1368). They recommend a variety of ways to pool gifts and grants from industry for research and education that do not identify individual donors or link recipients to specific donor companies.

This new trend towards elimination of conflicts of interest between PMAs and the pharmaceutical industry is relevant for sexual medicine organizations that grew over the past decade largely as the result of industry sponsorship and gifts. Continuing sexual medicine education needs a new paradigm for operations and support that should evolve through industry-independent consensus meetings (as recommended by the IOM).

Conflicts of interest with regard to clinical research design, conduct and publication of results are also being scrutinized as the result of recent industry scandals and changing public values. Recent scandals regarding the suppression of data and ghostwritten articles provoked renewed regulatory attention, but popular awareness had been building around conflicts of interest in clinical research such as publication biases, lack of appropriate controls, and industry-supportive research endpoints. Marcia Angell, leading medical educator and former editor of the New England Journal of Medicine makes some observations that might especially pertain to the current picture in sexual medicine:

Physicians who would be quite skeptical about drug company advertisements and the pitch of sales representatives tend to trust the peer-reviewed medical literature. One result of this bias in the literature is that physicians learn to practice a very drug-intensive style of medicine. Even when lifestyle changes would be more effective... (p.1071) [10]
**Ethical issues regarding sexual pharmaceuticals**

Scientifically tested medical and drug treatments for sexual dysfunctions are relatively recent, although the history of popular sex enhancers or aphrodisiacs stretches back thousands of years. [11] Following the enormous sales success of the first prescription oral drug for erectile dysfunction, Pfizer’s Viagra (sildenafil citrate), many companies became interested in sexual dysfunction and sexual medicine. Since 1998, a few new products have been approved, several have been discontinued while still in clinical trials, and a few older drugs have been approved for sexual indications. More drugs are under development including vascular, hormonal and central nervous system agents.

In addition to the standard approach of drug development, testing, approval, and information circulated to doctors, the sensationalism of sexuality and the huge profits signaled by the blockbuster reception of Viagra have introduced new challenges into the domain of sexual dysfunctions and pharmaceuticals: unlicensed prescribing, off-label prescribing, and advertisement directly to the public.

Fallon [12] has recently reviewed the range of drugs now commonly being prescribed ‘off-label’ for sexual problems, especially for rapid ejaculation in men and desire and arousal complaints in women. He suggests that routine use of such medications is often appropriate and based on reputable published studies. Other independent experts [13] have challenged the widespread use of off-label prescriptions, suggesting “most lacked evidence of clinical efficacy” (p. 1023).

In any case, no one will argue that sexuality pharmaceuticals are among the best-advertised of all drugs in those countries (currently only the USA and New Zealand) that permit direct-to-consumer advertising (DTCA). This situation has introduced numerous problems regarding patient demand, overprescribing, and patients’ miseducation. However, the era of DTCA may be ending, and, with it, some of the ethical dilemmas sexual medicine professionals have faced will subside. However, this arena of practice will continue to offer thorny challenges to all careful practitioners.

**REFERENCES**

**COMMENT**

**Eusebio Rubio-Aurioles**

The committee assignment of reviewing the broad spectrum of topic proved to be a significant challenge that in fact created a longer period of agreement that expected. An unfortunate agreement in the committee was the decision to publish some of the members’ views in an independent way, that is, with the member supporting only what she has to say about the subject.

Although Leonore Tiefer’s statement is highly pertinent and provocative, other members of the committee felt obliged to state specific comments and additions to this contribution to present a more balanced view, since the clear anti-pharmaceutical approach that she chooses is at the same time biased and unbalanced. Also, in some instances the references and commentaries posed are expanded.

The conflict of interest ethical dilemma in sexual medicine is a real one. However, pointing out only the negative aspects of this dilemma might be unfair and unrealistic, especially when the precisely the current level of development of sexual medicine as a field of inquiry, research, medical diagnosis and treatment has had an unprecedented development because of the involvement of the pharmaceutical industry, as the report quoted by Tiefer states:

*Research partnerships among industry, academia,*
and government are essential to the discovery and development of new medications and medical devices that provide improved means for the prevention, diagnosis, and treatment of health problems. Historically, the federal government has taken the lead in supporting discoveries in basic science, whereas commercial firms have focused on the discovery of specific medicines and then their development through clinical trials to the regulatory approval of marketable products (p.97 [1]).

The ethical dilemma posed by the involvement of the pharmaceutical industry should of course be addressed and professional medical organizations, scientific journals and health professionals in general should be aware that profit oriented activities with health professional should always be conducted with the highest scientific standards and in all cases, all levels of possible conflict of interests should be acknowledged.

The comments on off-label use of drugs for sexual dysfunction, as stated by Tiefer, is also unfortunate. One of the most researched uses of off-label medication for sexual dysfunction is the use of Selective Serotonin Reuptake Inhibitors (SSRIs) for the management of premature ejaculation. The review quoted by Tiefer [b], where authors state that off-label used lacks of scientific evidence, does not include the use of ISSR for this off-label indication, therefore, suggesting that the use of off-label medication for the treatment of premature ejaculation lacks scientific evidence is misleading, especially in view of the fact that approval for drugs to treat this condition is still pending in many countries of the world.

The fact that pharmaceutical industry supports continuous medical education activities poses another ethical dilemma. The suggested ban of support from the industry can make sense in areas of the world that have sufficient economic resources as to ask Universities, and government supported agencies to take over the role of promoting continued medical education. However, we have to recognize the in many areas of the world, activities supported by industry are the only ones available to the health professionals. Rather that promoting a generalized ban that would result in a detrimental effect for the underdeveloped areas of the world, a strengthening of the ethical standards in industry supported activities should be encouraged. The pharmaceutical industry has responded to these problems issuing recently a series of modifications to a code of ethics that promotes self regulation of their relations with health professionals (Code on Interactions with Healthcare Professionals, available at http://www.phrma.org/iles/attachments/PhRMA%20Marketing%20Code%202008.pdf)

International proposals for ethics in sexual medicine

The World Association for Sexual Health (WAS) has produced two documents that are highly relevant for ethical considerations in sexual medicine: the WAS Declaration of Sexual Rights and the In 1999, the WAS issued a Declaration of Sexual Rights that includes the basic values that are needed for a healthy sexual development and life. This declaration is reproduced in Box A and is available at http://www.worldsexualhealth.org/sites/default/files/Declaration%20of%20Sexual%20Rights.pdf
Declaration of Sexual Rights

Sexuality is an integral part of the personality of every human being. Its full development depends upon the satisfaction of basic human needs such as the desire for contact, intimacy, emotional expression, pleasure, tenderness and love.

Sexuality is constructed through the interaction between the individual and social structures. Full development of sexuality is essential for individual, interpersonal, and societal well being. Sexual rights are universal human rights based on the inherent freedom, dignity, and equality of all human beings. Since health is a fundamental human right, so must sexual health be a basic human right.

In order to assure that human beings and societies develop healthy sexuality, the following sexual rights must be recognized, promoted, respected, and defended by all societies through all means. Sexual health is the result of an environment that recognizes, respects and exercises these sexual rights.

1. **The right to sexual freedom.** Sexual freedom encompasses the possibility for individuals to express their full sexual potential. However, this excludes all forms of sexual coercion, exploitation and abuse at any time and situations in life.

2. **The right to sexual autonomy, sexual integrity, and safety of the sexual body.** This right involves the ability to make autonomous decisions about one’s sexual life within a context of one’s own personal and social ethics. It also encompasses control and enjoyment of our own bodies free from torture, mutilation and violence of any sort.

3. **The right to sexual privacy.** This involves the right for individual decisions and behaviors about intimacy as long as they do not intrude on the sexual rights of others.

4. **The right to sexual equity.** This refers to freedom from all forms of discrimination regardless of sex, gender, sexual orientation, age, race, social class, religion, or physical and emotional disability.

5. **The right to sexual pleasure.** Sexual pleasure, including autoeroticism, is a source of physical, psychological, intellectual and spiritual well being.

6. **The right to emotional sexual expression.** Sexual expression is more than erotic pleasure or sexual acts. Individuals have a right to express their sexuality through communication, touch, emotional expression and love.

7. **The right to sexually associate freely.** This means the possibility to marry or not, to divorce, and to establish other types of responsible sexual associations.

8. **The right to make free and responsible reproductive choices.** This encompasses the right to decide whether or not to have children, the number and spacing of children, and the right to full access to the means of fertility regulation.

9. **The right to sexual information based upon scientific inquiry.** This right implies that sexual information should be generated through the process of unencumbered and yet scientifically ethical inquiry, and disseminated in appropriate ways at all societal levels.

10. **The right to comprehensive sexuality education.** This is a lifelong process from birth throughout the life cycle and should involve all social institutions.

11. **The right to sexual health care.** Sexual health care should be available for prevention and treatment of all sexual concerns, problems and disorders.

Sexual Rights are Fundamental and Universal Human Rights

Adopted in Hong Kong at the 14th World Congress of Sexology, August 26, 1999

---

A relatively short statement of ethical issues related to the practice of sexuality related professions was produced by the World Association for Sexual Health: The WAS Guiding Ethical Principles are available at http://www.worldsexualhealth.org/sites/default/files/Guiding%20Ethical%20Principles.pdf and are reproduced in BOX B
WAS- World Association for Sexual Health [4 ]

Guiding Ethical Principles*

Preamble

In our endeavors to achieve international recognition as the peak reference group for all matters associated with human sexuality, the World Association for Sexual Health (WAS) is committed to ethical practice in all areas. The Guiding Principles have application for clinicians, researchers, therapists, educators, and administrators. WAS acknowledges that most professions enunciate a specific code of conduct for their members, the WAS Guiding Ethical Principles are designed to enhance existing codes and provide guidance in the sensitive area of human sexuality.

The term sexologist implies a professional with specialist knowledge and skills in the area of human sexuality. Sexologists employ their specialist skills as educators, researchers, sociologists, clinicians, counselors, therapists and administrators. These Principles apply to all Sexologists when working within their professional capacity.

Various terms are used throughout this document to describe those persons, whether they be individuals, couples, groups, societies or any other entity, receiving services from or potentially affected by the professional activities of Sexologists. The terms include client, patient, student and research participant. These terms are not exclusive, nor are they intended to be definitive.

These ethical principles are designed to encompass all areas of sexology.

The Foundation Principles

The Code is founded on those principles recognized internationally through the agency of the United Nations, the World Medical Association and other, professional bodies.

The major principles are:

**Autonomy.** The obligation to support the individual’s right to self-governance through free and rational decision making.

**Beneficence** The obligation to act for the benefit of those who request professional services.

**Non-Malfeasance** The obligation to do no harm

**Justice** The obligation to act on the basis of fair adjudication between competing claims.

The Principles

**Principle 1: Sexologists shall have appropriate professional preparation and maintain an ongoing commitment to continuing education. Application:** Sexologists must hold a relevant, recognized professional qualification for their area of practice. It is the Sexologists responsibility to maintain standards of professional education and knowledge, based on current research and the development of procedures and techniques. This should be achieved through regular attendance at continuing professional education programs, professional seminars, meetings, congresses and the reading of appropriate professional literature.

**Principle 2: Sexologists must operate only within their area of professional expertise and competency. Application:** Sexologists should recognize the professional boundaries and the limits of their professional competency. They should declare the parameters in which they work and, where appropriate, refer people to another, appropriately qualified sexologist.

**Principle 3: Sexologists should inform clients, patients and research participants of their professional qualifications and affiliations. Application:** In their place of work, where applicable, Sexologists should display their qualifications in a manner that is readily observable. Qualifications should be from recognized institutions and organizations. Limitation: The display should be professional in nature commensurate with the dignity of the profession.

**Principle 4: Sexologists should uphold and enhance the integrity of the profession. Application:** Sexologists should act in a manner that supports and enhances the integrity of the profession. Thoughtful application of each of these principles achieves this.
**Principle 5: When available, Sexologists should engage in science-based practice** Application: Sexologists should employ techniques and procedures that have demonstrated efficacy, based on appropriate research. *Limitation* In behavioral, clinical or social research, experimental and developing procedures may be employed when the risk/benefit ratio has been carefully assessed and there is full disclosure to the research participant. In education and health promotion innovative techniques may be used giving due regard to the social and cultural context and participants are appropriately informed.

**Principle 6: Sexologists have a responsibility to maintain and enhance the knowledge, health and welfare of their communities** Application: Actions taken on behalf of a client, patient or community may have an undesired affect on others, including groups within a society or the society itself. Sexologists should have regard for the impact of their proposed actions and make a decision based on the greater good.

**Principle 7: Sexologists should exercise respect for colleagues.** Application: Sexologists should act in a manner that does not bring disrepute upon their colleagues or their profession. They should act on principles of fairness at all times and not take actions that undermine individual colleagues. *Limitation:* Where a Sexologist has evidence that a colleague has acted unprofessionally is incompetent or otherwise acting inappropriately, the matter should be first discussed with that colleague and, if necessary, brought to the attention of relevant authorities.

**Principle 8: Sexologists shall not breach the professional relationship.** Application: Within the context of the professional relationship the Sexologist must act with integrity at all times. A Sexologist must not engage in intimate relations with a client, research participant, student or patient, or otherwise place them in a position where the professional relationship is compromised. When the service is of a psychotherapeutic nature a Sexologist should not provide services to a close family member.

**Principle 9 The sexologist shall respect and uphold the autonomy and dignity of those receiving their professional services.** Application: This principle applies irrespective of age, gender, race, ethnicity, educational level, sexual orientation, social circumstances, or political affiliation. It obliges the Sexologist to facilitate the exercise of autonomy through providing necessary and sufficient information to enable rational decision-making. *Limitation:* Individual autonomy is limited by the recognition of the rights of others and the avoidance of harm. It is also limited through the capacity of an individual to make rational decisions on their own behalf. Under such circumstances an advocate may act on behalf of that person. (Appendix 1.)

**Principle 10 The Sexologist shall maintain professional confidentiality** Application: Sexologists should maintain confidentiality at all times. Informed consent must be first obtained prior to disclosing information to third parties. *Limitation:* Under certain jurisdictions there is a legal obligation to report particular activities to certain authorities. The Sexologist is morally obliged to make a reasoned decision as to disclosure. Such decisions should be based on the legal and political circumstances and on what is deemed to be the greater good.

**Principle 11 Where appropriate, the Sexologist should obtain informed consent.** Application: Prior to implementing any action the Sexologist should provide sufficient and necessary information on the recommended activities and alternatives. The possible benefits and risks must be disclosed. The Sexologist may disclose which option is, in their professional opinion, the optimum action within a particular context. *Limitation:* Where the person is not in a position to provide informed consent, an advocate may act on their behalf.

**Principle 12 Sexologists will maintain appropriate records.** Application: Sexologists will maintain records on clients, client groups, patients or research participants. Such records may be used for research purposes when prior, written consent has been obtained.

**Principle 13: Sexologists will provide information on their fee schedule to potential clients** Application: Prior to the provision of services, information on fee schedules, insurance rebates and tax provisions, where relevant.

**Principles for the conduct of ethical research**

**Principle 14: Sexologists shall employ recognized research protocols** Application: All research activities should follow an acknowledged research protocol that is deemed by peers to be appropriate to the nature of the study.

**Principle 15: Sexologists shall employ recognized protocols in the use of human research subjects** Application: The use of human subjects requires adherence to the Helsinki Declaration, which includes the following: informed consent, potential benefit(s) must outweigh potential risk(s), freedom to withdraw without
Prejudice and confidentiality

**Principle 16: Sexologists shall employ recognized protocols in the use of animal research subjects.**  
*Application:* The use of animal subjects requires adherence to the protocol set down for the humane treatment of experimental animals, which includes the following: appropriate housing of the animal subject minimization of pain and discomfort and appropriate disposal at the conclusion of the study.

**Principle 17: Sexologists shall utilize peer review to evaluate their work.** *Application:* Research proposals and research reports should be made available for expert and peer review.

**Principle 18: Sexologists have an obligation to provide support for, or to conduct research and to disseminate findings.** *Application:* Sexologists should contribute to the development of the body of knowledge through the conduct of appropriate research and through dissemination of findings. This applies to adverse outcomes as well as positive one.

*Approved by the WAS General Assembly on July 13th, 2005, Montreal, Canada*
III. SOCIO-CULTURAL ASPECTS IN SEXUAL MEDICINE

Eusebio Rubio-Aurioles

The influence of culture on sexual behavior has been extensively studied and documented. In a classic book reporting the differences on a variety of sexual behaviors comparing information from more than 200 societies “culturally independent” as: “patterned and customary ways of behaving and acting that characterize the members of a society” [5]. Sociology has studied culture in several ways but one of the clearest concepts proposed to study the relationship of culture with human sexual behavior is the concept of “sexual script” that basically proposes that members of a group are prescribed how to behave in terms of what to do, with whom to do it, when and how to do it and with a rationale to do it to have the why [6]. Thus, culture acts through sexual scripts at an individual level.

A large number of anthropological and sociological studies have documented the variability of sexual behavior that can be attributable to culture [7]. While the objective of this review is not to present a full account of the cultural variability of human sexual behavior, there is a need for the clinician working in sexual medicine to be aware of the fact that culture has a very significant impact on how sexuality is understood and experienced in people’s lives. This need is particularly important for practitioners of sexual medicine who serve culturally diverse populations.

I would be out of the scope of this chapter to cover the amount of information which is published that refers to the specific differences among cultural groups. The reader is referred to valuable resources that have summarized the characteristics of different areas and cultural groups around the globe, in particular the work edited by Robert Francoeur and Raymond Noonan [8] with descriptions on the views and ways in which human sexuality is lived on 60 countries and places with information relatively recent, with the additional advantage of having its contents freely available over the internet at http://www2.hu-berlin.de/sexology/IES/xmain.html. A clinician, who finds himself or herself in a situation where he or she is serving a patient from a culture not familiar to him, could find it valuable to review what is available on the particular culture with this resource or others.

Another problem that Cross-Cultural research on human sexual behavior has encountered is the fact that many cultures (i.e. groups of people who were originally isolated in a single cultural milieu) have encountered a process of acculturation that has made that the westernized cultural view of sexuality has been present and absorbed by many societies originally isolated from the mainstream of westernized culture. An attempt to overcome this problem was carried out by a group lead by Murdock and White in 1969 [9] who assembled a sample of culturally “pure” societies with information obtained by a large number of anthropological reports. This sample has been utilized by many researchers to make sense of the variability observed amongst cultures.

One particular review of these attempts merits mention: In 1986, the American sociologist Ira Reiss published a report using the standardized sample of Murdock and White and performed several statistical analyses to attempt to identify culturally variable sexual scripts, and culturally invariable sexual scripts [10]. Reiss conclusion after this analysis was that the following propositions could be held after the analysis: 1. Societies judge stable social relationships as of great importance. 2. Societies view physical pleasure and self disclosure as the building blocks of social relationships. 3. Physical pleasures and self-disclosure are the common outcomes of sexual behavior. 4. Therefore, sexual behavior will be seen as important due to its ability to promote stable relationships. 5. Such stable bonding between genetic males and females produces a context for the nurturance of offspring- 6. Stable heterosexual relationships are the rudimentary bases for husband-wife and parent-child roles; and thus in this sense, kinship an gender roles are derivative from the bonding properties of the sexual relationship. 7. Important social relationships are culturally defined in ways that are intended to institutionalize protective mechanisms and, 8. Therefore, marital sexuality will involve jealousy norms concerning the ways, if any, to negotiate extramarital sexual access without disturbing the existing marriage relationship.

CULTURALLY SUPPORTED SEXUAL PRACTICES THAT HAVE BEEN IDENTIFIED AS HAZARDOUS TO HEALTH.

A number of practices held in areas of the world where culture prescribes what the World Health Organization (WHO) denominates hazardous sexual practices remain in today’s world. Among them, female genital mutilation (FMG), in its various forms and ways of practice, remains a classic example where cultural values collide with the minimum requirements to attain sexual health. Specific recommendations to prevent FMG from occurring have been issued [11]

In addition to FMG practices such as dry sex, where the value of a lubricated vagina is not recognized but dryness is preferred. Vaginal dryness is promoted by certain cultures as means of increasing male sexual pleasure but the health consequences on the female have been documented as deleterious [12].
In any event, the possible conflict between health promoting values and culturally held values continues to pose a big challenge for the promotion of sexual health. In general, it can be said that when a cultural practice challenges the chance of fulfilling a human right, the practice should be revised and perhaps challenged and eliminated.

A PROGRAM FOR CULTURAL CHANGE PROMOTING SEXUAL HEALTH

Recently, the World Association for Sexual Health produced a document where the available evidence was reviewed by a panel of experts from around the globe [13]. Eight cultural changes were identified as necessary to promote a sexually healthy world and they are summarized as follows:

1. Recognize, promote, ensure and protect sexual rights for all

Sexual rights are an integral component of basic human rights and therefore are inalienable and universal. Sexual health is an integral component of the right to the enjoyment of the highest attainable standard of health. Sexual health cannot be obtained or maintained without sexual rights for all.

2. Advance toward gender equality and equity

Sexual health requires gender equality, equity and respect. Gender-related inequities and imbalances of power deter constructive and harmonic human interactions and therefore the attainment of sexual health.

3. Condemn, combat, and reduce all forms of sexuality related violence

Sexual health cannot be attained until people are free of stigma, discrimination, sexual abuse, coercion and violence.

4. Provide universal access to comprehensive sexuality education and information

To achieve sexual health, all individuals, including youth, must have access to comprehensive sexuality education and sexual health information and services throughout the life cycle.

5. Ensure that reproductive health programs recognize the centrality of sexual health

Reproduction is one of the critical dimensions of human sexuality and may contribute to strengthening relationships and personal fulfillment when desired and planned. Sexual health encompasses reproductive health. Current reproductive health programs must be broadened to address the various dimensions of sexuality and sexual health in a comprehensive manner.

6. Halt and reverse the spread of HIV/AIDS and other sexually transmitted infections (STI)

Universal access to effective prevention, voluntary counseling and testing, comprehensive care and treatment of HIV/AIDS and other STI are equally essential to sexual health. Programs that assure universal access must be scaled up immediately.

7. Identify, address and treat sexual concerns, dysfunctions and disorders

Since sexual concerns, dysfunctions and disorders impact quality of life, it is critical to recognize, prevent and treat sexual concerns, dysfunctions and disorders.

8. Achieve recognition of sexual pleasure as a component of holistic health and well-being

Sexual health is more than the absence of disease. The right to sexual pleasure should be universally recognized and promoted.

206
INTRODUCTION

The economical aspects of sexual dysfunctions (SD), primarily erectile dysfunction (ED) has changed significantly over the years. Limited data indicate that the economic considerations in SD therapy continue to increase. There are several reasons for this increase, including greater acknowledgment of the widespread prevalence of sexual disorders, SD's as undertreated conditions, a broader spectrum of individuals at risk, aging of the population with more concern about quality of life, the success of oral therapy and other new therapies under development. The global aging process and dramatic improvements in longevity are expected to strongly influence the economic issues of SD management. However, there are little published data on the economic aspects of SD. Further research is necessary to determine the various components of the economic impact of ED and other SD. Research should also explore cultural and ethnic determinants in the economics of these conditions and societal impact of their treatment. Therefore, studies should be both cross-sectional and longitudinal due to the cumulative effect of SD and the unknown long-term issues such as rates. Cost-effectiveness analyses can be informative because they systematically distill medical decisions down to the quantity and quality of life gained by intervention and may help determine specific algorithms for ED and other SD management including cost. Drug comparative and drug combination studies have shown safety and efficacy of the therapy but more longitudinal studies are needed to further elucidate ineffective and unnecessary expensive combinations. The mission of the Committee on Economical Aspects is to identify, research, summarize and report on all medico-economic issues related to ED and other SD for both male and female. In addition, the Committee is charged to produce observations, conclusions and recommendations regarding the economic aspects. The study of the economics of medical conditions may be performed at different levels, namely;

1. DESCRIPTIVE ECONOMICS

This involves a precise definition of the condition under study, as accurate identification of the disorder and the subject is fundamental in the description of the economic consequences.

2. ANALYTIC ECONOMICS

This involves the search for recognition of trends, correlations, predictors and other statistical indicators. This is important in the understanding of market or consumer behavior and the identification of influencing factors.

3. INTERVENTIONAL ECONOMICS

This involves the planning of an intervention and the investigation of a consumer or market response. This chapter is mainly confined to descriptive and to a lesser extent analytic economics.

I. EPIDEMIOLOGY OF SEXUAL DYSFUNCTIONS

Sexual dysfunctions in both males and females have a substantial prevalence throughout the world. Greater public health awareness surrounding SD, population growth and the global aging population...
will unequivocally continue to increase the prevalence of SD. The population growth and increased life spans predispose more people for SD as longevity allows for more active sex life in couples. Sexual dysfunctions of male and female includes a broad spectrum of disorders. Male SD includes ED, Peyronie’s disease, early (premature, rapid) ejaculation, desire disorder, hypogonadism and priapism. Female sexual dysfunction involves disorders of sexual desire, arousal, orgasm and dyspareunia, which lead to personal distress. Therefore, sexual dysfunction epidemiology can be further appreciated when dissected into both male and female SD.

1. MALE SEXUAL DYSFUNCTION

Even though numerous studies have been published in the last five years on prevalence of ED, limited data is available for the different facets of male SD, thus, this review will mainly focus on ED and premature ejaculation (PE). The first major large-scale community based study of ED in the US was the Massachusetts Male Aging Study (MMAS), which estimated a prevalence of 30 million men for minimal, moderate and complete ED [1] and up to 100 million men worldwide. [2] The Health Professions Follow-up study comprised of more than 31,000 men aged 53-90 years in the United States (US) found that ED ranged from 25% among those younger than 59 years to 61% in those older than 70 years old. [3] The National Health and Nutrition Examination Survey (NHANES) representing both racial and ethnic groups in the US with a sample of 2,126 men from age 20-75 years established an overall ED prevalence rate of 18.4% based on self-reporting of being “sometimes able or never able to keep an erection adequate for sexual intercourse.” In this study an association between age and ED was shown, with prevalence steadily increasing from 6.5% in men 20-39 years to 77.5% in those ≥ 75 years old. Notably, Hispanic men younger than 50 years reported ED at approximately twice the rate of Whites (12.5% vs. 4.9%), after controlling for hypertension, diabetes and obesity which are risk factors for ED. [4]

The Global Study of Sexual Attitudes and Behaviors (GSSAB) was an international survey comprised of 13,618 men in 29 countries that systematically calculated sexual problems among adults aged 40-80 had an overall prevalence of 10%, mainly in Asian countries. [5] Their analysis also showed that ageing effects are quite strong across most regions with respect to erectile difficulties. In all regions, except Central/South America and Southeast Asia, men aged 60-80yrs are significantly more likely to report erectile difficulties than those aged 40-49yrs (OR from 2.7 to 6.9). The Male Attitudes Regarding Sexual Health survey was a nationally representative study of men older than 40 years of age and minority groups. The study estimated the prevalence of moderate or severe ED to be 22% overall. ED prevalence rates were 21.9% among 901 White men, 24.4% for 596 Black men and 19.9% among 676 Hispanic men. [6]

More recently, the National Social Life, Health and Aging Project (NSHAP) with published data from 2005-2006 comprised of 1455 men 57-85 years of age surveyed adults about sexual function and behavior via in-home interviews [7]. Analysis of the data indicated that the most prevalent sexual problem were erectile difficulties (37%), where 90% of these people were bothered by this condition. The likelihood of being sexually active declined steadily with age but yet a substantial number of older men regard sexuality as an important part of life.

Despite variations in definition, methodology and study populations, these studies substantiate the global extent and presence of male SD. The prevalence of ED is not the same in different continents, countries, and ethnic groups. One of the reasons for this difference may be a non-uniform definition of ED. [8-9]

While substantial data exist on the prevalence of ED, there is little knowledge regarding the incidence of drop out from treatment programs or discontinuation of follow-up visits. Approximately 9 to 25% of sildenafil responders discontinued successful treatment because of medication cost. [10] In a recent study conducted by Cooke et al, [11] sildenafil prescriptions were–filled by 51.4% of members in a managed care organization in the first quarter of 2001 but significantly decreased to 13.9% by the fourth quarter. In order to obtain accurate data of ED prevalence, it is important to build homogenous reports with uniform nomenclature regarding definition and severity of ED. The prevalence of ED should always be calculated among groups of the same age range.

The understanding and assessment of premature ejaculation (PE) has increased over the past five years.[12] Although there are varied conceptualizations of PE, the standards committee of the International Society of Sexual Medicine defined lifelong PE as a male sexual dysfunction characterized by ejaculation which always or nearly always occurs prior to or within about one minute of vaginal penetration, and the inability to delay ejaculation on all or nearly all vaginal penetrations, and negative personal consequences, such as distress, bother, frustration and/or the avoidance of sexual intimacy.[13-14] Current data suggest that PE is the most frequent male SD with an estimated prevalence of 20% to 30%.[15] The prevalence of PE varies widely between different countries. The Keele (UK) study reported a prevalence of 18%, with less than 50% of sufferers expressing a desire for treatment. Prevalence in the Middle East and Japan
have rates as high as 45-50%. Past data on the prevalence of PE are varied, once again, in great part owing to the lack of prior standardization of the definition of PE and criteria for patient enrollment in epidemiologic studies.

2. FEMALE SEXUAL DYSFUNCTION (FSD)

Female sexual dysfunction (FSD), a multidimensional medical condition with organic (biological), psychological and social (interpersonal) determinants. FSD has detrimental effects on a woman’s quality of life and also has economical and societal impact. The data derived from the US National Health and Social Life Survey (NHSLS), which evaluated a national probability sample of 1,749 women, is widely cited due its methodological approach. The authors reported that 43% of women are affected by SD. The recent Global Study of Sexual Attitude and Behaviors (GSSAB) international survey of 13,882 women 40-80 years of age found that 39% of women reported a problem with sexual activity. More currently, the NSHAP data of 1550 women 57-85 years old reported that the most prevalent sexual problem was low desire (43%).

The Sexual Function Health Council of the American Foundation for Urologic Disease (AFUD) devised the first consensus-based definition and classification system for FSD. It is disorders of sexual desire, arousal, orgasm and pain that lead to personal distress. Sexual desire disorder include low desire, with a prevalence of 43% of women between 57-85 years of age. Sexual arousal disorders, characterized mainly by vaginal dryness, have been reported in 39% of women. Orgasmic disorder is reported in 34% of women. Sexual pain disorders include dyspareunia and vaginismus, which is reported to have a prevalence of 12.8%.

In conclusion, there is still great potential for advancing our understanding of women’s sexual function. The use of quantitative and validated questionnaires would help to investigate the extent and importance of this emerging problem. Additionally, further research on risk factors, quality of life issues, and development of effective treatment solutions are needed to determine the economic impact of FSD.

II. AGING AND SEXUAL DYSFUNCTION

Aging is a key risk factor for the development of male ED as revealed by the classical work of Kinsey et al, which is the first epidemiological study of male sexual behavior published in 1948. They recruited a total of 15,781 men up to 80 years of age and found a prevalence of erectile dysfunction ranging from <1% for young men to 80% in the uppermost age group. A half of century later, the MMAS reported a similar trend. Specifically, the prevalence of ED increased from 39% in men in their 40’s to 67% for those in their 70’s. The validated questionnaire used in the MMAS was also utilized by a cross-sectional epidemiological study conducted in four different countries (Brazil, Italy, Japan and Malaysia). Collectively, these studies affirm the global extent of ED with an age-dependent increase in prevalence.

A notable aspect of the global aging process is the progressive demographic ageing of the older population itself. For most nations, regardless of their geographic location or developmental stage, the 80 or over age group is growing faster than any younger segment of the older population. The most remarkable increase is expected to occur in Japan, where in 2050; more than 1 in every 3 persons aged 60 or over will be at least 80 years old. In 2050, six countries will have more than 10 million people aged 80 years or over: China 99, India 48, US 30, Japan 17, Brazil 10 and Indonesia 10 million. Together, they will account for 57% of all those 80 or over in the world. The recent UN report showed significant increase in the average life expectancy in the whole world (Fig 1) projecting substantial increase in old men and women with sexual dysfunctions.

Fig. 1 Projections of Populations > 80 y.o.

Since age has been shown to be a significant risk factor for all types of SD, we anticipate an enormous number of patients with ED or SD due to the growing population for those over 80 (Fig. 2).

General practitioners are typically the first point of contact for men experiencing health problems and are a primary source of help for SD. Despite this, many men find it difficult to address this condition in a clinical setting. Recently, Australian prevalence data indicated that while 21% of men aged over 40 years suffer from ED; only 30% discuss their problem with a health professional. Shabsigh and associates reported treatment-seeking behavior in 6 different countries (USA, France, Germany, Italy, Spain and
They found that barriers to addressing ED include patient assumptions that it is a normal part of aging, apprehension discussing sex and fear of a negative response. Therefore, aging itself did not directly increase the cost of ED diagnosis and treatment. We have to estimate the cost by combining the age demographics and the treatment-seeking rate in each country or culture. However, increased acknowledgement and acceptance of SD worldwide, as well as professional cognizance will drive the cost of ED much higher.

III. RISK FACTORS

The United Nations has reported over 374 million men worldwide aged 65 years and older by 2025, an increase of 164 million from the current number. In 2002, the global proportion of men aged over 65 years was 10%; this is set to rise to 20% by 2050. The strong correlation between ED and ageing will inevitable increase the prevalence of ED in the future. Although ED is an age-dependent medical condition, it is also highly associated with co-morbidities such as vascular, hormonal, neural, psychogenic factors and drug adverse effects.

Despite the prevalence and implications of ED on quality of life, current data on ED among the healthy population is scarce, particularly for physiological and psychosocial variables.

1. ERECTILE DYSFUNCTION

Erectile dysfunction is a prevalent condition associated with co-morbid conditions such as diabetes, hypertension, hyperlipidaemia and metabolic syndrome that share an underlying pathophysiology mechanism with endothelial dysfunction. For instance, in a cohort of 1,519 healthy men, those with a total cholesterol >240 mg/dl and LDL of >160 had a 2.7 and 2.6 fold increased risk for moderate to severe ED, respectively. [25] By the same token, in the case of hypertension, analysis of 3,906 men using Sexual Health Inventory in Men (SHIM) questionnaire, (where ED was determined by a SHIM score of < 21) found that about 67% of men with hypertension have some degree of ED. [29] Although ED is a natural consequence of aging, its severity is directly related to vascular risk factors, all of which are associated with endothelial dysfunction.

a) Diabetes

Erectile dysfunction is common in men with diabetes. Prevalence rates range from 20 to 85% in men. Men with diabetes are at a 3-fold risk for ED than those without this health problem. ED affects those with diabetes at an average of 10 to 15 years earlier than the general population regardless of insulin dependency status. [1] In diabetic men, ED may be multifactorial involving possible vascular, neurological and components, any of which as a causal factor significantly impacts the quality of life for these men.

b) Depression

Depression and ED clearly are associated. In the landmark MMAS, men who had untreated depression were almost twice as likely to report ED than men without depression. [1] Of sexual complaints among depressed men, low libido is most prevalent, followed by orgasmic difficulty and finally ED. [26] Co morbid
ED and depression are seen commonly in practice. The association between the two conditions is bidirectional, with each factor reinforcing the other.

c) Cigarette Smoking

The underlying pathophysiology of ED in smoker’s remains poorly understood. However, most investigators still consider smoking as a risk factor for vasculogenic ED. The duration of smoking, the number of cigarettes smoked per day, and the number of years smoking directly correlates with ED and confer not only a higher prevalence but also heightened ED severity [27]. Epidemiological and clinical studies suggest that smoking causes peripheral vascular disease and adversely affects erectile function by impairing endothelium-dependent smooth muscle relaxation. [28] With some studies reporting a dose response pattern [29-30].

d) Alcohol Consumption

Although alcohol is considered to improve erection and sexual drive when utilized in small amounts due to vasodilatory effects and suppression of anxiety, excessive alcohol consumption has long been regarded as a risk factor for ED. In fact, chronic, heavy alcohol consumption may have an irreversible effect on erectile function due to neurological damage. Polsky et al [29] reported a significantly higher OR with >8 drinks/day than 1-7drinks/day (2.09 vs. 1.96) after adjusting age, education levels, presence of diabetes and smoking.

e) Overweight/Obesity

Excess body weight and obesity may increase the risk of ED by 30-90% compared to normal weight subjects. The Health Professionals Follow-up Study reported that men with a BMI higher than 28.7 are likely to carry a 30% higher risk for ED than those with a normal BMI (<25). [3] The 9-year follow-up MMAS reported that body weight was an independent risk factor for ED, with a risk exceeding 90% of controls (OR 1.93 and 1.96).[31] In addition, in a case-control study, compared with age and weight matched control subjects, patients with the metabolic syndrome had higher OR with >8 drinks/day than 1-7drinks/day (2.09 vs. 1.96) after adjusting age, education levels, presence of diabetes and smoking.

2. PEYRONIE’S DISEASE

Peyronie’s disease is a fibrotic disorder of the tunica albuginea of the penis resulting in varying degrees of penile curvature and veno-occlusive dysfunction that leads to sexual dysfunction in some men. Information on the prevalence of Peyronie’s disease is mixed but generally suggests that approximately 5% of men aged 50 years or older will experience this condition. The most convincing population based data was reported by a community, cross-sectional study of 8,000 men from Germany, where 3.2% showed symptoms consistent with the disease. A linear trend was observed for the prevalence of the disorder ranging from 1.5% for men 30-39 years old to 6.5% for men over 70.[33] Similar prevalence was seen among 100 men screened for prostate cancer in Brazil, where 3.7% of men 50 years and older reported symptoms of penile angulation or plaque.[34]

3. PREMATURE EJACULATION

ED and early ejaculation coexist. Poor overall health and/or a simultaneous urological condition increase the risk of premature ejaculation (PE). The NHSLS found that men who self-report “poor to fair health status” have a significantly elevated risk of PE, as well as ED and low sexual desire.[17] Youth as long been postulated as a significant risk factor for PE because some younger men have limited sexual experience. Surprisingly, the NHSLS results showed that younger individuals (18-29 years) do not appear to be at any greater risk for PE than older men, up to 59 years old. PE is likely the only major SD to manifest in healthy young adults and is worth increased efforts for early diagnosis and treatment.

4. FEMALE SEXUAL DYSFUNCTIONS

Female sexual problems do not increase with biological age, unlike in men. The NSHAP data demonstrated a strong relationship of stress, anxiety, depression and poor mental health with women’s endorsement of sexual problems.[9] Additionally, results indicated that certain health conditions strongly affect the likelihood of sexual problems among women. For instance, any life-time history of STDs roughly quadruples women’s odds of reporting sexual pain (OR=3.8) and triples their lubrication problems (OR=3.1). Similarly, lower urinary tract syndrome increases women’s lack of sexual interest (OR=6.5) and lack of sexual pleasure (OR=4.2). Women’s lack of pleasure is also higher among those with poor self-rated physical health (OR=2.7). Relative to white women, Hispanic women reported sexual pain 2.5 times more (OR=2.4) and black women reported 60% lower incidence of lubrication problems. Having some college education lowers women’s performance anxiety by half or more relative to women with less than a high school diploma. Also, women with high school or equivalent education had lower incidence of lack of sexual interest.[35]
IV. IMPACT OF SEXUAL DYSFUNCTION

1. ECONOMICAL

The prevalence of ED is high and is strongly age-related. In 2002, the global proportion of men aged over 65 years was 10%, this is set to rise to 20% by 2025. The projections made in 1998, that a fourfold increase in the ED budget would occur in the next 4 years to 2002, from about $0.9 billion to $5 billion have been proven.[36] The economical impact of any medical condition is not restricted to the cost of diagnosis and management. The impact may include lost time at work, decreased productivity, and the effect on partner, family and co-workers. The impact is further confounded by the correlates of ED, which have high economical implications such as, atherosclerosis, myocardial infarction, diabetes mellitus, hypertension, depression, BPH and prostate cancer.

2. QUALITY OF LIFE

The quality of life for men as it relates to both general and disease specific issues have been evaluated and reported in several studies of prostate cancer and ED.[37-39] In a recent study conducted in France, men with ED that were treated with intracavernous injections (ICI) of prostaglandin E1 (PGE1) reported satisfaction and improved sex life. Assessments were made using validated questionnaire to evaluate overall satisfaction with ICI, impact on quality of life, ease of use, perceived partner satisfaction and quality of erections. The overall satisfaction rate for ICI was 78.3%, 81.1% found the injections easy to use, 86% were ready to recommend ICI to friends, 70.1% had improvements in their sex life, 50% had improved relationships with their partner, 44.8% had improved quality of life and 80.3% had confidence in attempting sexual intercourse.[40] Another recent study of 553 men with ED from the US, Brazil, Mexico, Australia and Japan assessed psychosocial measures after treatment with sildenafil citrate. The IIEF and Self-Esteem and Relationship (SEAR) questionnaires were utilized. The sildenafil group reported significantly greater improvements in self-esteem, confidence, sexual relationship satisfaction and all sexual function domains of the IIEF.[41]

Many studies have used different assessment tools for quality of life issues in men suffering from ED. Various questionnaires are used to ascertain psychosocial factors associated with ED. Despite the methodology or lack of consistent assessment tool, these studies demonstrated significant improvement in quality of life for men with ED.

3. RELATIONSHIP

Erectile dysfunction is a common condition with diverse sequelae affecting men and their partner’s, disrupting their relationship due to a lack of intimacy. The negative impact of ED such as depression, anxiety and low-self esteem seen in these patients can influence their partner’s satisfaction as well. A recent study reported different modalities for organic ED led to couple satisfaction. Approximately 354 couples were classified according to their line of therapy into five treated groups. The Erectile Dysfunction Inventory of Treatment Satisfaction (EDITS) and IIEF were used for assessment. Sildenafil citrate-treated group represented the highest mean value of satisfaction domains of IIEF and penile implants group was second. The testosterone group represented the highest mean value for sexual desire. Domains of quality of life were significantly improved among satisfied cases more than unsatisfied subjects after therapy.[42]

The aggregate findings from all these cross-cultural studies highlight the universal improvement in psychosocial function and well-being in men after successful ED treatment.

4. CO-MORBID CONDITIONS

Co-morbid conditions affect erectile function and quality of life, and treatments of these conditions usually improve these issues. Conditions such as arterial insufficiency may predispose men to ED at an earlier stage, thus, PDE-5is have now been implicated as useful therapy for both ED and cardiovascular disease. Sildenafil has been shown to improve cardiac output and cause vasodilation in men with congestive heart failure and pulmonary hypertension also suffering from ED.[43]

V. TREATMENT SEEKING BEHAVIOR

Patterns of help-seeking behavior among men with ED are important to recognize and identify in order to improve access to treatments, and limit the psychological burden. In a study by Moreira et al [44], behavioral factors related to seeking help for ED were identified from the GSSAB international survey in 29 countries among men aged 40-80 years. They found that 77.8% of men sought no professional help or advice for their sexual problems. Only 18% made an attempt to seek medical help. Men from East Asia were the least likely to seek medical help (6.5%), whereas those from South-east Asia were the most likely (22.5%). The most frequent action taken by men was ‘talk to partner.’ Countries from East Asian and Middle Eastern clusters reported the lowest frequencies, while South-east Asia and Southern Europe had the highest frequencies of this action. The frequency of seeking psychological help
(psychiatrist, psychologist or marriage counselor) was low and varied widely among men (2-12%). However, higher frequencies were reported in countries from the Middle East and South-east Asia. As they got older, men from Southern Europe and Central/South America were more likely to seek medical help. Generally, those more likely to seek medical help were respondents who have been asked by a doctor about possible sexual difficulties in a routine visit in the past 3 years or those who think a doctor should routinely ask patients about their sexual function. The most common reasons for not seeking help by 74% of men was that ED is a normal part of ageing. Some felt comfortable accepting this notion. Another 68% didn’t think this was serious or the problem would go away. Similar studies have reported these same beliefs of acceptance and complacency.[45] A Japanese study specifically addressed patient’s attitudes toward ED treatment through a national mail survey sent to married couples 30-79 years of age. Of the 2,034 males that responded to questions about sexuality, 29.9% felt they had ED. Only a small percentage sought treatment, and 4.8% consulted a physician. Reasons for not doing so were cited as ‘not bothered by ED’ or cultural shyness.[46] In a cross-sectional study in Australia, 409 men were evaluated for ED duration and treatment seeking behavior. Their results demonstrated that men with ED of longer duration were more likely to have discussed their ED with their partner and doctor. Also, these patients sought information and treatment for their ED problem. The reason might be that men with a longer duration of ED are more likely to perceive their ED as severe and permanent, thus, lower frequency of sexual activity would make them more willing to seek help for this problem. [47] There is a high level of abandonment of ED medication therapy (50-60%), only few patients appear to remain on oral therapy for more than a year. [48] The reasons for drop-out rates or patient dissatisfaction with oral ED therapy is unclear. However, Kloetz et al [49] reported that patients discontinued treatment due to a lack of opportunity or desire for sex, or that their partner had shown no sexual interest.

It is clear that there are behavioral factors which become barriers as it relates to seeking medical help for ED and other SD in men. These patterns of behavior result in high drop-out rates for therapy and low utilization of medical service. Therefore, further research is warranted in addressing this issue.

### VI. DIAGNOSTIC EVALUATION

The evaluation of any patient with SD should proceed in a stepwise manner. The latest American Urological Association guidelines on ED state that “the typical initial evaluation of a man complaining of ED is conducted in person and includes sexual, medical and psychosocial histories as well as laboratory tests thorough enough to identify co-morbid conditions that may predispose the patient to ED and that may contra-indicate certain therapies.”[50] One important goal of a diagnostic evaluation is to identify any correctable cause of SD. As it pertains to FSD, little standardization of the diagnostic evaluation exists. However, the diagnostic assessment for male sexual dysfunction is well established. The remainder of this section will deal with the evaluation of ED only. Overall, the economic impact of diagnostic evaluation is poorly understood as the data on this topic is approximated and remains speculative.

The diagnostic flow-chart is comprised of three levels ranging in invasiveness and expense. This includes 1) non-invasive 2) semi-invasive 3) invasive tests. The first level consists of history, physical examination and limited laboratory tests. Routine lab tests include blood glucose, lipid panel, and hormonal assessment. A complete medical history and psychosexual assessment may include validated questionnaires, such as IIEF or Aging Male Symptom (AMS). This is followed by a thorough focused physical examination. The accuracy of this initial evaluation to establish a differential diagnosis between organic and psychogenic ED was determined by Davis-Joseph and associates.[51] They concluded that medical history and physical examination had a sensitivity of 95% but specificity of only 50%, which is quite reasonable considering the simplicity and low cost of this evaluation.

Semi-invasive tests include nocturnal penile tumescence (NPT) and rigidity recording, ICI pharmacotesting, and color duplex Doppler ultrasonography (CDDS). The evaluation of nocturnal erectile activity helps to differentiate organic from psychogenic ED. In general, the Rigiscan it is neither sensitive nor specific enough to diagnose ED because of the high incidence of false-negative and false-positive results. This test costs approximately US $140 as reported in CPT (current procedural terminology) codes and insurance reimbursement policy.

Intracavernosal Injection (ICI) testing is useful in the initial evaluation and treatment of ED. It involves a single intracavernosal injection of either 10 or 20mg of a vasoactive agent (prostaglandin E1) and then an assessment of the response. This evaluation costs approximately US $104 as reported in CPT (current procedural terminology) code and insurance reimbursement policy.

Color duplex Doppler ultrasonography (CDDS) can assess penile blood flow. CDDS has been found to be specific and accurate. This study is often
performed in conjunction with a stimulant, such as an injectable, intracavernosal agent (PGE-1) or genital plus audio-visual to overcome anxiety and sympathetic stimulation brought on by the test itself. The cost for the test and necessary drug/stimulant is approximately US $141 as reported in CPT codes and insurance reimbursement policy.

More invasive studies include dynamic infusion cavernosometry/ cavernosography (DICC) and arteriography. DICC were gold standard in the diagnosis of veno-occlusive dysfunction. However, veno-occlusive dysfunction is often a multifocal problem and a result of degeneration of vascular smooth muscle rather than a site specific venous leakage. This evaluation costs approximately US $163 as reported in CPT codes and insurance reimbursement policy. Penile angiography is reserved exclusively for patients who are candidates for penile revascularization (such as patients that suffered trauma or perineal crushing injury). It has limited role in the evaluation of patients with ED.[52]

VII. RESEARCH AND DEVELOPMENT

Research-based and pharmaceutical companies invested $58.8 billion in research and development in 2007, an increase of nearly $3 billion from 2006. The majority of this money was focused on diseases related to hematology/oncology, central nervous system, infection, cardiovascular and endocrinology. The expenditure for the development of products related to the genitourinary system was minimal. The enormous success of the oral ED therapy will be unlikely to stimulate much further development of new drugs. The investigational strategies of gene therapy is promising for future ED therapy as more advancements occur in molecular biology, as well better understanding of the physiology of erection and pathophysiology of ED. The non-pharmacological therapies, such as vacuum erection device and penile implant must be included in the overall analysis of the ED market. While this data is limited, it appears that the annual dollars allocated to R&D for penile implants has remained at roughly the $7 million level.

VIII. COST OF THERAPIES

1. SALES

Worldwide pharmaceutical sales were estimated at $712 billion in 2007, an increase of $178 billion over the past five years. The worldwide growth rates by year in ED therapies are shown in Fig. 3. In addition, Worldwide sales of all ED therapies and PDE5Is is shown in Fig. 4. The United States accounts for 45.9% of global pharmaceutical sales. The total health-care expenditure in the US is expected to reach $4.2 trillion in 2016[53] and pharmaceutical sales are forecast to grow 5.5% next year, which comprise 10% of national healthcare spending. The total market for drugs to treat ED represents a very minute portion of this total. In the US, the PDE-5i accounts for majority of ED prescriptions. Sildenafil sales in 2007 were $1.7 billion, an increase of 6% worldwide compared to 2006.[54] Levitra sales in 2007 were $421 million, a 5.7% increase from 2006.[55] Cialis total revenues were $1.1 billion in 2007, where worldwide sales grew 25% in 2007, driven by increased demand and higher prices. As of 2007, Cialis seem to be gaining market share worldwide.[56] While Viagra held a stronger lead in the US, with 56.6% total market share and sales of $615 million in 2006 according to IMS Health, sales were down 6%. Cialis held 27% of the US market, with sales up 26% to $294 million, while Levitra claimed 13.3% with sales up 30% to $144 million.[57] These big gains for Cialis might be due to the 36 hour effectiveness from a longer half-life of 17.5 hours, compare to 4 and 5 hours for Viagra and Levitra respectively. Additionally, the number of prescriptions filled weekly increased for both Cialis and Levitra but markedly decreased for Viagra between 2004-2005. Cialis 5 and 2.5mg was introduced for daily dosing in Europe and the US in 2007/8 was patients who anticipated more frequent sexual activity. At this stage it is too early to assess the impact of this new formulation. The growth in sales for Cialis, Viagra, and Levitra can be seen in Fig. 5.

In addition, annual US testosterone therapy sales have been going up (Fig. 6). In 2008, Testim sales reached $141M, and Androgel $547M, with overall testosterone market approaching $811M Fig. 7.

2. COST-EFFECTIVENESS

Cost-effectiveness analysis is a welcome addition to the factors that health insurers should consider when deciding what treatments to cover. When sildenafil was introduced to the US market in 1998, it created much ambivalence from the health insurance companies in terms of coverage because they anticipated the likelihood of explosive costs. Health plans have been concerned about the impact of PDE-5i will have on their pharmacy budgets because of the nature of the disease it treats, namely, that ED is a self-reported condition, hence, potentially a large portion of men could seek PDE-5i therapy. However, insurance plans should be cautious of this rationale, since ED has now been proven to be a marker for more serious co-morbid conditions such as cardiovascular disease, diabetes mellitus or the metabolic syndrome. There are limited data on the
newer ED drugs, hence, more attention will focus on sildenail. The introduction of sildenail and growing awareness of ED has yielded an 84% increase in the number of men seeking and using treatments for ED from 1998 through 2002. Within 2 years of the introduction of sildenail, the number of patients visits for the chief complaint of ED increased in Germany (55%), Spain (90%), UK (103%), US (250%) and Mexico (279%). Wilson et al ascribed the rising cost of managing ED in the UK to a 3-fold increase in the number of men presenting to generalists for ED, which eventually were referred specialists under Schedule 11 restrictions. Primary care physicians continue to be the leading prescribers of PDE-5i, accounting for 65%, followed by non-urological specialists (23%) and urologists (17%).

The anticipated economic burden of sildenail has been proven otherwise in several studies. Smith et al used a Markov decision model based on conservative assumptions so that the cost-effectiveness of sildenail would not be exaggerated. They found that the cost-effectiveness of sildenail treatment compared favorably with accepted interventions for other medical conditions, such as coronary artery bypass grafting, renal dialysis and cholesterol-lowering medications. They concluded that sildenail treatment costs about $9000 per quality-adjusted life-year, which is well below the $50,000 threshold often used as a benchmark in such analyses. Recently, Cooke and colleagues assessed the cost and utilization of sildenail in a large managed care organization (MCO) with a quantity of 6 units per 30-day supply for 20,281 members. They reported that the total allowed charges for sildenail pharmacy claims in 2001 were $3.56 million, of which patients paid 26.6% in average cost-share resulting in a net drug cost of $0.18 per member per month (PMPM). The impact of sildenail on the MCO’s pharmacy budget was only 0.5% and 91.7% of members did not exceed their sildenail quantity limit. Another study demonstrated the cost-effectiveness of ED therapy for 285,436 patients from 51 health plans from 1999 to 2001. They reported that health plans spent an average of $83.91 in 1999, $95.41 in 2000 and $119.26 in 2001 on ED care in a patient. The largest category of ED care expenditures was PDE-5i, estimated at 37% of the total cost that amounted to $27.46 in 1999, $32.92 in 2000 and $44.22 in 2001. For other ED therapy 8.45% was spent on testosterone hormone therapy, 3.85% on penile implants, 4.41% on ICI, 2.68% on alprostadil pellet insertion and 0.81% on VED. Notably, PDE-5i had the lowest annual cost per user ($121), while testosterone therapy had the highest $404. The
authors further dissected the average annual cost of ED therapy to demonstrate the minute amount spent by health plans per member yearly.

They reported that health plans spent an average of $0.91 in 1999, $1.03 in 2000 and $1.29 in 2001 per member annually for ED related services and treatments. Of the $1.29 spent in 2001 per member yearly, $0.48 were spent on PDE-5i. When the investigators converted these costs from per member yearly into per member monthly, the average costs were $0.025 in 1999, $0.03 in 2000 and $0.04 in 2001 for PDE-5i.[63] Additionally, 3 studies in abstract form, found lower than expected pharmacy benefit costs associated with adding sildenafil coverage in a managed care drug benefit plan. Lehman et al.[64] discovered that the drug costs PMPM of adding sildenafil coverage to 4 health plans with 15 million members ranged from $0.04 to $0.21. Similarly, Cherayil and colleagues found that sildenafil coverage in a MCO without restriction of quantity was $0.03 to $0.24.[65] When MCOs did impose restrictions on sildenafil quantity per prescription but without prior authorization, drug costs were also lower than expected, at $0.07 to $0.08 PMPM.[66] The aggregate findings of all these findings showed very similar values for ED therapy and supports the notion that coverage of sildenafil is cost-effective. Perhaps, insurance companies who limit or deny coverage for sildenafil may not have based their decisions on empirical cost or cost-effectiveness calculations by several studies. [63-66]

X. ECONOMIC IMPACT

1. THE DESCRIPTIVE ECONOMICS OF ED

The introduction of sildenafil to US commercial markets in 1998 affected the nation immensely. Sildenafil was seen as a palatable oral treatment for ED, where prior therapy was more labor intense but were covered by most insurers. The simplicity of sildenafil and direct to consumer advertising attracted many individuals with ED that were suffering silently. The prevalence of ED in 30 million US men from MMAS and an estimated incidence of 20% increase by 2010 with 921,000 cases predicted annually befuddled the health insurance industry. The combined cost of sildenafil ($10 per pill then) and prevalence data from MMAS initiated immediate reaction from health care providers to reject coverage, demand higher copayments or limit monthly quantity. Similarly in the UK, the prevalence of ED is high and the total expenditure of ED in the National Health System (NHS) further dampened any motivation of sildenafil coverage by insurance agencies. A study conducted in the UK reported that from 1997 to 1998,
the cost of ED in the NHS for 113,600 men was estimated at £53 million.[67] Drugs only accounted for 25% of the total cost and 4% as indirect costs to society due to lost productivity. In essence, the authors concluded that ED imposes a relatively small dent in the economy of UK society. In spite of this, NHS enforced restrictions for ED under Schedule 11 in an attempt to curb expenditure, which ironically increased NHS cost and utilization of all resources including sildenafil. This occurred mainly from a 3-fold increase in the number of men presenting to GPs, who are the referred to specialists under the Schedule 11 restrictions.[60]

Besides the growing prevalence of ED worldwide and reported expenditure in the NHS of UK society that might be seen as costly by most insurers, other factors account for the resistance to reimburse ED therapy. Part of the motivation for denying sildenafil coverage is its classification of a “lifestyle drug”, which is the perception that it doesn’t cure or even treat an illness or disease, and that the function it temporarily restores are not life-threatening or critical enough. As a result of this, most patients are paying full private cost for their treatment which may force them to “prioritize” their medications, especially for critical ones such as lipid-lowering or anti-
hypertensive drugs. However, this rational may have potential ramifications of neglecting serious medical conditions when they present for ED. Available data has now proven the strong association of ED with co-morbidities such as diabetes mellitus, cardiovascular disease, hyperlipidaemia, depression, hypertension and the metabolic syndrome.[26, 31-32] These factors have yet to be established in the cost-effectiveness of ED therapy in the future.

2. UTILIZATION OF HEALTH CARE SERVICES IN ED

Various health care systems have responded differently to the increased demand for oral ED therapy. Most countries, with the exception of the UK and initially, Sweden banned state sponsored prescribing of oral ED therapy. Some, including Holland allowed more expensive injection therapy to be available on the assumptions that the inconvenience would decrease the frequency. The UK NHS treats all drugs equally and therapy has been restricted to patients with certain defined conditions, including severe distress. In Japan, sildenafil was approved for use in 1999 but the government would not reimburse under the NHS. The rationale is that sildenafil improves quality of life but does not cure an underlying condition. In the US, 40% of sildenafil prescriptions are covered by third-party payers and 2% are covered by Medicaid. In a study conducted by Titlow et al [68] they concluded that instead of costs, value judgments seemed to play a central role in drug coverage decisions, which is largely unspoken. The authors discovered that among 53 MCO surveyed, the most common method of controlling sildenafil cost was by limiting the quantity or the duration of its use. Approximately, 64% of MCOs placed limits on sildenafil coverage, 23% did not cover treatment for ED at all, 21% required prior authorization and only 2% covered sildenafil without any restrictions. The Veterans Health Administration (VHA) system manages 5.2 million male patients aged 18 years and older. Nearly 10.5% were dispensed PDE-5i between 2004-2005, a period that coincides with the introduction of vardenafil and tadalafil. In spite of these new oral therapy, sildenafil still comprised 99.53% of all PDE-5i pharmacy claims, followed by vardenafil at 0.46% and tadalafil at 0.01%. However, the aggregation of these data might have influenced the VHA system to replace sildenafil coverage with vardenafil since January 2006. [69] The reason for this is unclear but perhaps it just may be another method employed by a health care system to control pharmacy costs.

Limited access to ED therapy has led to a high price black market, indicating that consumers were willing to pay more than the market price in many countries. These prices range from $20 to $30 per pill in Malaysia, Hong Kong and Thailand but even more in China $50. [70] In the UK, internet sales are illegal for prescription only medication and concerns were raised that the requirement to pay for oral medication may lead to patients with serious co-morbidities, such as ischemic heart disease seeking internet therapy over a comprehensive assessment from their physician. This may have important health economic implications caused by failure to diagnose a critical disease.

3. SD MANAGEMENT COSTS WORLDWIDE

The release of sildenafil to the US commercial market in 1998 has increased the ED market in the US from $100 million in 1995 to $3.1 billion in 2006. In 2003, the market for non-oral (transurethral and injectable) therapy for ED was $85 million worldwide and $32 million in the US. In 2006, sildenafil remained the market leader for ED therapy, with $1.6 billion in sales and represents 58% of all prescriptions and also, representing 3.4% of Pfizer’s total revenue of $48 billion. Cialis is the most recently released ED drug, becoming available in 2003. It differentiates itself by having a significantly longer half-life of 17.5 hours versus 4-5 hours for sildenafil and vardenafil. Eli Lilly had sales of $971 million in 2006, representing 6.2% of their total revenue $16 billion. Levitra in 2006 had the smallest market share of the three drugs, with $464 million in sales, representing 1.1% of Bayer’s total revenue of $43 billion (Fig. 5). Treatments used for ED suggest shifting forms of health care. The use of diagnostic tests markedly decreased, suggesting that the diagnosis of ED is being established by history and physical examination. While the pharmacological therapy with oral PDE-5i has increased tremendously, the market sales of other options (MUSE, alprostadil and prosthesis) has decreased. Although 30 million men are affected with ED in the US, only 22,000 men received penile implants in the US and Europe 2007, which clearly shows a greater preference for the oral agents.[71] Although the utilization of sildenafil continues to grow, the rate of growth has slowed down possibly due to competition from Cialis, deceleration of growth of the ED pharmaceutical market and saturation of a single medication market. Interestingly, known facts about ED as a symptom of hypogonadism and the metabolic syndrome has influenced the sale of testosterone replacement therapy (Androgel). Androgel sales in 2007 were £308 million worldwide, an increase of 25% since 2004.[72] The efficacy and safety of transcutaneous delivery systems accounted for this growth. Although the approved indication is for hypogonadism, the growing prevalence of ED could further impact greater market sales for this treatment. Additionally, the burden of testosterone deficiency that can cause a wide range of symptoms leading to significant morbidity highlights the benefits and cost-effectiveness of testosterone treatment, further driving market sales. The exact cost of FSD is unknown currently because the treatment is complicated by the lack of a single
causative factor, limited proven treatment options, overlap of different types of disorder and limited availability of treatment and limited expertise in the treatment of FSD.[73] The PDE-5i have not been shown to improve diminished desire. Testosterone hormone therapy, topical and systemic estrogen in postmenopausal women and progesterin therapy are the main pharmacological treatment of FSD.

4. FUTURE PREDICTIONS FOR THE SEXUAL DYSFUNCTION MARKET

The burden of diseases associated with ED worldwide will increase with the aging of the male population, increasing prevalence of co-morbid conditions, expanded treatment seeking behavior, costs of pharmaceutical therapy and direct consumer advertising will undoubtedly impact the commercial market for ED. Extrapolating from the prevalence of ED and current utilization trends implies that the cost of treatment worldwide could be tremendous.

There is clear evidence in the literature that demonstrated FSD to be a significant health problem for patients and their partners, yet women may not come forward to discuss it. FSD remains a controversial, complex and under-researched clinical issue. Progress in this field is slow, such that testosterone remains the only treatment specifically approved for the treatment indication of FSD, and this approval is limited to European countries and oophorectomised women. However, there is widespread off-label use by women of testosterone products approved for men and extensive prescriptions of compounded testosterone products for women in clinical practice. In order to accurately assess costs implications for FSD further efforts should include standardized diagnostic and treatment algorithms (pharmacological and non-pharmacological) suitable for clinical practice in addressing the varied symptoms of FSD.

5. PREMATURE EJACULATION

Premature Ejaculation (PE) is believed to be the most common male sexual dysfunction [74] affecting 5-40% of all sexually active men [75]. PE can lead to devastating consequences to the man and his partner, including increased anxiety, lowered self-esteem, impaired quality of life, relationship difficulties, decreased libido, erectile dysfunction (ED), among others. But, despite this and similar to other sexual disorders, very few men with PE look for help from a healthcare professional [74,76]. The lack of a widely accepted definition of PE can also contribute to the under diagnosis of this condition. A recent multinational and large survey, internet-based – PEPA survey – [74] showed that only 9% of men with self-reported symptoms of PE had spoken about this to their doctor and only 4% had talked to a sex therapist or to a psychologist about their condition. Why don’t men seek help for their problem? Possible explanations include:

- No perception of the problem (especially if the partner doesn’t complain)
- Embarrassment to talk about sexuality
- Not knowing which health professionals to consult regarding their PE
- Physicians not prepared or reluctant to talk about sexual disorders
- The lack of an approved medication to specifically treat PE. Pharmacological treatments currently available for PE include:
  - Topical anaesthetics
  - Tricyclic antidepressants
  - Selective serotonin reuptake inhibitors (SSRIs)

Although 60% of men in the PEPA survey were aware of the existence of medications to treat PE, only 13% reported having used them.

The social and personal impact of PE is well established in the literature but very little is known about the economic impact of this condition. Since there is no medications approved to treat PE (other than Dapoxetine in Europe) and the most commonly used drugs are the tricyclic antidepressants and the SSRIs – which are also prescribed for other conditions – it’s impossible to detect whether a prescription was issued for the treatment of PE with these medications. This means we cannot identify the real treatment cost of PE treatment with these compounds and indirect measures can only estimate the true cost. A recently published study [77] had the aim to better understand the health profile and the needs of men who seek help for PE in the US. In this retrospective study, men with PE were compared to non PE men control group, whereby those in PE group were found to consume more medical resources, primarily because of a higher number of physician visits (3.03 for non PE vs. 5.23 for PE group) and greater use of prescription medications. After diagnosis the mean total cost of diagnosis and medication (whether PE or non PE related) decreased by 24% from US$ 1,320 in the year before to US$ 998 in the year after diagnosis. Total diagnosis cost in the year before PE diagnosis was US$ 1,036 per patient and fell 36%, to US$ 630 per patient in the year after diagnosis. It is not known which components of the cost decreased but the total prescription costs in the year rose 37% from the year prior to a PE diagnosis (US$ 283 per patient) to the year after diagnosis (US$ 368 per patient). However, this increased cost associated with the treatment of PE is offset by a large reduction in the per-patient diagnosis costs – the total per-patient costs of diagnosis and treatment decreased by 24% after PE diagnosis (from US$ 1.320 to US$ 998). Among men with PE, the percentage with a prescription for any SSRI more than doubled after their diagnosis, from 21% prior to diagnosis to 54%
after diagnosis. This increase does not correlate with an increase in a co-morbid diagnosis of depression. Prescription for sildenafil rose from 8 to 11% prior and after diagnosis of PE. This increase either does not seem to be correlated to an increase in the diagnosis of ED. Some men may have received both classes of drugs. Total cost for both diagnosis and prescription per patient-year were much greater for men with PE than for controls (PE, US$ 1,320 vs, control US$ 447). Based on regression analysis to account for contributing costs of the top co-morbidities, men with PE had an overall higher total prescription cost per patient per year when compared with the control population (US$ 422 vs, US$ 148, p<0.0001). Men diagnosed with PE were also more likely to be diagnosed with “disorders of the penis”, “hyperplasia of the prostate” and “urinary system symptoms”. Men with PE who have these other conditions appear more likely to seek medical treatment, which presumably provides them with more directed treatment, reducing the number of future visits, and thus, the healthcare costs. Furthermore, the diagnosis of PE is associated with a decrease in treatment costs; therefore encouraging patients to seek a diagnosis if they believe they have PE and asking patients about their sexual health at routine office visits are ways physicians may help to reduce healthcare costs of men with PE.

6. PEYRONIE’S DISEASE

Nelson estimated the US patients of Peyronie’s disease as 4.5 million and depression patients from Peyronie’s disease as 2.16m. [78] From this number they estimated Peyronie’s disease induced depression cost yearly in US 250 million workdays missed, 66 billion of replacement costs for absenteeism, and 2,5 billion in incremental medical costs. If it is applicable to the whole world the cost will be enormous.

Economic impact on relationship and divorce

The direct cost of treating Peyronie’s disease is not reported to have a major economic impact on relationship with partners. The cost of managing Peyronie’s disease-induced depression might have a larger impact on relationship with partner as mentioned above.

7. PRIAPISM

a) Epidemiology

True incidence of priapism is unknown. The first epidemiological study was done in Finland.[79] They reviewed hospital discharge diagnoses from 1975 to 1990. They calculated the incidence rate from 0.34 to 0.52/100,000 person-years in these 10 years if ICI-induced priapism was excluded. A Dutch study followed this. [80] They investigated 145,071 men cohort by using general practitioner research database. They found the incidence rate of 0.9/100,000 person-years annually. If the ICI-induced priapism is included, the rate will be doubled. PGE1 injection is known to induce priapism in 15% and papaverine injection is in 17%. [81] Priapism in sickle cell disease patients has unique clinical manifestations. The life-long prevalence of priapism in SCD patients is believed to be from 29 to 42%. [81] In summary, the incidence rate of spontaneous priapism will be 0.34 to 0.9/100,000 person-years. If ICI-induced priapism is included, this number will be doubled. Moreover in the society where many SCD patients exist this number will increase proportionally.

b) Relationship with ageing

The effect of aging on priapism is not clear.

c) Relationship with other medical risk factors

Genitourinary and hematologic malignancies are known to cause priapism. [81] Many atypical antipsychotic medications are known to cause priapism. [82] Cocaine use is also known to cause priapism. [81]

d) Impact on QoL

British group in SCD and thalassaemia center made a qualitative study by interviewing six SCD-related priapism patients. [83] They found a profound psychological impact on each patient. The patients feel despair, embarrassment and isolation. They could not sleep well since the priapism usually occurs in the night time. This deprivation of sleep cause bad effect on general quality of life. [83] These results might be applicable to patients of other causes.

e) Treatment seeking behavior and patient preference

The aforementioned British study also revealed that the patients don’t seek prompt treatment because of embarrassment or lack of knowledge. [83] The patients do not have enough time to show preference of therapy since they usually receive medical help in ER.

f) Diagnosis

The complete history taking and physical examination of the penis are the key diagnostic tool. Therefore the cost is minimal. To differentiate ischemic type from non-ischemic type the blood gases analysis of corpus cavernosum will be done.[81] This procedure is not so expensive.

g) Research and Development

UCSF group found in hypoxic rat corpus cavernosum the PDE5 expression was significantly reduced.[84]
They postulated that SCD patients may have low PDE5 expression, predisposing them to recurrent priapism. [84] In accordance with this basic data, Burnett gave PDE5 inhibitors to the SCD-induced recurrent priapism patients. [85] Six out of seven patients showed efficacy. Since PDE5i may be effective to priapism, [85] pharmaceutical companies who have PDE5i might invest money to this field.

**h) Cost of therapies**

The sooner a patient seeks medical help, the less invasive treatment, aspiration and phenylephrine injection will be applied. This maneuver is not expensive. If not, the more invasive treatment, shunt surgery will be necessary. The cost of this surgery is expensive. Moreover, if ED is induced, the cost of severe ED treatment will be added to the initial costs.

**i) Similarities and differences between priapism and other condition**

Urinary retention is a urological emergency and cause pain and anxiety in patients. The prevalence of acute urinary retention is 2.2 to 6.8 episodes /1000 person-years,[86] one-hundred times more frequent than priapism episodes. Retention is embarrassing but the patients seek treatment promptly. The cost is very minor since catheterization can resolve the problem quickly. It is desirable to educate primary care physicians to treat priapism easily just like to treat urinary retention.

**j) Economic impact of PD on society, patients, health care providers, insurance**

The sooner the less expensive treatment is available and effective. The education to health care professionals and high-risk groups like SCD patients or patients on ICI program or patients on antychicotic drugs is manadatory. This investment to medical education will cut the cost of the aforementioned treatment.

**k) Economic impact on relationship and divorce**

Complete ED induced by long-time priapism episode might cost expensive ED treatment and big economic burden might cause a big impact on relationship.

**8. FEMALE SEXUAL DYSFUCTION**

**a) Introduction**

Epidemiological studies have shown that FSD is highly prevalent.[87-89] Indeed, the international consensus group estimated that it affects more than 20% of women.[90] HSDD is the most prevalent type of FSD and occurs in both pre- and postmenopausal women.[87-89, 91,92] The European cohort of the Women's International Study of Health and Sexuality (WISHeS) – a cross-sectional study carried out in France, Germany, Italy and the United Kingdom among 2,467 women – found the prevalence of HSDD to range from 7% for pre-menopausal women to 16% for surgically menopausal women in the 20 – 49 years age group.[93] The prevalence among women aged 50-70 years was 9% for naturally postmenopausal women.[92]

It is difficult to estimate the current costs of managing female sexual dysfunction (FSD), although it is acknowledged to have an economical and societal impact. [94] The reason stems from the fact that although 30% of women reported discussing sexual problems with their general practitioner, only 3% had an entry relating to sexual difficulties recorded in their medical records [95]The number of diagnosed cases of female sexual dysfunction therefore remains relatively small and many women remain untreated. The cost of treating FSD is therefore likely to be relatively low when set against its health burden.

It is also important to note that because female sexual dysfunction is often experienced alongside other health problems (e.g. menopausal transition, depression, cancer, diabetes) or secondary to medications (e.g. SSRIs, oral contraceptives) it can be difficult to isolate the costs of treating FSD from the costs of the contributory factors.

**b) Use of healthcare services**

Primary care physicians are often the first port of call for women suffering from sexual problems, especially in healthcare systems where they have a role as a gatekeeper to specialist / secondary care services. Humphrey et al [95] found that general practitioners in the UK see on average 2.6 patients with sexual dysfunction each month, 62% of consultations being related to erectile dysfunction in men. If it is assumed that the remainder of the consultations (38%) are for women, then this would equate to approximately one consultation per month. Assuming a similar consultation rate among the UK’s 42,876 general practitioners [96] (RCGP 2006), would result in approximately 500,000 GP consultations for FSD annually, at a cost of £13.5m to the National Health Service based on a cost of £27 per consultation. [97]

Moreover, physician attitudes and practices regarding HSDD in the primary care setting further adds to the problem. Laumann et al found that 90% of respondents had little confidence in making a diagnosis of HSDD and that 90% had not screened a patient for HSDD.[88] These results are consistent with an earlier international survey of people aged
40–80 years, which found that only 8–10% of subjects had been asked about their sexual health during a routine visit to their doctor.[89]

c) Management Options in FSD

The mainstay of treatment for FSD is psychosexual therapy or counselling. Access to and availability of these services is variable and may be provided within a variety of settings including mental health services and genitourinary medicine (GUM) clinics. Treatment is often funded privately by sufferers limiting access to care to those who can afford it. Services may also be provided by voluntary sector organisations, such as RELATE in the United Kingdom. The fragmented nature of service provision makes it very difficult to estimate the total number of women receiving psychosexual treatment based on currently available data and may explain the low number of consultations recorded in the Hospital Episode Statistics.

Recent study [103] estimated that 152 patients with female sexual dysfunction were seen annually in a single clinic by a multi-disciplinary team of physicians, psychologists and sex therapists. This study estimated an average cost per woman of £472 over a three-month period. This would equate to an annual management cost of £1,888 per woman and a total cost of £286,976 for the estimated 152 women treated (clinic practitioner costs only, not including any medications or referrals to other services). If it is assumed that the 25% of GUM clinics which hold sexual dysfunction clinics [103] see a similar number of patients annually to that reported in Goldmeier et al 2004, and that these patients were to receive similar levels of treatment, this would equate to an annual cost of just under £20 million for FSD services provided by GUM clinics alone [103].

These studies demonstrate that relationship and behavioural interventions are not inexpensive and that relapse rates can be significant. Pelvic pain disorders such as vaginismus and dyspareunia along with sexual aversion disorders are likely to require management along behavioural principles. Guidelines in FSD are likely to suggest that sex therapy and relationship interventions will be important to compliment pharmacological therapies with corresponding increase in the overall cost of care.

d) Pharmacological Treatments

Few pharmacological treatments are currently approved for the treatment of female sexual dysfunction. Hormone replacement therapy (HRT) may be used to treat symptoms of the menopause, including sexual symptoms, although its use has steadily declined since 2002 due to publication of data suggesting that HRT may increase the risk of cardiovascular disease and several types of cancer. The cost of HRT prescribing attributable to FSD is difficult to estimate because sexual dysfunction may be one of several manifestations of the menopause and a formal diagnosis of FSD is unlikely to be recorded by doctors treating a number of menopausal symptoms. Recent trends in the prescribing costs of HRT can be seen in Figure 8.

Since 2007 the testosterone patch, Intrinsa, has been approved in the European Union (but not USA) for the treatment of hypoactive sexual desire disorder in bilaterally oopherectomised and hysterectomised individuals.

Figure 8: HRT prescribing costs
women receiving oestrogen therapy [106]. Approval was based primarily on the results of two six-month, double-blind, placebo-controlled trials: the Investigation of Natural Testosterone In Menopausal women Also Taking Estrogen in Surgically Menopausal women (INTIMATE SM) 1 and 2 trials. [112] The primary endpoint in both trials was total satisfying sexual activity, which increased by 74% (INTIMATE SM 1) and 51% (INTIMATE SM 2) following treatment with Intrinsa® for six months, compared with placebo. [112] In real terms, this equated to 1 additional satisfactory sexual experience per month and this was considered by prescribing authorities insufficient to endorse the prescribing of INTRINSA by physicians, although in some patients the benefit was marked. In both trials, there were also significant improvements in distress related to sexual dysfunction in testosterone- vs. placebo-treated patients. [112]

From start of trial to January 2009, 3,900 women in the UK received at least one prescription for Intrinsa, with an average of 106 days on therapy. This equates to an annual prescription cost of approximately £438,000 [109].

Approximately 4,000 women in the UK received a prescription for other androgens in the year to January 2009 [109], however it is unknown whether these were prescribed for female sexual dysfunction or in connection with other diagnoses. Despite the poor evidence base for the use of the phosphodiesterase inhibitors (PDE5Is) in female sexual dysfunction, there is evidence of some limited use in women. There has been considerable interest in the use of PDE5Is (particularly sildenafil) to treat FSD in antidepressant associated sexual dysfunction. Women consult physicians three times as often as men and are twice as likely to be prescribed antidepressants. Rates of FSD with these medications are reported at 30-70% in the first months of treatment [111] lead to increasing relapse, recurrence, disability and resource utilisation by affected patients. Non adherence to antidepressant therapy in women approaches 70% with sexual side-effects are a major (probably understated) cause of discontinuation. Decreased sexual interest, lack of genital sensitivity and vaginal lubrication: delayed or absent orgasm: dyspareunia; reduced satisfaction and loss of pleasure in sexual relations are all common symptoms. Nurnberg et al[108]investigated 98 pre-menopausal women (mean age 37.1) with previously normal sexual function prior to antidepressant therapy and treated them with 50 or 100mg sildenafil or placebo on demand prior to sexual activity. The investigators found significant improvement in female sexual function (both arousal and desire) scores for sildenafil over placebo and no withdrawals due to adverse events.

Despite this evidence, there appears to be no plan for the manufacturers to seek licence for the use of PDE5Is in women.

1,112 women received a total of 3,420 prescriptions for sildenafil, tadalafil or vardenafil in the year to January 2009. Most of these prescriptions (3,160) were for sildenafil, with 180 and 40 for tadalafil and vardenafil respectively (CSD patient data 2009). Conservatively assuming that each dose was for a single pack containing four tablets of the standard dose, the total cost of NHS prescriptions for phosphodiesterase inhibitors in women would be approximately £73,000 per annum (MIMS 2009).

It is important to note that the above estimates take into account the costs of NHS general practice prescriptions only. In 2008 approximately 3.5% of Intrinsa sales in the UK were in the private market (IMS Exponent data 2008). This proportion may be higher for the phosphodiesterase inhibitors given current NHS prescribing restrictions for men. The above data also takes no account of prescriptions made within the secondary care setting.

For the treatment of Female arousal and orgasmic disorder the FDA licensed EROS, a battery operated clitoral suction device available for $200-250 on physician prescription. EROS has not yet achieved approval in the UK but is available for private purchase at £200. In 2005, an estimated 5M vibrators were purchased in the UK with prices ranging from £2 to £120 [113].

\[e)\] Funding Implications for Pharmacological Preparations

With the exception of the UK, drugs for erectile dysfunction in men have been funded privately. The UK department of health has allowed therapy for men with diabetes, prostate cancer, multiple sclerosis, pelvic surgery and a few rare conditions but also those suffering severe distress. It is difficult to see how such a model could be applied to licensed medication for FSD, as personal distress or relationship difficulty form a pre-requisite for diagnosis. Much negotiation will be required to balance possible gender inequalities with the economic cost of funding new medications for women, which will require regular rather than on-demand dosing. INTRINSA was granted a full licence for a small group of surgically post-menopausal women in the UK and this was always unlikely to result in high health care costs particularly with almost immediate questions on efficacy and long term safety.

\[f)\] Conclusion

It is difficult to paint an accurate picture of the economic costs of female sexual dysfunction for a number of reasons. FSD diagnoses are poorly recorded in NHS datasets. This may be due to clinicians' lack of
familiarity or comfort with FSD as a genuine diagnosis and also to the complex relationships between FSD and common co-morbidities and concomitant medications. In addition, women with FSD are seen by a variety of healthcare professionals, across a variety of settings within both the NHS and private sector. There are no widely followed authoritative UK or European guidelines for the treatment of FSD and women follow a variety of treatment pathways. There is currently no clear referral and commissioned pathways for FSD within the UK. It is clear from the emerging literature that management of FSD could have a significant impact on NHS resources, with the highest costs being associated with general practice consultations and psychosexual consultations within sexual dysfunction clinics. The cost of psychosexual therapy is considerable and relapse rates are high and this needs to be considered rather than a pre-occupation with the more easily measured cost of drugs. At present, spending on pharmacological treatments is relatively low and uptake of new treatments such as the testosterone patch has been relatively limited. New treatments for women will require delicate discussions on what can be funded by health providers particularly in the light of past experiences with drugs for sexual dysfunction in men.

XII. POLICIES REGARDING SEXUAL DYSFUNCTIONS

1. HEALTH INSURANCE

Health coverage in the US is far from universal. Approximately 40% of third party payers cover oral ED therapy. Although SD encompasses different problems, available information from these insurance companies mainly addressed ED and Peyronie’s disease. The specific details covered by each plan vary, however, there are some general guidelines set forth by most of these insurance agencies. For example, Blue Cross/Blue Shield and Aetna policies consider the diagnosis and treatment of ED medically necessary. Their diagnostic workup includes most imaging and lab tests. They share some differences here, Blue Cross require the patient to be at least 18 years old for ED evaluation but Aetna doesn’t specify an age limit. Aetna will cover most diagnostic test, except NPT because of its low specificity, whereas Blue Cross does but only in a sleep lab. As for treatment, most ED therapies are covered, except oral medications (PDE-5i) or limited quantity. Blue Cross covers 6 tablets per month, as well as Cigna, United Healthcare and Kaiser Permanent but Aetna and many others do not. Regarding Peyronie’s disease, Aetna considers surgical correction medically necessary if the patient had significant morbidity for 12 months or more who failed conservative medical treatment.

2. GOVERNMENT

Medicare is a social insurance program administered by the US government, providing health insurance coverage to people who are aged 65 and older, or who meet other special criteria. Prior to January 2007, many Medicare plans limited ED prescriptions to 4 pills per month and usually required prior approval. However, new change went into effect January 2007 to dissolve all coverage in an effort to save millions of dollars a year. While they did not provide statistics on how much Medicare spent on drugs, their decision was due to the Congressional Budget Office estimate that the Medicare coverage would cost $2 billion over a ten year period. Interestingly, the Department of Veterans Affairs covers 4 pills per month, which leads one to question why the federal government support ED drugs for one group of seniors but not for another. The NHS under the UK government limits 1 tablet per week for ED, provided that men met the criteria under Schedule 11 or suffered severe distress from ED.

3. RESEARCH AGENCIES

The National Institute of Health (NIH) organization for research on ED is the National Institute of Diabetes and Digestive and Kidney Disease (NIDDK). The important points they emphasized about ED are as follow: ED is the repeated inability to get or keep an erection firm enough for sexual intercourse, ED affects 15 to 30 million American men, ED usually has a physical cause, ED is treatable at all ages and treatments can include psychotherapy, drug therapy, VED and surgery.

XII. SUMMARY

Review of the economic aspects of sexual dysfunctions reveals the following observations:

1) The global ageing process will continue to influence the high prevalence of SD.

2) The global trend of increasing obesity and metabolic syndrome is expected to result in increased burden of SD.

3) There continues to be many barriers to treatment seeking and access to care. In the light of the established gender difference in treatment seeking and the known higher treatment seeking in women, the introduction of new therapies for FSD is expected to have a substantial impact.

4) Although SD’s are mainly age-dependent conditions, they are associated with many serious
5) The economic impact of SD’s especially ED is further confounded by medical conditions, such as cardiovascular disease, DM, HTN, hyperlipidemia, BPH, prostate cancer and depression.

6) Majority of patients with SD are managed by PCP, followed by specialists.

7) Although limitations exist for oral ED therapy, PDE-5i sales continues to grow.

8) Oral therapy has expanded the patient base for ED.

9) Several studies have reported the cost-effectiveness of PDE5i that health insurers can use as a model to aide decisions about oral ED coverage.

10) Testosterone replacement therapy for male hypogonadism has grown substantially, despite under diagnosis.

11) Testosterone replacement therapy is currently licensed in European Union for FSD/HSDH in surgical menopause. This narrow indication currently limits the economic impact. But, concern exists about efficacy and long term safety.

12) The economic issues of FSD have remained largely unexplored due to the lack of licensed therapies. However, with the advent of new therapies, such as the transdermal testosterone and Flibanserin, the understanding of the economic impact of FSD is expected to improve in the future.

13) HRT for postmenopausal women continues to decline. Nevertheless, this decline may result in unmet need for treatment of menopause related FSD.

14) Very little data is available on the economics of: premature ejaculation and Peyronie’s disease.

15) Health care systems and government agencies remain cautious about coverage of SD therapy. There appears to be significant knowledge needs in such systems and agencies, especially about the link of SD’s to overall health.

16) R&D for pharmacological treatments of male and female sexual dysfunctions continues to expand globally.

1. Development and Role of Self-Administered Scales or Questionnaires (SAQ's)
Clinical Evaluation and Symptom Scales in Men and Women with Sexual Dysfunction

INTRODUCTION

Sexual problems are prevalent in men and women of different ethnic and social backgrounds, ages and health statuses, as shown in numerous recent epidemiological studies [1-6]. These studies have also identified several correlates, major risk factors and associated comorbidities. However, sexual health problems are often neglected in clinical practice [7,8]. Many patients have difficulty discussing their sexual problems or concerns with a physician due to a sense of frustration, confusion, embarrassment or distress; moreover, patients often feel that physicians are reluctant, disinterested, or unskilled in sexual problem management. Such patients' perceptions frequently guide behavior, as clinicians are often reluctant to ask about sexual issues due to their negative attitudes towards sexual issues and concerns, time constraints, as well as a growing knowledge gap between developments in sexual medicine and the clinical skills of practicing physicians [9,10]. The challenge is to create uniform, widely accepted diagnostic and treatment approach for sexual problems and dysfunctions, based on understanding the common language between clinicians and patients. Such a strategy would improve not only doctor-patient communications and treatment outcomes, but most importantly, it would lead to the development of educational materials and curricula to provide practicing physicians across specialties with the needed skills to meet modern patients’ needs in sexual medicine healthcare delivery [11-13].

In that effort, our committee reviewed current literature and have provided basic guidelines for the broad approach for assessing sexual problems in a medical practice setting. Initially, principles of sexual evaluation are presented and a diagnostic and treatment algorithm for all sexual dysfunctions in both genders. A review of current diagnostic approaches for erectile dysfunction (ED) is presented, which this committee has evaluated in the previous Consultation [14]. Other diagnostic approaches are briefly considered and readers are referred to more detailed description in other chapters. Finally, an overview of scales and questionnaires for sexual problems is presented. Accordingly, the chapter is divided into 3 major sections: A. Overview and basic principles of clinical evaluation B. Overview of diagnostic tests for erectile dysfunction and C. Overview of standardized sexual function scales and questionnaires, as well as broader outcome (HQL, treatment satisfaction) measures in men and women.

A. OVERVIEW AND BASIC PRINCIPLES OF CLINICAL EVALUATION IN SEXUAL MEDICINE

Considering clinical evaluation and use of symptom scales in sexual medicine, we should keep in mind the main aspects of human sexuality, as well as the definitions of health, sexual health and sexual medicine, in order to define the scope of the process. It is also essential to consider patients’ rights and the goals of diagnostic procedures; these definitions, which are specified as follows, permit us not only to provide a broad framework of scientific understanding, but also to establish core principles for the development of a simplified and broadly applicable diagnostic and treatment algorithm.

I. DEFINITIONS

The World Health Organization (WHO) has offered widely accepted definitions of health and sexual health, defining also sexual rights.
1. HEALTH

“Health is a state of complete physical, mental and social well-being and not merely the absence of disease or infirmity”. Of note, this definition has not been amended since 1946 [15].

2. SEXUAL HEALTH

“Sexual health is a state of physical, emotional, mental and social well-being in relation to sexuality; it is not merely the absence of disease, dysfunction or infirmity. Sexual health requires a positive and respectful approach to sexuality and sexual relationships, as well as the possibility of having pleasurable and safe sexual experiences, free of coercion, discrimination and violence” [16].

3. SEXUALITY AND SEXUAL RIGHTS

Sexuality is a central aspect of human experience throughout life and encompasses much more than sexual intercourse: sex, gender identities and roles, sexual orientation, eroticism, pleasure, intimacy and reproduction. Sexuality is influenced by the interaction of multiple factors, including biological, psychological, social, economic, political, cultural, ethical, legal, religious and spiritual, and historical factors. Human sexuality can include multiple dimensions, including thoughts, fantasies, desires, beliefs, attitudes, values, behaviors, practices, roles and relationships. While sexuality can include all of these dimensions, not all of them are always experienced or expressed [16].

According to the WHO declaration, all persons have the right to “seek, receive and impart information related to sexuality, as well as receiving the highest attainable standard of sexual health, including access to sexual and reproductive health care services are fundamental sexual rights. Sexual rights embrace human rights that are already recognized in national laws, international human rights documents and other consensus statements”. The WHO declaration furthermore describes sexual rights as “the right of all persons, free of coercion, discrimination and violence, to: 1) the highest attainable standard of sexual health, including access to sexual and reproductive health care services; 2) seek, receive and impart information related to sexuality; 3) sexuality education; 4) respect for bodily integrity; 5) choose their partner; 6) decide to be sexually active or not; 7) consensual sexual relations; 8) consensual marriage; 9) decide whether or not, and when, to have children; and 10) pursue a satisfying, safe and pleasurable sexual life” [16].

4. SEXUAL MEDICINE

The only available definition of sexual medicine is derived from the European Academy for Sexual Medicine (EASM) [17]: Sexual medicine is the branch of medicine concerned with human sexuality and its disorders. Sexual medicine attempts to improve sexual health through the prevention, diagnosis, treatment, and rehabilitation of conditions or diseases that involve:

- sexual function,
- sexual and/or partnership experience and behavior,
- gender identity, and
- sexual trauma and its consequences.

EASM also emphasized in the definition that “sexual medicine takes into account the individual and couple dimension as well as the knowledge and methods of medical, psychological and social sciences. It recognizes that many of the conditions or disorders may be caused by other medical conditions and/or their treatment” [17].

II. MANAGEMENT PRINCIPLES IN SEXUAL MEDICINE

Three basic principles underlie the management of sexual problems in both men and women; when taken together, these three principles provide a balanced and integrated approach to clinical evaluation and treatment of sexual problems and dysfunctions. These 3 principles are described bellow (Table 1).

**Table 1: Management principles in sexual medicine.**

</tr>
</tbody>
</table>

1. ADOPTION OF A PATIENT-CENTERED FRAMEWORK, WITH EMPHASIS IN CULTURAL COMPETENCE IN MEDICAL PRACTICE (CCM)

**a) Patient-centered care**

Traditionally, the dominant model in medicine has been the “disease-centered” approach, which assumes that disease is accounted for by deviations from the norm of measurable biological variables. The “disease-centered” model focuses on medical consultation and establishment of an essentially patriarchal doctor-patient relationship, in which the patient fulfils a passive role and the doctor embod-
ies medical expertise. It aims to measure outcomes in an objective and quantifiable way, while often neglecting that people come to be made well, made whole, to recover the sense of health, of being well [18-20]. This applies particularly in the case of sexual medicine.

Patient-centered care, is an interactive process (Table 2) [18], an approach that consciously adopts the patient’s perspective and respects his or her ideas, feelings, expectations and values, as the physician tries to enter the patient’s world, to see the illness through the patient’s eyes[19]. Patient-centered medicine assumes a holistic approach that takes into account not only the biological dimension of disease, but also its psychological and social implications, in accordance with the definition of health provided by the World Health Organization [20].

b) Cultural competence in medical practice (CCM)

In keeping with the concept of “patient-centered” medicine, it is important for health providers and physicians to offer culturally and linguistically appropriate services to their patients. When patients do not understand what their healthcare providers are offering or telling them, and when providers either do not speak the patient’s language or are insensitive to cultural differences, the quality of health care can be severely compromised [21]. The field of cultural competence focuses on overcoming language barriers, improving communication between culturally competent physicians and patients, understanding patients’ conceptualization of their condition, improving negotiation of approaches that allow for the best option available within the health and social system, and all within the framework of patients’ own worldview. Table 3 [22] summarizes the essential cultural competencies that apply to sexual medicine and should be incorporated in every sexual medicine encounter with a patient.

Cultural competence in sexual medicine is fundamental, as providing culturally competent sexual health services becomes more complex when care providers and patients possess different genders, racial or ethnic identities, countries of origins, social statuses, and sexual behavior patterns.

c) Patient-centered criteria in sexual medicine

In defining patient-centered care in sexual medicine, the following criteria should be considered:

1. **Sexual dysfunction exists only when satisfaction arising from the integrated components of sexual function, e.g. sexual desire, arousal, and orgasm or climax are reduced or absent.**

A person may have a specific dysfunction, such as erectile dysfunction or anorgasmia, but not consider it as a personal and/or relationship problem.

**Table 2: The interactive process of patient-centered care. Adopted from [18].**

</tr>
<tr>
<td>4. Awareness of one’s own prejudices and tendency to stereotype</td>
</tr>
<tr>
<td>5. Ability to transfer information in a way that the patient can understand and to use external help (e.g. interpreters) when needed</td>
</tr>
<tr>
<td>6. Ability to adapt to new situations flexibly and creatively.</td>
</tr>
</tbody>
</table>

2. **Sexual dysfunctions are essentially self-reported conditions.**

Sexual dysfunctions may have major impact in quality of life and psychosocial and emotional well-being; in some cases there may be no biological findings, although the patient may feel that he/she has a sexual problem, due to interpersonal, psychological or social problems. Therefore, the diagnostic approach has as a primary goal not to prove the existence of the problem, but to unmask the underlying etiology and consequences of the problem, and to consider appropriate management options.

3. **Outcomes assessment should focus not only on reduction of distress or resolution of certain symptoms, but on the overall sexual well-being of the individual.**

2. **APPLICATION OF EVIDENCE-BASED MEDICINE (EBM) IN DIAGNOSTIC AND TREATMENT PLANNING**

a) Why EBM in sexual medicine?

Evidence-based medicine is the integration of best available research evidence with clinical expertise and patient values [23].

Clinical decision-making is guided increasingly by
the results of randomized, clinical trials (RCT’s), prospective patient registries, cohort and case-control studies, meta-analysis and systematic reviews. According to the principles of evidence-based medicine (EBM), clinicians should consider evidence from multiple sources in making a diagnosis and in formulating a treatment plan for each individual. Although not applicable in every case, findings from controlled trials, patient registries and systematic reviews can inform the decision-making process in multiple ways. In selecting among available diagnostic and treatment options, clinicians and patients should both evaluate the potential risks and benefits as determined by the weight of clinical evidence. [24].

Specifically in sexual medicine, where sexual problems are a) not life-threatening, b) involve intimate aspects of people’s life, c) are self-reported conditions, and d) involve treatment options that are multiple and diverse, each patient has the right to be fully informed concerning his or her sexual health status, as well as the evidence-based diagnostic and treatment options that are available, in order to participate actively in the decision-making process. Since it is evident that available treatments and diagnostic approaches for sexual dysfunction are proliferating, the patient should be given every opportunity to choose among available options, and to determine which option fits best to his/her special needs. Patients’ needs vary also in their preference for information and involvement in the decision-making process, and for this reason the approach should be flexible and individualised. This is ultimately why communication is the royal pathway to both evidence-based and patient-centered medicine [25].

b) EBM in diagnostic procedures

Strong consideration should be given to the evidence basis for diagnostic evaluation in each case. The goals of the diagnostic procedures are well defined (Table 4) [26].

Specific tests or procedures should not be recommended without controlled clinical data or research evidence supporting their use. Particularly in the case of costly or invasive procedures, these should not be recommended in the absence of supporting evidence and their applicability to the specific case. Both physicians and patients should be encouraged to consider the available scientific evidence prior to selecting among specific treatments or diagnostic options. Accordingly, this chapter considers the currently available diagnostic approaches for sexual dysfunction in the context of evidence-based literature in support of their use. In conclusion, EBM and patient-centered medicine are viewed as highly complementary and equally applicable in the clinical management of sexual dysfunction.

3. USE OF A UNIFIED MANAGEMENT APPROACH IS RECOMMENDED IN EVALUATING AND TREATING SEXUAL PROBLEMS IN BOTH MEN AND WOMEN.

Gender disparities in sexual medicine have traditionally been a major barrier for women in obtaining adequate clinical services for sexual difficulties or dysfunctions. Gender stereotypes have also hampered understanding and appropriate diagnostic evaluation in women, as terms like “frigidity” have been used indiscriminately in psychoanalysis and other branches of medicine. Fortunately, sexual medicine in recent years has become more aware and sensitive to the need for gender equality and the need for a unified management approach. In the diagnostic algorithm below, we propose a unified, step-wise management approach for both men and women with sexual problems. The proposed algorithm has been based on the algorithm presented by this Committee in the previous Consultation [14].

**III THE ICSM-5 DIAGNOSTIC AND TREATMENT ALGORITHM**

The International Consultation in Sexual Medicine (ICSM) proposes the ICSM-5, as a step-wise diagnostic and treatment algorithm for sexual dysfunctions in men and women (Figure 1). The main goal of ICSM-5 is to unmask the underlying aetiology and/or indicate appropriate treatment options according to men/women’s individual needs (patient-centered medicine), using the best available data from population-based research (evidence-based medicine).

The **first step** includes the **basic evaluation**; medical, sexual and psychosocial history are mandatory for every patient, while focused physical exam and laboratory tests are highly recommended; **step 2** includes the **interpretation of the findings** and identification of needs for specialized tests. In the majority of the patients optional tests are not necessary. In one study (**FIGURE 2**), the impact of the different diagnostic steps on the management strategy for erectile dysfunction has been explored in a sample of 1,276 patients visiting an andrology
outpatient clinic; basic evaluation allowed diagnosis in 79.7% of the patients, therefore specialized diagnostic procedures were necessary in only 1 out of 5 patients [27]. However, physicians may make the final decision either to proceed with specialized tests/referral or to treatment [28]. Step 3 includes patient/partner education, which is of major significance and a necessary prelude for shared decision making. Step 4 includes the development of a mutually-agreed upon treatment plan, equally considering the available treatment options for a certain diagnosis, as well as patients’ needs and preferences. Finally, step 5 refers to the important phase of follow-up, emphasizing that the overall goal of treatment is improvement of patient’s subjective sexual well being and not merely relief of symptoms and/or restoration of sexual function.

**STEP 1: BASIC EVALUATION**

Clinical evaluation for sexual dysfunction has unique
challenges and opportunities that can make the process difficult for some clinicians and underline the need for specific skills, as sexual medicine clinical practice has some unique characteristics (Table 5). Initial assessment of a sexual problem should include sexual, medical, and psychosocial history in every case. Physical examination and laboratory tests are highly recommended if appropriate, but are not always necessary.

1. SEXUAL HISTORY

A detailed sexual history should be obtained for all patients presenting with a sexual problem. In obtaining a history with men or women with sexual problems, special attention should always be paid to personal, social or cultural sensitivities. Patients may or may not be comfortable with direct inquiry into their sexual function and issues related to sexual problems. The interview should ideally be conducted as a face-to-face interaction with a sympathetic examiner [29]. Attention should be paid to the setting of the interview, in particular the need for privacy and confidentiality, and the clinician should make every effort to ensure patient trust, comfort and openness.

Since the type and duration of the problem is not always apparent at the outset, and since individuals frequently present with one type of dysfunction (e.g. lack of erection, early ejaculation), but may have other sexual or interpersonal problems, a detailed sexual history should always be obtained. While briefchecklists or questionnaires may be of value in the recognition and initial evaluation of a sexual problem, these should not substitute for a detailed sexual history. The examiner should always be attentive to both the intra- and inter-personal aspects of sexual dysfunction. Careful attention should be paid to both the style and content of the initial evaluation. Overall, the clinician should strive to maintain an attitude of comfort and flexibility throughout the evaluation process. Emphasis should be given to the education of physicians to deal with sexual issues and their level of knowledge; alternatively clinicians should refer their patients to specialists.

a) Physician-patient communication

The first step in the evaluation of any patient with sexual problems should be to establish an effective physician-patient-partner relationship. Only by encouraging the patient or the affected couple to discuss their sexual experience, will the physician fully ascertain the patient’s sexual concerns, their feelings and expectations about the sexual problem, and especially their concerns about the condition, its impact on patient’s/partner’s quality of life, and their expectations regarding the therapeutic outcome [30]. A second important focus of a patient-centered approach is the attempt to understand the whole person, including the patient’s culture and background, his/her life setting, family and clues about the sexual partner.

Patients typically desire the doctor to take the initiative in clinical interactions, to use simple and direct language, to be nonjudgmental, caring, and respectful, and to provide clear explanations and allow for questions, to acknowledge and explore the patient’s responses, and to promote an optimistic attitude when possible.

b) The physician-patient barriers: education and communication

It is not uncommon for physicians to be embarrassed, ashamed or reluctant to address sexual issues or concerns of their patients, despite the fact that the most important intervention is simply to ask or bring up the topic [29,31-35]. Several barriers to taking sexual history have been reported (Table 6) [11]. Characteristics identified by physicians as causing discomfort include interviewing opposite gender patients, patients aged less than 18 or more than 65 years, patients whose academic achievement is below college level, and patients who are divorced or single [32]. Training physicians in communication skills has been shown to be fundamental for sexual history-taking and the management of sexual problems, as it improves their level of comfort in dealing with sexual issues. Essentials in education include undergraduate curriculum, sexual medicine courses, psychosocial orientation and modification of physicians’ personal sexual attitudes [9,33-37].

</tbody>
</table>
Typical questions that have been recommended to initiate the sexual history or discussion of sexual issues include: ‘Are you happy with your sexual life?’; ‘Do you have any questions or concerns about sexual matters?’ and concluding with the question ‘Is there anything else about your sexual life that I need to know about to ensure you good sexual health care?’ Listening attentively to one’s patients, male or female, and clarifying their concerns or questions are invariably important elements in defining the nature of the problem, its severity and duration, as well as patients’ motivations for treatment [34-36].

c) ALLOW : Forming a healing physician-patient relationship

In order to establish a holistic physician-patient relationship and to obviate the usual communication barriers, the “ALLOW” acronym (Figure 3) is recommended [38]; it is a 5-step communication plan that enables the clinician to manage sexual issues while recognizing the limitations and varied needs and qualifications of clinicians for managing sexual problems.

The first stage in assessment is represented by the letter “A” - “asking” the patient about sexual function and activity. There are many ways to inquire about sexual problems, for example, when the social history is discussed or a review of systems is performed. The main purpose is to give the patient an opportunity to discuss sexual matters in a non-threatening manner; a statement about the confidentiality of the information being discussed is therefore necessary. The second step is represented by the letter “L” - “legitimizing” the patient’s problem and acknowledging that sexual dysfunction is a relevant clinical issue. In contrast, if the patient perceives that his or her sexual problem is being ignored or dismissed, this can delay or discourage the patient from seeking further help. The third step is again represented by the letter “L” - “limitations” the clinician may bring to the evaluation of sexual problems. These can include lack of knowledge or personal discomfort with discussion of sexual matters, even clinician’s personal values. Based on this self-evaluation by the clinician, the next step may be a referral, as the clinician has done it “ALL” for the patient. Step 4 involves “Opening up the discussion”. The discussion should explore the sexual problem and its context; biological, psychosocial and relationship. The final stage, represented by the letter “W” - “Work together to develop a treatment plan”, involves dialogue with the patient to identify an appropriate goal and mutually acceptable management plan. It is essential at this point for the clinician to evaluate patient and partner’s values and discuss risks and benefits of different treatment options.

d) Screening tools for sexual dysfunction

Sexual problem identification should be regarded as a routine and necessary aspect of medical care for both men and women. This principle is applied to all new patient visits, especially for individuals at risk, such as men or women above the age of 50, patients with chronic illnesses or medical conditions, following major surgery or hospitalization, during major life changes (e.g., divorce, childbirth), as well as during return or follow-up visits for these patients. The depth and extent of sexual inquiry should be individualized, based on the clinical setting, patient characteristics, and type of visit. Screening checklists can provide a valuable resource in identifying and assessing sexual problems in men and women. These simple tools have the obvious benefits of providing validated and cost-efficient identification of the problem, as well as preliminary assessment of current and past sexual functioning. To facilitate initial identification of a sexual problem, two brief screening checklists have been developed by the ICSM committee on diagnosis in the previous consultation [14] and more recently by the Standards Committee of the ISSM. It should be emphasized that, although valuable in recognizing and identifying sexual dysfunction, screening tools should not be substituted for a thorough sexual, medical, and psychosocial history. Moreover, further evaluation of these symptoms is always recommended prior to initiating sexual medicine therapy.

1. THE BRIEF SEXUAL SYMPTOM CHECKLIST FOR MEN (BSSC-M) AND WOMEN (BSSC-W) [14]

This brief checklist consists of 4 simple questions and it is suitable for use in primary care settings, as well as for screening and addresses the patient’s
level of satisfaction with sexual function (the major outcome measure in sexual health) [14]. Additionally, it assesses duration, the type/s of sexual problems experienced, as well as the willingness of the person to discuss the problem with a health care provider. Three of the four questions are common for men and women, while the fourth question (type of problem) is specific for gender (APPENDIX 1 and 2). BSSC has been used in the literature [39], however, validation data are lacking.

2) The Sexual Complaints Screener for Men (SCS-M) and Women (SCS-W)

More recently the Sexual Complaints Screener for Men (SCS-M) and Women (SCS-W) have been developed by the Standards Committee of the International Society for Sexual Medicine [pers comm, H. Porst, Hamburg, Germany] (APPENDIX 3 and 4). The SCS consists of a series of questions concerning sexual experiences during the last 6 months. Validation of the SCS is in process.

e) Differentiating Sexual problems S (sexual) CDDD

Misinformation and ignorance about sexual function and dysfunction are commonplace [40]. Many individuals are misinformed or unaware of basic information about sexuality and reproduction, and have sexual concerns or questions, such as penile size, refractory period after ejaculation, and morning erections for men, while frequency of sexual desire and achievement of orgasm for women are frequent areas of misunderstanding. Misinformation or myths may lead to uninformed sexual decisions with serious consequences, e.g. unintended pregnancy, a sexually transmitted disease or other avoidable problems [41]. Other individuals have specific problems, e.g. situational premature ejaculation, different levels of sexual desire between partners, which may also lead to psychogenic sexual dysfunction or the initial phase of a sexual dysfunction, e.g. change in erection hardness due to mild arterial insufficiency. Sexual dysfunctions are highly prevalent, while disorders that cause sexual problems, e.g. Peyronie’s disease and vulvodynia are also common. During the initial phase of assessment, physicians need to discriminate between such sexual concerns, difficulties, dysfunctions and disorders [41]. It is not uncommon that a sexual concern or worry may be the cause of sexual difficulty, which in some cases may lead to a sexual dysfunction. Conversely, anatomic or medical problems e.g. penile deviation or Peyronie’s disease, may be the cause of difficult sexual penetration and diminished sexual satisfaction, which may lead in turn to relationship problems and concerns about masculinity or femininity. Therefore, it should be acknowledged that sexual inquiry is a dynamic process involving different levels and domains of concern, difficulty and dysfunction (Figure 4) [41].

f) Types of sexual dysfunction: defining the underlying aetiology of sexual dysfunction

It is evident that Step 1 of ICSM-4 diagnostic algorithm has a major goal to identify and characterize the underlying aetiology. The presence or absence of biological findings will be a clear determinant of organic component that may include: a) anatomic (including surgery-related), b) vascular, c) neurogenic, d) hormonal, and e) drug-related. There is increasing awareness and interest in the clinical literature regarding the addition of distress/interpersonal difficulty to the diagnostic criteria of sexual dysfunctions. While most authors recognize the necessity for inclusion of personal or interpersonal distress for both men and women, others present evidence that some persons with sexual dysfunction are not distressed by it [42]. A classification of the degree of distress associated with dysfunction can be described as Type II and III sexual dysfunctions as follows:

- not significant mental (cognitive) or emotional (affect) distress: resolution of the main symptom (e.g. restoration of erections) will adequately diminish mental and/or emotional distress.
- significant mental (cognitive) or emotional (affect) distress: resolution of the main symptom (e.g. restoration of erections) will not diminish mental and/or emotional distress. In this case, complementary psychotherapy is indicated.

Therefore, clinically, the Committee proposes categorization of sexual dysfunctions in 3 types (Table7) according to their predominant aetiology.

g) Differentiating Organic and Psychogenic Etiologies

An essential point in clinical formulation of sexual
dysfunction in men and women is that organic and psychogenic factors coexist in many cases, particularly in those individuals or couples with longstanding or chronic sexual dysfunction. Key aspects of the history may be used to identify the potential role of specific organic and psychogenic causes or etiologies. The following table provides an overview of specific aspects of the patient’s history that may be useful in differentiating organic from psychogenic sexual dysfunction (Table 8) [43]. It should be emphasized however that psychogenic and organic etiologies co-exist in a large number of cases.

h) Initiating the discussion

A single question (e.g., “Do you have questions or concerns about your sexual functioning?”) may be sufficient in some circumstances, whereas a series of questions is indicated in others (Table 9) [38]. Sexual inquiry is most often conducted by face-to-face interview with the patient, although paper-and-pencil questionnaires or internet-based methods may be of value. Each of these methods has distinct advantages and limitations. The style or manner in which sexual inquiry is conducted is most important. This should reflect a high level of sensitivity and regard for each individual’s unique ethnic, cultural and personal background. TABLE 10 offers a simple way to ask the critical initial questions in order to achieve a quick review of the case [44].

Sexual history taking should be aimed at ascertaining the severity, onset and duration of the problem, as well as presence of concomitant medical or psychosocial factors. It is necessary to determine whether the presenting complaint, (e.g. erectile dysfunction, anorgasmia) is the primary or major sexual problem, or if some other aspect of the sexual response cycle (desire, ejaculation, orgasm) is involved. Other sexual problems may exist as concomitant disorders (e.g. hypoactive sexual desire), or as secondary to the primary sexual complaint [29,32,33]. The medical and sexual history is the most essential, and frequently the most revealing aspects of the assessment process.

A comprehensive sexual history is essential in confirming the patient’s diagnosis, as well as in the evaluation of the patient’s overall sexual function. Sample topics or questions for inclusion in the sexual history are illustrated in TABLE 11 below. These questions apply specifically to the evaluation of male arousal, desire and orgasm/ejaculation difficulties. In principle, these questions may be addressed to all patients presenting with sexual difficulties.

2. MEDICAL HISTORY

Although not always definitive, a detailed medical history may provide suggestive evidence for or
against the role of specific organic or psychogenic factors and should be obtained in all cases of sexual dysfunction. The goals of medical history-taking are:

(i) to evaluate the potential role of underlying or comorbid medical conditions. Sexual dysfunction may be symptomatic of an underlying medical disorder, such as atherosclerosis or diabetes. It is also a common presenting problem of depression in both men and women.

(ii) to differentiate between potential organic and psychogenic causes in the etiology of a patient’s sexual problem.

(iii) to assess the use of concomitant medications. Some of these medications can either cause or contribute to the patient’s sexual difficulties, and a change in medication may result in improvement in sexual function. Additionally, the use of certain medications may be important contraindications for the use of specific treatments.

Medical history may include all medical conditions that may interfere with sexual function [45-52]. TABLE 12 includes a list such conditions.

3. PSYCHOSOCIAL HISTORY

Potential etiologies for sexual dysfunction include a wide range of organic/medical factors, but also multiple psychological or interpersonal factors (e.g. anxiety, depression, relationship distress) [30, 36, 40-45, 48]. A detailed psychosocial assessment is essential in every case of sexual dysfunction. Given the interpersonal context of sexual problems in men and women, the physician should carefully assess past and present partner relationships. Sexual dysfunction may affect the patient’s self-esteem and coping ability, as well as his or her social relationships and occupational performance. These aspects should be assessed in each case. The physician should not assume that every patient is involved in a monogamous, heterosexual relationship. For this reason, it is advisable to begin the history with a broad question, such as: “Are you sexually active at the moment”, or “Do you have a regular sex partner?” and then to ask a follow-up question, such as “Is this a same-sex or opposite-sex relationship?” The early stages in the development of a problem are often of crucial significance to assessment and treatment. Were there particular times of change in the sexual relationship? If so, what events occurred in the patient’s life at those times? In addition, questions should be asked about other relevant aspects of the patient’s life, including interpersonal relationships, occupational status, financial security, family life and social support.

4. PHYSICAL EXAMINATION

The etiology or causal factors for sexual dysfunction may or may not be apparent from the patient’s history alone. In specific sexual dysfunctions, e.g.
anatomic problems or erectile dysfunction, further investigation by means of a physical examination and selected laboratory testing may be of value in confirming or disconfirming specific etiologies or comorbidities. In most cases, the physical examination will not identify the specific etiology or cause of sexual dysfunction, however a focused physical examination is highly recommended [14, 27]. The physical examination should include a general screening for medical risk factors or comorbidities that are associated with sexual dysfunction, such as body habitus (secondary sexual characteristics), assessment of the cardiovascular, neurological and genital system, with particular focus on the genitilia and secondary sex characteristics (TABLE 13). The physical examination may corroborate aspects of the medical history and can sometimes reveal unsuspected physical findings (e.g. decreased peripheral pulses, vaginal atrophy, atrophic testes, penile plaque). In addition to identifying specific etiologies or comorbidities, the physical examination may provide an opportunity to inform the patient about aspects of their sexual anatomy or physiology, as well as providing reassurance about body appearance and function. However, it should be recognized that the physical examination can also be a source of shame, embarrassment or discomfort for many patients. Every effort should be made to ensure the patient’s privacy, confidentiality and personal comfort while conducting the physical examination.

The physician should always review the major findings of the examination and should address any questions or concerns of the patient regarding their physical appearance or normality. In some settings, it may be advisable for the physician to perform the physical examination in the presence of a nurse or chaperone.

Specific considerations in conducting physical examinations in women with sexual dysfunction.

In some instances, a physical examination may be desirable, although not strictly essential. Possible examples include: a) situational problems; b) generalized dissatisfaction with sexual activity in the absence of specific sexual dysfunction; c) mood disturbances; or d) generalized dysfunction secondary to a change in socioeconomic status or a recent adverse life event. In these instances, a detailed history may provide adequate evidence for the diagnosis and evaluation of the problem. However, even in such cases, the physical examination may uncover occult organic or physical factors, as well as providing opportunity for reassurance and education of the patients. It may also be valuable in assessing the patient’s overall health status in potentially uncovering the presence of important comorbidities, such as cardiovascular disease or diabetes [46, 48-49].

5. LABORATORY TESTING

Recommended laboratory tests for men and women with sexual problems typically include fasting glucose, cholesterol, lipids and hormonal profile (TABLE 14) [14]. As with the physical examination, these tests are performed primarily to identify or confirm specific etiologies (e.g. hypogonadism), or to assess the role of potential medical comorbidities or concomitant illnesses (e.g. diabetes, hyperlipidemia). A detailed discussion of the role of hormonal assessment and treatment of sexual problems in men is reviewed in other Chapters. Additional laboratory tests (e.g., thyroid function) may be performed at the discretion of the physician, based on the medical history and clinician’s judgment.

**STEP 2: REVIEW OF FINDINGS**

Results of the initial evaluation should be reviewed with the patient and patient’s partner whenever possible, prior to initiating therapy. This review should be used as an opportunity to educate patients on the anatomy and physiology of sexual function, and to provide appropriate understanding of the pathophysiology (“what is wrong”). Potentially modifiable risk factors, such as cigarette smoking or alcohol abuse, should be addressed at this stage in the process. The potential role of prescription or nonprescription drugs, including psychotropic agents (e.g., SSRIs), cardiovascular drugs or other iatrogenic causes of sexual dysfunction, should also be addressed. Patients with specific endocrine deficiencies, such as hypogonadism, should be placed on hormone replacement therapy (in the absence of medical contraindications, such as prostate or breast cancer) prior to initiation of direct therapies for sexual dysfunction. A specialist referral is generally indicated in these cases. Additionally, sexual problems in the partner such as a lack of lubrication, hypoactive sexual desire or dyspareunia (painful intercourse) should be addressed whenever possible.

If psychological issues are evident at this time,
referral should be considered to a suitable sex therapist or mental health professional. Patients and partners should be fully informed about the range of treatment options available and the risks and benefits associated with each should be addressed.

1. REFFERALS

Physicians currently manage the majority of cases of male sexual dysfunction. This is largely true for women also, although the number of women seeking help from mental health or gynecologically-trained practitioners varies from one region or country to another. Only in a minority of patients, is referral for specialized consultation or testing absolutely necessary. However, either the patient or physician may wish to obtain further diagnostic evaluation for several reasons [31, 36, 41]. TABLE 15 indicates reasons for referral either for further consultation or for a specialized test.

2. SPECIALIZED TESTS

As shown, further diagnostic evaluation may be conducted at the patient’s request, in cases of lifelong or primary sexual dysfunction, in the presence of specific anatomic or endocrine factors, or in cases of complicated psychiatric or interpersonal problems [14]. Additionally, specialized diagnostic assessment may be indicated following failure of initial therapy. When referring patients for specialized testing or consultation, patients should be fully informed of the reasons for the referral and the possible implications for treatment discussed. In accordance with the principles of patient-centered medicine, patients (and partners where possible) should be included in the decision-making process regarding the need for specialized or additional diagnostic evaluation. Patients should be fully informed of the cost and potential risks of these procedures, as well as potential benefits and evidence-base in support of their use.

a) Specialized tests for women

Specialized diagnostic procedures for women are less advanced and less widely used than in men. In particular, a variety of measures have been used in laboratory studies to measure vaginal blood flow or vasocongestion during sexual stimulation. However, all of these methods suffer from methodological limitations and have not been found to be generally useful in the diagnostic assessment of female sexual dysfunction. All of the existing measures have important shortcomings and disadvantages and none are adequately validated. Moreover, there has been an inability to correlate most physiologic measures with subjective measures of sexual arousal [53, 54]. Given the complex nature of the sexual response in women, specialized diagnostic or physiologic measures should be considered in context of other data, including the history, physical examination, and validated questionnaires. Nonetheless, the existence of appropriate physiologic measures is vital to our understanding of female sexual function and dysfunction. TABLE 16 presents the level of evidence of specialized tests for women; detailed information regarding physiological measures and specialized tests for women are given in other chapters.

b) Specialized tests for men

A broad array of specialized diagnostic tests and procedures are available, particularly for assessing ED [14, 55]. Erectile dysfunction diagnostic tests have been extensively studied in the literature, and despite certain limitations, some of these tests are widely used in the everyday clinical practice, and are supported to varying degrees by published data. These tests may be used to separate organically based from purely psychogenic cases (e.g. nocturnal penile tumescence and rigidity testing), or to tailor specific vascular surgery in patients with arterial disease or veno-occlusive dysfunction. In the
majority of patients, however, the specialized diagnostic evaluation has little impact on the selection of therapeutic options. Diagnostic categorization is particularly indicated for those patients in whom a reversible form of ED is suspected (e.g. hypogonadism, Peyronie’s disease). Diagnostic procedures for ED are extensively discussed in a specific section of the chapter.

Following completion of the diagnostic evaluation, patients (and partners where possible), should be given a detailed description of the findings with specific explanations of the causes and the underlying pathophysiology. Furthermore, physicians should consider carefully the potential role of unrecognized comorbidities – or refer the patient for further diagnostic assessment - and afterwards offer the available treatment options. These should include both medical and non-medical options, whenever indicated.

Although certain options may be preferred by the majority of individuals with some sexual dysfunctions (e.g. PDE5 inhibitors for men with ED), all patients should be informed about the availability of other treatment options, including psychological treatment options. Similarly, patients should be informed about availability of treatment options for other male or female dysfunctions. This is in accordance with an essential principle of patient-centered medicine; viz., shared decision-making [24, 25]. Some patients may prefer “watchful waiting” or further consideration prior to selection of a specific treatment option. Additionally, some patients may wish to consult with their partner or other health-care provider before selecting a specific management approach. In each case, these options should be respected and encouraged, if appropriate. It is important for the clinician not to assume an authoritarian or patriarchal role in the selection (or rejection) of specific treatment options. Instead, the clinician should aim to educate the patient as fully as possible, making full use of evidence-based literature and guidelines wherever possible, regarding the risks and benefits of each treatment. The clinician should also provide a supportive and empathic environment for shared decision-making. Treatment of sexual dysfunction should not be delayed or postponed as most patients desire immediate treatment.

2. DEVELOPING A FOLLOW-UP STRATEGY: “FAST”

Follow-up is the final essential element in ensuring adequate management of common sexual problems. Sexual dysfunction should be managed in a similar way to other chronic medical or psychological conditions, including scheduling of regular follow-up visits. Follow-up visits are also essential to improve physician-patient communication, and to ensure the best treatment outcome. Monitoring of adverse events, assessing satisfaction or outcome associated with a given treatment, determining whether the partner may also suffer from a sexual dysfunction, and assessing overall health and psychosocial function, are important aspects of follow-up. Consideration should also be given as to whether an alteration in dose or treatment might be of value. Referral for specialist care with a urologist, gynecologist, endocrinologist, psychosocial therapist, or other appropriate specialist is important considerations in the follow up visit, especially in difficult-to-treat populations. The following “FAST” acronym (FIGURE 5) is a useful reminder of the key aspects of follow-up for ED, as well as sexual dysfunction generally [56]:

- FOLLOW-UP OF PATIENTS
Follow up to address treatment issues or problems that may have occurred (e.g., treatment administration, efficacy, adverse effects, partner’s acceptance), to identify changes in sexual function status or new medical conditions, and to offer continuing education and support to patients and their partners.

- ADJUSTMENT OF DOSING
Careful attention to prescribing instructions is necessary. Also, in patients who have more gradual or limited treatment response, such as those who are re-establishing sexual intimacy after a period of abstinence, repeated attempts or dosing may be necessary.

- SEXUAL STIMULATION
Currently available medical treatment, such as PDE5 inhibitors, enhances the physiologic response; therefore, sexual stimulation is essential and needs to be given at appropriate times following dosing. It may be also necessary to consider educating the patient and partner on suitable methods of stimulation.
3. EVALUATION OF SEXUAL WELL BEING

Treatment outcomes can be considered as having three major components; a) relief of symptoms and/or restoration of sexual function, b) tolerability and safety; and c) patient/partner adherence to treatment. In cases of positive outcomes, patient and partner satisfaction are expected, leading to relationship improvement and overall quality of life. The consequences of effective treatment should also involve diminished or abolished distress due to the resolution of the sexual problem, improvement of quality of life, increased life satisfaction and better perceived well-being (subjective well-being): i.e., better overall health and life satisfaction.

Figure 5: The “FAST” strategy. Modified from [56].

SUMMARY AND RECOMMENDATIONS IN EVALUATION

1. Sexual health is an integral part of overall health.

2. Health care providers should seek, receive and impart information related to sexuality. Individuals have the right to receive the highest attainable standard of sexual health, including access to sexual and reproductive health care services as a fundamental sexual right.

3. Sexual dysfunctions may have major impact on quality of life and psychosocial and emotional well-being. (Grade A)

4. The three principles for clinical evaluation and management of sexual dysfunctions are: a) adoption of a patient-centered framework, with emphasis on cultural competence in medical practice; b) application of evidence-based medicine in diagnostic and treatment planning; c) use of a unified management approach in evaluating and treating sexual problems in both men and women. (Grade C)

5. Sexual dysfunctions are essentially self-reported conditions. Therefore, diagnostic tests or procedures should not be recommended without controlled clinical data or research evidence supporting their use. (Grade C)

6. The ICSM-5 is a step-wise diagnostic and treatment algorithm for sexual dysfunctions in men and women. The main goal of ICSM-5 is to unmask the underlying aetiology and/or indicate appropriate treatment options according to men/women’s individual needs (patient-centered medicine), using the best available data from population-based research (evidence-based medicine). (Grade C)

7. Ignorance and knowledge gaps about sexual function and dysfunction are commonplace. Misinformation or myths may lead to uninformed sexual decisions with serious consequences. During the initial phase of assessment, physicians need to discriminate between sexual concerns, difficulties, dysfunctions and disorders. (Grade C)

8. For clinical purposes, sexual dysfunctions are categorized into 3 types according to their aetiology; type I: psychogenic, type II: organic, type III: mixed. Type II and III differ by the absence or presence of significant mental (cognitive) or emotional (affect) distress; in type II, resolution of the main symptom will adequately diminish mental and/or emotional distress, while in type III complementary psychotherapy is indicated. (Grade C)

9. Sexual, medical, and psychosocial history is mandatory in every case. (Grade B)

10. Physical exam and laboratory test are highly recommended, but not always necessary. (Grade C)

11. Specialized diagnostic procedures for women
are less advanced and less widely used than in men. Diagnostic procedures with the highest level of evidence should be used, when appropriate. (Grade B)

12. Improved management of sexual dysfunction depends on physicians’ inclination and ability to educate patients about their sexual function and dysfunction (Grade B)

B. OVERVIEW OF DIAGNOSTIC TESTS FOR ERECTILE DYSFUNCTION

The following section offers detailed guidelines for the clinical evaluation of erectile dysfunction (ED). Further guidelines for clinical evaluation of male orgasmic disorders, including early or delayed ejaculation, retrograde ejaculation and male anorgasmia are provided in other Chapters.

In the past decade, the scope of specialized evaluation of men with ED has shifted enormously [57]. Formerly, the primary purpose of testing was to define a treatment plan. To date, with the advent of effective pharmacological treatment modalities [58] and the knowledge that ED may be a predictor of cardiovascular dysfunction and a precursor of clinical cardiovascular disease in the majority of men consulting with ED, the focus of testing has moved towards the assessment of coronary risk [59-60]. The basic concept is that ED is an early symptom of urogenital ageing which is accelerated by a combination of multi (cardiovascular) co-morbidity and psychosocial factors. Endothelial dysfunction and autonomic hyperactivity are the basic pathological elements [61-65]. Current indications for specialized tests for ED patients are given in TABLE 17.

The frequent association of sexual and medical problems, especially in the aged population, make counselling, adjustment of lifestyle, and modification of risk factors, such as medication, overweight, smoking, alcohol consumption, and lack of exercise, the primary steps in a holistic approach toward the treatment of ED. It is especially important to educate these men to remain physically and sexually as active as possible for as long as possible. The phrase “use it or lose it” is particularly appropriate for the genitalia [63,67].

TABLE 18 presents the level of evidence of specialized tests for ED. However, with the change of scope came a change of tools, in part because the classical specialized tests – with the exception of pharmacodenile duplex ultrasound (PPDU) and measurements of nocturnal penile tumescence (NPT) or sleep related erections – are not equipped to specifically and accurately assess cavernosal neuro-endothel-
lial function. On the contrary, these tests frequently do not add to data already available from the clinical history and assessments based on patient self-report, including self-administered questionnaires, event logs, and patient diaries [68], physical examination and laboratory testing, but typically at best confirm an already expected diagnosis [27,69,70]. Moreover, they are expensive, time-consuming, invasive, complication-prone (prolonged erections), and rarely conclusive except in experienced hands. Thus, the focus of has shifted to use of tests with demonstrated reliability in other medical fields, such as measurements of brachial artery flow mediated vasodilatation, dynamic contrast enhanced Magnetic Resonance Imaging (MRI), laser Doppler flowmetry and measurement of carotid intima media thickness. Recently, molecular technology entered the field as Foresta et al have shown that the amount of circulating endothelial progenitor cells may be used as a measure of cavernosal vascular damage [71].

I. PENILE VASCULAR EVALUATION

Since their introduction in the early 1980’s, penile selective angiography, the intracavernous injection test (ICI), penile duplex pharmaco-ultrasoundography (PPDU) and dynamic cavernosometry/gyphography (DICC) have become the most commonly used clinical tests to assess the vascular status of patients with erectile dysfunction [72]. These tests are aimed at the functional and anatomical evaluation of the cavernosal arterial inflow tract and veno-occlusive mechanism.

1. ICI-TEST

To date, the utilization of ICI testing as a vascular diagnostic test has become largely obsolete for several reasons: if penile rigidity is suboptimal, the diagnosis may be: arterial insufficiency, structural venous leakage or venous leakage due to situational high anxiety or too low a pharmacological challenge [73-75]. If rigidity is adequate, cavernous arterial insufficiency cannot be excluded. (ICI may be normal in as many as 20% of patients with borderline arterial inflow) [76].

2. PPDU AND DICC

Although the methodology of PPDU is widely used and well accepted to assess the arterial inflow tract, a lack of agreement about stimulation protocols and interpretation of the blood flow velocity waveforms still exists. For example, for peak systolic velocity (PSV), which is a common parameter to estimate arterial response, variation of cut-off values between 22 and 35 cm./sec has been reported. Moreover, PSV in young men may be falsely low [77]. Probably the unavailability of a valid reference methodology is responsible for this situation. Nevertheless, when vascular evaluation is indicated, PPDU provides the least invasive and accurate option to assess the penile arterial inflow tract [78]. The parameters used to infer the integrity of the penile inflow tract are cavernous arterial diameters, direction of bloodflow in the cavernosal artery [79], peak systolic flow velocity (PSV) and acceleration time (AT) (measured in ms from the start of systole to PSV) in the first 5 minutes following ICI. PSV < 25 cm/s has a 100% and 95% specificity in selecting patients with abnormal penile angiography. A PSV > 35 cm/sec is associated with normal angiography and defines normal cavernous arterial inflow. Speel et al have shown that AT has more power than PSV to diagnose atherosclerotic ED [80]. The cut-off point for acceleration time to discriminate between atherosclerotic and non-atherosclerotic erectile dysfunction was determined at acceleration time 100 ms or greater. Sensitivity was 66% and specificity was 71% [80]. There is recently some evidence that PSV measurements in the flaccid state may have value in predicting cavernosal arterial insufficiency silent coronary disease and the clinical response to ICI) [81,82]. However, Chatterjee et al showed that penile arterial inflow in renal transplant recipients could only be reliably detected following pharmacological stimulation with a PDE-5 inhibitor [83].

With PPDU the cavernous veno-occlusive mechanism can be evaluated in the late post injection phase (over 5 minutes following ICI). End-diastolic flow velocity (EDV) and resistance index (RI) may be used to estimate the degree of veno-occlusive function. Thus, persisting diastolic blood flow or a low RI, 5 minutes or more following ICI reflects persistent high flow rates due to impaired veno-occlusion. It is noteworthy, that in a series of normal controls, 30% had veno-occlusive dysfunction, indicating the inability of PPDU to differentiate between a pathological and a functional (anxiety induced incomplete smooth muscle relaxation) cause of veno-occlusive dysfunction [84]. In cases of doubt, DICC under the controlled condition of complete smooth muscle relaxation may be utilized to differentiate between these two entities [85].

DICC under the controlled condition of complete smooth relaxation is the primary modality available for quantifying and mapping of pathological veno-occlusive dysfunction. Since Newman introduced infusion cavernosometry in 1964 [86], various techniques have been described. Cavernous veno-occlusive function is assessed by determining the relationship between the intracavernous flow rate of a saline infusion required to sustain an intracavernosal pressure that equals the mean arterial systemic blood pressure under conditions of complete cavernous smooth muscle relaxation. A roller pump is typically utilized to regulate the infusion flow rates. Puech Leao introduced an alternative technique that requires less complicated technology and is less expensive: gravity cavernosometry. Instead of utilizing a roller pump to regulate the infusion flow rate, an infusion set is used to generate a steady infusion pressure above mean arterial systemic pressure. The closer intracav-
taneous pressure equals infusion pressure, the better the status of the veno-occlusive mechanism [87]. For accurate testing, a condition of complete smooth muscle relaxation is mandatory [88]. This can be induced with repeated administrations of vasoactive agents (redosing) and demonstrated by a linear relationship between infusion rate and intracavernous pressure and that the resistance to venous outflow is constant and independent of intracavernous pressure [89]. Cavernosography may be utilized to identify the location of the venous leak, although this may prove difficult in men with low grade veno-occlusive dysfunction [90]. Kayigil et al postulated that the percent decrease in the amplitudes of the electrical activity of CC as assessed with ccEMG may be utilized as a measure of the degree of relaxation of the cavernous smooth muscle [91]. Because of its invasiveness, DICC is reserved for the rare patient who might have a site-specific venous leak, e.g. Peyronie’s disease with poor rigidity, history of penile fracture, perineal / pelvic trauma history and is only performed when surgery is considered a treatment option [92, 93].

3. SELECTIVE INTERNAL PUDENDAL ANGIOGRAPHY

Selective internal pudendal angiography is primarily reserved for imaging and subsequent embolization of arterio-cavernous fistula causing high-flow priapism [94, 95]. Moreover, the test may be of value in the few cases of young men with ED who have a history of pelvic / perineal trauma who may be candidates for operative revascularization [96, 97].

4. NEAR INFRARED SPECTROPHOTOMETRY

In 2000 Burnett et al described near infrared spectrophotometry of the penis as a possibility for non-invasive continuous monitoring of the hemodynamic events of erection in the human penis [98].

5. DYNAMIC CONTRAST ENHANCED MRI

Penile Magnetic Resonance Imaging (MRI) is a diagnostic technique with great opportunities of application in the field of sexual medicine. It allows a better definition of anatomical details and a better knowledge of penile micro-circulation [99]. The signal intensity is dependent on the rate of blood flow within the cavernous spaces that constitute the corporal bodies. Also visible are the layers of fibrous tissue that envelop the corporal bodies, the deep arteries and veins, subcutaneous connective tissue, tunica Darts, epidermis, and urethra. MR imaging may be used to detect and stage arterial insufficiency, assessment and visualisation of veno-occlusive dysfunction [100], identify penile fractures, evaluate penile prostheses, and identify plaques of Peyronie’s disease [101]. Departing from the idea that pelvic ischemia can manifest as vascular mediated ED and lower urinary tract symptoms (LUTS) and is associated with cardiac ischemia, Hou et al demonstrated that pelvic perfusion assessed with dynamic contrast-enhanced MRI correlates with validated measures of ED and LUTS [102].

6. MEASUREMENT OF INTIMA MEDIA THICKNESS (IMT)

High-resolution ultrasonography has been used to obtain measurements of the thickness of the intima and media of the carotid arteries. Previous studies have shown cross-sectional associations between common-carotid-artery intima–media thickness and cardiovascular risk factors[103], the prevalence of cardiovascular disease [104], an increased risk of myocardial infarction and stroke in older adults without a history of cardiovascular disease[105] and the involvement of other arterial beds with atherosclerosis [106]. Changes in common-carotid-artery intima–media thickness have also been adopted as a surrogate end point for determining the success of interventions that lower the levels of low-density lipoprotein cholesterol [107]. IMT measurements, in hypertensive men have shown that the presence of vasculogenic erectile dysfunction is associated with subclinical atherosclerosis[108]. Measuring IMT at the carotid and femoral artery, Foresta et al demonstrated that femoral IMT was significantly higher than carotid IMT in men with ED, suggesting that in ED patients atherosclerosis develops predominantly in the pelvic area [109].

7. ENDOTHELIAL-DEPENDENT FLOW-MEDIATED VASODILATION OF THE BRACHIAL ARTERY

Endothelial dysfunction is an important factor in the pathogenesis of ED. In the 1990s, high-frequency ultrasonographic imaging of the brachial artery to assess endothelium-dependent flow-mediated vasodilation (FMD) was developed. The technique provokes the release of nitric oxide, resulting in vasodilation that can be quantitated as an index of vasomotor function. The noninvasive nature of the technique allows repeated measurements over time to study the effectiveness of various interventions that may affect vascular health[110]. To what extend FMD of the brachial artery predicts FDM of the cavernosal artery remains a subject for further research [111]. The combined use of brachial FMD and carotid IMT may predict vasculogenic ED with 80% accuracy [112].

8. LASER DOPPLER FLOWMETRY (LDF)

Laser Doppler flowmetry (LDF) is a relatively novel way to explore the mechanisms of vasoregulation. By use of LDF at the glans penis, genital vasoregulation can be semi-quantitatively assessed. For example, sympathetic nervous system activity provides one of the fundamental mechanisms for the control of cutaneous microcirculation. Sympathetic nerves are continuously active. They
rhythmically discharge so that all innervated blood vessels are under some degree of continuous contraction and relaxation. Their control of the blood distribution to the end cells or organs is exerted in several frequency bands, including rhythms related to the cardiac and respiratory cycles [113].

Translation of this knowledge into a methodology to study penile hemodynamics is still experimental. One can hypothesize that vasodilatation in the early stage of sexual arousal is a parameter of the function of the parasympathetic innervation. Therefore, assessment of the oscillation of the vascular tone at the glans penis before and after visual erotic stimulation may be a method to monitor the process of neuronally induced vasodilatation. With the aid of LDF, Rubin et al demonstrated that post reactive hyperemia in patients with cavernosal vascular insufficiency is reduced and patient with neurogenic ED have signs of sympathetic denervation and decreased respiratory response [114].

II. PSYCHOPHYSIOLOGICAL EVALUATION

One of the questions in the differential diagnosis of ED is whether the neurovascular axis is intact. For this purpose psychophysiological evaluation may be utilized. It entails the direct observation of penile responses.

1. NOCTURNAL PENILE TUMESCENCE (NPT)

A sleep related erection or NPT is a recurring cyclic phenomenon associated with rapid eye movements during sleep [115]. Evaluation of NPT has the main advantage that it is relatively free from psychologically mediated effects. Therefore, it is useful for separating psychological and organic cases. Moreover, it appears to correlate well with corporeal smooth muscle content which is the key structure of erection [116-119]. The documented presence of a full erection indicates that the neurovascular axis is functionally intact and that the cause of the ED is most likely psychogenic. To measure not only tumescence but also rigidity a Rigiscan® device may be used [120]. The instrument has two loops, one to be placed around the base of the penis and the other towards the tip, that tighten every fifteen or thirty seconds to measure radial compression force. Disadvantages of NPT evaluation are that the equipment is costly and it is time consuming as accurate assessment of sleep-associated penile erection requires in nearly 50% of men at least 2 consecutive nightly recordings that are ideally done in a specially equipped sleep centre to exclude sleep disturbances as possible cause of disturbance of NPT [121]. Moreover, it has been questioned whether the methodology of measuring radial compression force as a parameter a penile rigidity yields a valid reflexion of real life ax-

All in all the diagnostic accuracy of NPT evaluations has been estimated to be at best about 80%. Factors such as depression, negative dream content, sleep disorders and smoking can produce false-negative NPT readings. False-positive NPT responses can be elicited in patients with pelvic steal syndrome and in certain cases of peripheral neuropathy [124].

To date, NPT evaluation is mainly used in clinical studies to quantify the erectogenic effect of oral agents and the potentially antierectogenic effects of environmental agents [125-135].

2. VISUAL EROTIC STIMULATION

Another methodology to evaluate the penile neurovascular axis is measuring erection in response to visual erotic stimulation (VES). A full erectile response makes a somatic cause of ED unlikely [136]. However, unlike NPT, response to VES, although possibly closest to normal sexual response, is strongly susceptible to psychological factors, such as erotic excitement inhibition, and can be normal in states of endocrine abnormality [137]. Moreover, the response to VES is negatively correlated with age, limiting its value in older men. To date, the most important application of VES is to investigate the erectogenic or anti-erectogenic effect of drugs in clinical pharmacological studies.

III. NEUROLOGICAL EVALUATION

Neurological testing is only recommended in specific research protocols or medico-legal investigations, including cases of trauma or surgical complications. Based on the available evidence, these tests lack adequate sensitivity and reliability for routine clinical use [138,139].

Penile erection is elicited by two different neurophysiologic mechanisms and mediated by somatic and autonomic pathways. Psychogenic erections, initiated in supraspinal centres in response to auditory, visual, olfactory, and imaginative stimuli, are mediated by sympathetic pathways. Reflexogenic erections, elicited by tactile stimulation at the genital level, are mediated by a spinal reflex arc consisting of afferent somatic and efferent parasympathetic nerve fibers [140]. The ideal neurophysiological assessment objectively and quantitatively evaluates the functional status of all parts of this neurological network; no one test alone achieves this [141].

In the last two decades, a series of tests has been developed, each of which reflects a specific part of the network. The medical history and physical examination provide the basis for these tests [142,143]. Tests can be classified as those detecting somatic efferent (motor) pathways, afferent (sensory) path-
ways, reflexes and autonomic responses [143]. The somatic nerves are evaluated by testing nerve conduction velocities and evoked potentials. These tests have well-known reproducibility, validity and range of confounding factors. Autonomic function tests are less reliable, because they simultaneously measure a chain of events or reactions involving receptors, small fibers, and target organs. Confounding factors such as medication, caffeine, temperature, hypovolemic, mental mood, and receptor or target organ dysfunction may influence each individual component. Additionally, the complex interaction between central and peripheral sympathetic and parasympathetic nerve systems, as in the pelvic plexus, makes autonomic testing difficult. Moreover, efferent autonomic function tests involve the evaluation of vasomotor and sudomotor fibers and target organs, which may not be equally affected by neuropathy. Toxic metabolic events, especially cause length-dependent neuropathy, because long fibers are more prone to metabolic damage than short fibers. Finally, current autonomic tests are not well standardised, therefore reproducibility, validity and comparability of test results between laboratories are difficult. Thus, autonomic testing is difficult and must be tailored to the specific small fibers or target organ to be tested, with elimination or standardisation of confounding factors. If these conditions are fulfilled, a normal test result rules out neuropathy, while an abnormal test result does not necessarily imply neuropathy.

A well known and extensively used test is the bulbo cavernous EMG, that can identify damage to the sacral motor roots and the pudendal efferents. It samples large myelinated fibers. It is relevant in ED associated with lesions to the low backbone, with nerve root damage. Clinical indications are lumbar disc disorders, pelvic anatomical lesions, pelvic surgery etc [144]. Dorsal nerve conduction velocity is a test for the large myelinated dorsal penile sensory fibers, which can be valuable in the evaluation of neuropathy, for example in patients with diabetes mellitus. Sensitivity and specificity of this test have not been established yet [145, 146].

Latencies of SEPs are a measure for the conduction velocity along the sensory pathways from the genital region to the sensory cerebral cortex [147]. Thermal threshold measurements yield data on the conductance of small sensory nerve fibres and therefore may reflect indirectly the function of the penile efferent (motoric) nerve fibers. The rationale of performing this test is that evidence of impaired thermal sensation might suggest similar impairment of the autonomic motoric innervation of the cavernous body [148, 149].

Cardiovascular reflex tests assess variations in heart rate and blood pressure in response to various stimuli such as forced breathing, standing up or tilting, Valsalva’s manoeuvre, sustained isometric hand-grip, mental arrhythmic task, or cold pressure. Heart rate variations reflect parasympathetic function, while blood pressure variations reflect sympathetic function. Loss of variation is indicative for autonomic neuropathy, presuming absence of confounding factors such as cardiac arrhythmia, nicotine, or caffeine use before testing, medication (especially antihypertensives), hypo, or hypervolemic, and dysfunction of baroreceptors or target organs [150].

CcEMG is a relatively new technique, in which needle or surface electrodes record the electrical activity of the CC [151]. Basic questions regarding the signal recorded, and how to interpret it, are still unresolved. Thus, despite some clinical use this test must be regarded as experimental [152-159].

Functional MRI and PET-scanning may be used to assess brain centers that are involved in different phases of the sexual response cycle: simultaneous audiovisual erotic stimulation (AVES) is required [160]. Radioisotopic penography assesses the rate of washout of a radioisotope from the penis following pharmacostimulation or visual erotic stimulation. This test remains experimental [161].

**SUMMARY AND RECOMMENDATIONS ON SPECIALIZED TESTING FOR ERECTILE DYSFUNCTION**

Multiple diagnostic tests and procedures have been reported in the literature for medical or urological evaluation of ED. The principal diagnostic methods described in this section and in Table 18, including first and foremost the Color Duplex Doppler Penile Ultrasound (CDDPU) test. This widely used and accepted test in urology was given a rating of 2B on the evidence available, and was ranked equally with the Intracavernous Injection Pharmacotesting (ICI) procedure, rated as 2B also, along with Dynamic Infusion Cavernosometry and Cavernosography (DICC), similarly rated as 2B on the evidence available. In the same evidence-based category (2B), the Nocturnal Penile Tumescence and Rigidity (NPTR) procedure was ranked by the committee. It should be noted that these four widely used tests can be performed alone, or in combination over several visits. Improvements in diagnostic accuracy or reliability with combined testing has not been systematically investigated overall, and accordingly was not reviewed by this committee.

Other diagnostic procedures for ED reviewed by the committee ranged from moderately highly recommended (2C) for selective penile or pudendal arteriography (PPA), followed by audiovisual sexual stimulation (VSS) which was ranked, with or without pharmacostimulation, as 3C based on the evidence. Other forms of CT angiography or
C. SYMPTOM SCALES AND QUESTIONNAIRES

I. INTRODUCTION

The use of symptom scales and questionnaires in sexual medicine is accepted into everyday practice, as sexual problems have the essential characteristic of being self-reported conditions, with potentially major impact on psychosocial and emotional well-being, while in many cases there may be no biological findings [162]. Therefore the use of self-administered symptom scales has become essential in clinical research in sexual medicine, and has been applied extensively in everyday clinical practice in many settings.

Sexual dysfunction, according to recent definitions, exists when satisfaction arising from the integrated components of sexual function, are reduced or absent [14]. Therefore, outcomes assessment questionnaires are essential in sexual medicine not only to determine reduction of distress or resolution of symptoms, but also to assess the overall well-being – sexual or otherwise - of the individual. This section of the chapter outlines the principles of scales and questionnaires and afterwards presents the most widely accepted questionnaires reporting on sexual function. Finally, recommendations are given based on the level of evidence.

II. STANDARDS OF SCALES AND QUESTIONNAIRES

A questionnaire, sexual function scale or quality of life measure has to meet several standards [163] : (1) The scale should be developed and validated according to currently accepted standards of psychometric evaluation, including both quantitative and qualitative methods. (2) The scale should be acceptable to clinicians, who will be using it in everyday clinical situations; and (3) The scale should be acceptable to scientific reviewers and journal editors and others involved in everyday use or interpretation of these scales. The scale should have at minimum an evidence-based rating of Grade B or C for consideration in clinical or research settings. Several of the scales and questionnaires the committee reviewed are able to meet this standard.

Most importantly, although valuable in recognizing and identifying sexual dysfunction, screening tools and questionnaires should not be substituted for a thorough sexual, medical, and psychosocial history [162]. For patients with multiple sexual dysfunction symptoms (e.g., ED and low libido), further evaluation of these symptoms is always recommended prior to initiating sexual medicine therapy.

Whenever possible, the temporal association or causal relationship between the symptoms should be assessed.

III. PROCESS OF SCALE DEVELOPMENT

The process of scale development and evaluation consists of three phases, including the development of: (i) a conceptual model based on the most recent evidence in the field; (ii) domains and a draft item pool derived from qualitative interviews with well-selected patients – either individual or focus-group based; and (iii) psychometric validation studies in both patient and non-patient groups [164]. Typically, at least two quantitative validation studies are required to establish discriminant validity (patient with a diagnosis (i.e., cases) versus healthy individuals (i.e., non-cases)) and treatment sensitivity or responsiveness – i.e., if the scale is being evaluated for use as an endpoint measure [165]. For questionnaires which are designed to serve as diagnostic
screeners only, this latter type of validation (treatment sensitivity) may not be necessary or required.

1. DEVELOPMENT AND ROLE OF SELF-ADMINISTERED SCALES OR QUESTIONNAIRES (SAQ’S)

The primary format for evaluation of sexual function or sexual symptoms is the self-administered questionnaire (SAQ). In common with all psychometric scales or instruments, the two fundamental and necessary psychometric requirements for such instruments are reliability and validity [163]. Reliability refers to the consistency or replicability of data, with reliability «coefficients» serving as formal indicators of measurement consistency. These need to be reported with every scale or questionnaire, and should include both test-retest and inter-item reliabilities. Each of these aspects of reliability can be determined using standard psychometric measures (e.g., Cronbach’s alpha).

In contrast to consistency of measurement, validity addresses the essence of what is being measured; it reflects the degree to which an instrument measures what it purports to measure. Unlike reliability, which is established through a specific, rigorously prescribed series of statistical exercises, the validation of a measuring instrument is iterative in nature. Validation is much more of an enduring process, which accumulates evidence from numerous studies and trials; it is an ongoing process, at least theoretically, and serves to test and extend the generalizability of the validation statement. Nunnally [163] has likened the validation process to «...an expanding network of circumstantial evidence» supporting the validity of the measuring instrument.

The two essential indicators of validity for measures of sexual function are, sensitivity to functional versus dysfunctional status (discriminant validity), and sensitivity to therapeutically induced change (treatment responsiveness) [164,165]. The former refers to an instrument’s capacity to discriminate sexually dysfunctional individuals from those persons who are sexually healthy (its sensitivity and specificity in epidemiological terms, or discriminant validity in psychometric terms), while the latter refers to an instrument’s capacity to register treatment-induced change (longitudinal validity in psychometric terms).

Both are essential features of instruments designed to serve as diagnostic and/or efficacy measures in both clinical settings and in clinical research. In evaluating the treatment sensitivity or responsiveness to change (another term for this concept), it is important to assess the specific scale or instrument in the context of a clinical trial or other intervention study associated with significant change over the measurement period. The finding of the intervention study can be used to demonstrate the responsiveness of the scale to change, and most importantly, to develop mathematically from the study data a cut-point or criterion of clinically meaningful change.

2. SEXUAL SATISFACTION, TREATMENT SATISFACTION AND SEXUAL QUALITY OF LIFE MEASURES

An important distinction should be made between self-report measures of sexual function (e.g., IIEF) and validated, self-report measures of sexual satisfaction or quality of life (e.g., SEAR, SQLL). Some of these measures (e.g., EDITS) address treatment satisfaction and others are directed at psychosocial outcomes of treatment (e.g., SEAR, PAIRS). It is important to make distinctions between the conceptual focus or theoretical rationale for each of these outcome measures, in addition to the psychometric strengths and weaknesses of each scale. These measures differ also in the degree to which they are couples-oriented or more directed at the individual male or female patient. Substantial progress has been made in recent years in the development and validation of several excellent tools in this area, which can be reviewed according to pre-set criteria. Specific measures in the field can be reviewed in terms of: (i) the conceptual focus of the measure; (ii) qualitative and quantitative psychometrics; (iii) extent of clinical use; (iv) overall recommendations.

SUMMARY AND RECOMMENDATIONS

Self-administered questionnaires and symptom scales are valuable tools in the assessment of sexual function in both research and clinical settings. Recent guidelines have emphasized the need for these measures to be based on: (i) qualitative interviews with patients (and partners) whenever possible for content validity assessment; (ii) psychometric validation studies to establish the reliability and discriminant validity of the measure; and (iii) treatment sensitivity studies to establish the responsiveness to changes and minimally important change (MIC) of the measure. Development of any new measure of sexual function should include all three of these components of scale development and validation. In addition to questionnaire measures of sexual function in men and women, various questionnaires have been developed for monitoring sexual satisfaction and quality of life. These are valuable adjunctive measures for use in either research or clinical settings.

IV. RECOMMENDED QUESTIONNAIRES IN SEXUAL PROBLEM ASSESSMENT

The following review, along with the detailed information contained in Tables 19-20, characterizes 16 contemporary instruments designed to measure the status of an individual or couple’s sexual function. With the exception of two, all of these instruments
have been developed during the past decade, with the majority having been published during the past few years. Although not all of these measures were designed specifically for use in clinical trials, most have been designed as outcomes measures that are suitable for use in clinical trials. Most of these instruments are relatively early in their validation programs; however, all have performed well against established psychometric criteria and have demonstrated sound early-stage empirical evidence of reliability and validity. The instruments described in Table 1 meet minimal criteria; the instruments described in Table 2 meet more extensive criteria and are recommended for use in assessing sexual function status in the indicated populations. These latter instruments are presented in greater detail in the next section. The order of presentation is alphabetical.

1. RECOMMENDED QUESTIONNAIRES FOR USE IN BOTH MEN AND WOMEN

A small number of questionnaires have been developed and validated for use in both men and women (i.e., the same questionnaire can be administered to men or women). Specific questions within each of these questionnaire are designed for men and some for women to answer. This varies from questionnaire to questionnaire as follows.

a) Changes in Sexual Functioning Questionnaire (CSFQ)

1) DESCRIPTION

The CSFQ was developed by Clayton et al (1997 [166]). The women's version is a 34 item instrument designed to be a global measure of women's current sexual function, and differentiates between those who have poor lifelong psychosexual adjustment and those who have acquired sexual dysfunction after prior normal functioning. It was designed to detect changes in sexual function due to illness (e.g. depression) or the administration of medication (e.g. SSRIs). A 36-item version was designed for men. Fourteen core sexual functioning items are rated on a five point Likert style scale. The CSFQ is comprised of 5 factor-analytically determined dimensions, labeled sexual desire-interest, sexual desire-frequency, sexual pleasure, sexual arousal/excitement, and orgasm/completion. In addition, a Total CSFQ score representing overall sexual function may also be derived. Higher scores on total score and each of the subscales indicate better sexual function. A 14-item short-form has been developed and validated [167] and is scored into three scales: desire, arousal and orgasm.

2) ADMINISTRATION TIME

The CSFQ interview requires approximately 15 minutes. The 14-item self report scale can be completed in about 5 minutes.

3) TARGET POPULATION

The CSFQ is designed to be appropriate for heterosexual and homosexual respondents.

4) RELIABILITY AND VALIDITY

Reliability for the dimensions of the CSFQ has been demonstrated in the acceptable range (r's = .64 to .80). Concurrent validity has been established by comparisons with analogous measures from the Derogatis Interview for Sexual Functioning (DISF), with r's ranging from .66 to .68 [8]. Discriminative validity of a specific type was demonstrated by its ability to discriminate between a clinical sample (depressed patients) and a non-clinical sample [168]. The instrument was also able to demonstrate differential rates of sexual dysfunction associated with specific antidepressant medications [169].

5) NORMS – CUT-OFF VALUES

Norms are available for the CSFQ based on the medical student/resident sample, and medical outpatients.

6) LANGUAGES

Validated in English and Spanish [170], with linguistic validation in 50 other languages. It is available on request from Dr. Anita Clayton, University of Virginia Medical Center.

7) RATING ON AVAILABLE EVIDENCE : GRADE B AND LEVEL 3

b) Derogatis Interview for Sexual Functioning (DISF/DISF-SR)

1) DESCRIPTION

The DISF has been developed by Derogatis (1997) [171]. The DISF is a semi-structured interview comprised of 25 items and reflects quality of sexual functioning in a multi-domain format. The DISF-SR is a matching self-report inventory designed to accomplish the same goal in a patient self-report mode. There are gender specific male and female versions of both the DISF and the DISF-SR. The instruments in the DISF series are designed to be interpreted at three distinct levels: discrete items, functional domains, and aggregate summary (Total) score. DISF items are arranged into five primary conceptual domains of sexual functioning: sexual cognition/fantasy, sexual arousal, sexual behavior/experience, orgasm, and sexual drive/relationship. The primary conceptual domains have been empirically confirmed through factor analysis [172]. An aggregate DISF Total Score summarizes quality of sexual functioning across the five primary DISF domains.

**SR = Self Report, CI = Clinical Interview**
2) **Administration Time**

Both the DISF and the DISF-SR take approximately 12 to 15 minutes to administer.

3) **Target Population**

Both male and female versions of the DISF/DISF-SR are designed to measure quality of sexual functioning in community and medical populations.

4) **Reliability and Validity**

Internal consistency reliabilities for measures of the DISF-SR are within acceptable ranges (.74 to .80), as are test-retest coefficients (.80 to .90). Inter-rater reliability estimates for the DISF interview were in the range .84 to .92. The DISF/DISF-SR series has demonstrated good discriminative validity and sensitivity to treatment-induced changes in both general clinical research and in clinical trials.

5) **Norms**

Gender-keyed actuarial norms (in terms of area T-scores) are available for all versions of the test.

6) **Languages**

The DISF/DISF-SR are currently available in 10 languages. It is available from www.Derogatis-tests.com, or Clinical Psychometric Research (410-321-6165).

7) **Rating on available evidence: Grade B and Level 3 evidence.**

c) **Golombok Rust Inventory of Sexual Satisfaction (GRISS)**

1) **Description.**

The GRISS was developed by Rust and Golombok [173]. The GRISS is a 56-item questionnaire (28 items for women and 28 items for men) self-report instrument, designed to assess the existence and severity of sexual problems in the context of sexually active individuals and heterosexual couples. It is designed to assess each individual partner’s function and the overall relationship. For assessment of individuals the men’s and women’s items can be presented as two separate forms. The GRISS is comprised of 12 domain scores, 5 for women, 5 for men and 2 scores common to both. An aggregate total score for each respondent is also used to summarise the quality of relationship and sexual functioning in the couple. Domains pertaining to men include premature ejaculation (4 items), impotence (4 items), avoidance (4 items), nonsensuality (4 items) and dissatisfaction (4 items). Equivalent domains pertaining to women include anorgasmia (4 items), vaginismus (4 items), avoidance (4 items), nonsensuality (4 items) and dissatisfaction (4 items). The 2 domains common to both women and men are frequency of sexual contact (4 items) and non-communication (4 items). This instrument was designed for use with sex therapy clients and was originally standardized using 44 heterosexual couples (88 individuals) seeking marital or sex therapy [173]. A transformation key allows couples to see their scores plotted on a profile provided for the couple as part of therapy.

2) **Administration Time**

Approximately 15 minutes

3) **Target Population**

The GRISS was designed for use with heterosexual sex therapy clients.

4) **Reliability and Validity**

Internal consistency of the subscales was acceptably high and ranged from .61 to .83. Test-retest assessment involved a comparison of scores from both pre and post therapy for 41 of the couples. Test-retest calculations for women ranged from .47 to .82. Women in therapy showed higher rates of dysfunction across subscales compared to the control sample of general practitioner patients. A Dutch translated version of GRISS showed a similar factor structure to that of the English version, and demonstrated reasonably high internal consistency for the each of the subscales. The GRISS has demonstrated utility in establishing lowered sexual functioning among women with obsessive compulsive disorder and psychiatric comorbidity among women identified as having FSD using scales from the GRISS.

5) **Norms**

Norms are available from the development sample of therapy clients as well as for a comparison nonclinical sample of 59 general practitioner patients.

6) **Languages**

Dutch and English language versions are available on request from the authors.

7) **Rating on available evidence: Grade B and Level 3 evidence.**

II. **MEASURES OF FEMALE SEXUAL FUNCTION**

The following questionnaire measures have been validated and developed for use specifically for use in women. The FSFI (below) is currently the most widely used measure in research and clinical settings. It is available from MAPI Institute (see website link below).

a) **Female Sexual Function Index (FSFI)**

1) **Description**

The FSFI was developed by Rosen et al., [174]. It is similar to the IIEF questionnaire used in men, but was developed separately for use in women [175,176].
Qualitative interviews were used to complement other sources of item construction. The FSFI scale is a 19-item self-report questionnaire which assesses sexual function in 6 partially overlapping domains of sexual function, including sexual pain [174]. Respondents were asked to base their responses on a period of recall of the “past 4 weeks”. Factor analysis was used to identify six components of sexual functioning; Desire, Arousal, Lubrication, Orgasm, Satisfaction and Pain. A total score is computed by summation of all 19 items and is used to represent overall sexual function. The FSFI refers to this total score as the Full Scale score. Higher scores on total scale and each of the subscales indicate better sexual function.

2) Administration Time

10 to 15 minutes

3) Target Population

Clinical trial and community populations. This instrument was designed for use among heterosexual and homosexual respondents.

4) Reliability and Validity.

The female validation sample included 131 healthy controls (age 21 to 69) and 128 women diagnosed with FSAD (age 21 to 69). Alpha coefficients for the five subscales were all above .82. Test-retest data over a 2 to 4 week period was relatively high for all the subscales (r=.79 to .86) and total score (r=.88). Women diagnosed with FSFI had significantly lower scores on all subscales of the FSFI than healthy women, demonstrating discriminant validity. Divergent validity was successfully established using the Locke-Wallace Marital Adjustment Test [177]. Correlations showed acceptably modest magnitude across subscales. As would be expected, the Locke-Wallace Marital Adjustment score correlation (r=.57) was highest with the FSFI Satisfaction (with partner) subscale. Other correlations with the Locke-Wallace ranged from r = .41 for FSFI Full Scale score to r = .19 for FSFI Desire. These correlations indicate an expected level of association between the theoretically related constructs of Marital Adjustment and Sexual Function. This finding provides support for the construct validity of the FSFI.

In a second validation study [175], the FSFI was shown to discriminate well between women without sexual dysfunction and women who met criteria for female orgasmic disorder (FOD) or hypoactive sexual desire disorder (HSDD). Highly significant discriminant validity was shown on all domains, as well as the total FSFI score between sexually dysfunctional and non-dysfunctional samples in both studies. Overall, the FSFI shows strong reliability and discriminant validity, although treatment sensitivity data has not been demonstrated to date. In a subsequent study, a cut-point for the total score was shown to be optimal for diagnostic classification across dysfunctions: a score of < 26 indicates sexual dysfunction [176].

Most recently, Sand et al (2009) [178] reviewed a total of 212 separate intervention or diagnostic publications in which the FSFI was featured. This broad array of studies included psychometric studies (n=8), studies in which FSFI was used as a comparator in the development of new diagnostic tools (n=3), studies of models of female sexual function (n=2), psychophysiological studies (n=6), studies assessing sexual function and/or the prevalence of FSD in specific geographical populations, or populations of women with particular diseases or conditions (n=111), and clinical trials and studies assessing the efficacy of different types of therapies for FSD (n=82). Overall, the reviewers of this systematic review concluded that the FSFI has been widely accepted and utilized by researchers worldwide, becoming in the process the “gold standard” measure of female sexual dysfunction for outcome and diagnostic studies in FSD [178]. The measure is available on-line without charge and has been translated into multiple languages.

5) Norms

Norms are available for both pre- and post-menopausal women and women with medical and sexual disorders [178].

6) Languages

The FSFI is available in multiple languages. Validation studies have been performed in multiple languages. The FSFI is available from the MAPI Institute at: www.mapi-institute.com

7) Rating on available evidence:

Grade A, Level 1

b) Monash Female Sexual Satisfaction Questionnaire (MFSSQ)

1) Description

The MFSSQ (Monash Questionnaire) was developed by Davison et al. [179]. It was developed to assess the broad aspects of female sexual experience and specifically to assess acute therapeutic effects. The 12-item measure was developed from ten interviews with women and the scoring of items was based on structures of similar female sexual dysfunction measures, which led to domains of receptivity, arousal, lubrication, sexual pleasure, sexual satisfaction and orgasm.

2) Administration Time

Approximately 5 minutes.

3) Target Population

For use in pre and post-menopausal women who are dissatisfied with their sexual function.
4) **Reliability and validity**

Strong correlations were demonstrated for the MFSSQ with similar domains on the Sexual Self-Self Rating Scale (orgasm (0.60), pleasure (0.72) and satisfaction (0.71)). Known-groups validity was shown with women who were dissatisfied with their sexual function having significantly lower scores than women who were satisfied with their sexual function. Reliability of the measure was, in the main, demonstrated (ICC > 0.70) (receptivity and orgasm domains showing poorer reliability, ICC = 0.52).

5) **Norms**

Norms are available.

6) **Languages**

English. Available on request from the senior author.

7) **Rating on Available Evidence:**

*Grade A, Level 3*

c) **Sexual Function Questionnaire (SFQ)**

The initial version of the Sexual Function Questionnaire (SFQ-V1) was developed by Quirk et al. [180]. The SFQ was developed as a patient-centered multidimensional measure of sexual function in women. Systematic pilot interviews and semi-structured interviews were used to focus the instrument. Women from seven countries (UK, U.S., Australia, the Netherlands, Denmark, France and Italy) reviewed key terms in sexual function to assess the appropriateness of the wording used. Those subjects with FSD diagnoses were asked to discuss feelings associated with their experience of FSD. Key phrases obtained in this way were incorporated into the questionnaire. Factor analysis was used to obtain seven domains. The SFQ can be reliably employed in three forms; a 34 item version which includes all 8 domains (Desire, Arousal-sensation, Arousal-lubrication, Arousal-cognitive, Orgasm, Enjoyment, Pain and Partner) and additional items; a 26 item version which includes the 7 domains only and a short 15 item version (Abbreviated SFQ) which includes 4 of the 7 domains (Desire, Arousal-sensation, Arousal-lubrication and Orgasm). It has been validated also as a screening tool for female sexual dysfunction [181].

1) **Administration Time**

10 to 15 minutes

2) **Target Population**

Women in a sexual relationship or having taken part in sexual activity within the previous month.

3) **Reliability and Validity**

The initial validation sample included 982 women, which incorporated women with a diagnosis of FSD and a normal aged-matched comparison group. Women were aged between 19 and 65 years. Internal consistency of the subscales was acceptably high and ranged from .65 to .91. Test-retest correlations, based on a four-week re-administration of the SFQ, ranged from .42 to .78. The SFQ was successful – for all of the domains – in discriminating between women with FSD and those without. In addition, women who by the end of the study indicated an improvement in sexual functioning had significantly higher SFQ scores compared to women who did not report an improvement in sexual functioning by the end of the study. Construct validity has been demonstrated in correlations between the SFQ domains, the DISF-R, the Life Satisfaction Checklist and the Hospital Anxiety and Depression Scale. Cut-scores for each domain have been developed to indicate likelihood of a given sub-type of FSD e.g. a score between 5 & 16 on the desire domain suggests a high probability of desire disorder [181].

5) **Languages**

The SFQ is available in twenty-one language versions and has been independently validated in Japanese [182]. Requests for use can be made at www.prolutssh.com

6) **Rating on Available Evidence:**

*Grade B and Level 3 evidence.*

d) **Female Sexual Distress Scale (FSDS)**

1) **Description**

The FSDS questionnaire was developed by Derogatis et al [183]. The FSDS is a brief 12-item self-report inventory designed specifically to measure sexually related personal distress in women – a necessary feature of HSDD and other sexual dysfunctions in women. The impetus for the development of the FSDS grew from a contemporary awareness of the importance of personal distress in defining women’s sexual dysfunctions accompanied by an equally compelling awareness that no operational measures of sexually-related personal distress existed [183]. The FSDS is unidimensional and serves as a valid and effective quantitative definition of personal distress.

1) **Administration Time**

The FSDS can be completed in 5 minutes.

2) **Target Population**

Women presenting for an evaluation concerning sexual dysfunction.

3) **Reliability and Validity**

Reliability estimates for the FSDS are available from
3 distinct trials. Coefficients $\alpha$ range from a low of .86 to a high of .97, while test-retest reliability coefficients ranged from .80 to .92. In a discriminative validity trial with samples of both natural and surgically menopausal women with sexual dysfunction compared to healthy controls, the FSDS demonstrated both sensitivity and specificity of .93, and a positive predictive value of approximately .90. In another of the trials the scale showed a high sensitivity to treatment induced change. There is also good evidence of convergent validity with other measures of distress, and ROC analysis produced an AUC of .95.

More recently, a 13-item revised version of the FSDS (the FSDS-R) was validated, designed to be more sensitive to distress arising from low sexual desire problems [183]. Consistent with the original FSDS, the FSDS-R showed very good internal consistency and test-retest reliabilities. The FSDS-R also demonstrated high discriminant validity, successfully identifying 92.7% of patients diagnosed independently with HSDD.

4) NORMS

Provisional cut-off score of 15 for distress level is currently recommended.

5) LANGUAGES

The FSDS is currently available in 14 languages and may be obtained from Dr. Leonard R. Derogatis (Lderogatis@sheppardpratt.org.)

6) RATING ON AVAILABLE EVIDENCE:

Grade B, Level 3 evidence.

e) Sexual Interest and Desire Inventory – Female (SIDI-F)

1) DESCRIPTION

The Sexual Interest and Desire Inventory (SIDI) was developed by Sills et al, [184]. It is a brief, clinician-administered rating scale focused on measuring severity and change in response to treatment of HSDD in premenopausal women. The SIDI was developed and tested for appropriateness in patients and then Item Response Theory analysis was used to elicit the most pertinent items, resulting in a 13-item measure [184]. The SIDI has a unique measurement format in that items address both intensity and frequency of events.

2) ADMINISTRATION TIME

The SIDI-F can be completed in 5-10 minutes.

3) TARGET POPULATION

Premenopausal women with low desire.

4) RELIABILITY AND VALIDITY

The SIDI has high internal consistency ($\alpha=0.90$), and has demonstrated discriminant validity [185]. Convergent validity was tested with the FSFI and CSFQ. The SIDI was highly correlated with the arousal, desire and satisfaction domains of the FSFI (all correlations >0.8) and the arousal, desire/frequency, desire/interest, and pleasure domains of the CSFQ (all correlations >0.7).

NORMS

Norms are available for women with no sexual dysfunction.

LANGUAGES

Linguistically validated in 12 languages. Available on request from the senior author.

RATING ON AVAILABLE EVIDENCE:

Grade C, Level 4

f) Hypoactive Sexual Desire Disorder Screener

1) DESCRIPTION

The HSDD Screener is a diagnostic screening tool developed by Leiblum et al. [186] for use in screening or evaluating women for HSDD. It is a simple 4-item screening tool for use in post-menopausal women. It was developed by an internationally recognized group of experts in female sexuality and then optimized based on feedback from groups of patients and physicians in Europe (Italy, the Netherlands, United Kingdom) and the United States. Both a validation study and subsequent convergent validity study against expert clinician have demonstrated this to be a valid and simple tool to aid in screening post-menopausal women for low sexual desire [186].

1) ADMINISTRATION TIME

The HSDD screener is brief (approximately 2 minutes) and simple to complete.

2) TARGET POPULATION

For use in post-menopausal women to determine sexual desire level.

3) RELIABILITY AND VALIDITY

The HSDD Screener is scored as a total score, as confirmed by principal component analysis. It showed good internal consistency ($\alpha=0.79$) and excellent test-retest reliability (intraclass correlation coefficient = 0.94). To determine the cut-score, sensitivity, specificity, positive predictive value and negative predictive value were calculated; a score of 7 or less suggests HSDD. Additionally, the Screener was tested for accuracy in determining presence/absence of HSDD in a group of post-menopausal women when compared against Clinician diagnosis. There was 83% agreement between the Clinician and
Screener, the associated Kappa statistic was 0.67 (95% CI, 0.5-0.78) indicating substantial agreement.

4) **NORMS**

Norms have been reported.

5) **LANGUAGES**

Available in US and Canadian English and, Canadian French. Requests for use can be made at www.prolutssh.com

6) **RATING ON AVAILABLE EVIDENCE**

Grade C and Level 4.

g) **Decreased Sexual Desire Screener (DSDS)**

1) **DESCRIPTION**

The DSDS is a diagnostic screener developed by Clayton et al. [187] for use in diagnosing acquired, generalized hypoactive sexual desire disorder (HSDD) in pre- or post-menopausal women. It is a 5-item screener, which includes both self-report questions (Items 1-4) and clinician-based differential diagnosis (Item 5). It was developed as a guide to diagnosis of acquired, generalized HSDD in women with or without other sexual disorders. Results of a recent validation study [187] showed excellent diagnostic accuracy of the DSDS when compared with expert, in-person diagnostic evaluation of women with and without HSDD.

2) **ADMINISTRATION TIME**

Approximately 15-20 minutes

3) **TARGET POPULATION**

The DSDS was developed for use in pre- or post-menopausal women with HSDD, with or without other sexual disorders.

4) **RELIABILITY AND VALIDITY**

Diagnostic assessment by means of the DSDS compared to standard diagnostic assessment by an expert sexual medicine clinician, were in in 85.2% of cases, with the sensitivity and specificity of the DSDS as 83.6% and 87.8% respectively. Content validity was also demonstrated by means of cognitive debriefing interviews

5) **NORMS**

Norms have not been reported.

6) **LANGUAGES**

Available in multiple languages. The DSDS is in the public domain [187].

7) **RATING ON AVAILABLE EVIDENCE**

Grade C and Level 4.

### III. MALE SEXUAL FUNCTION SCALES

a) **International Index of Erectile Function (IIEF)**

1) **DESCRIPTION**

The IIEF is a widely-used, 15-item self-report inventory developed by Rosen and colleagues [188] to provide a brief, standardized measure of erectile function and capacity. It measures 5 domains of sexual function in men. The IIEF was developed in conjunction with the clinical trial program for sildenafil (Viagra), and has since served as a major endpoint in over 50 clinical trials [188]. The principal domains of the IIEF were identified through literature search, review of existing instruments, and interviews with patients suffering from erectile dysfunction. The IIEF represents quality of male sexual function in terms of 5 domain scores: erectile function, orgasmic function, sexual desire, sexual satisfaction, and overall satisfaction. The IIEF does not yield a total score.

2) **ADMINISTRATION TIME**

The IIEF takes approximately 10 to 15 minutes to complete.

3) **TARGET POPULATION**

Men from the community and medical populations.

4) **RELIABILITY AND VALIDITY**

Both internal consistency (.73 to .95) and test-retest reliabilities (.64 to .84) are superior for the scale, and there is factor analytic confirmation of the principal domains. Sensitivity and specificity are very good, and concurrent validation against other comparable measures has been demonstrated. Discriminative validity has been well established in comparisons of functional versus dysfunctional samples, and sensitivity to therapeutic change has been consistently shown within the context of clinical trials of sildenafil and other treatments for ED. More recently, a 5-item brief form of the IIEF termed the Sexual Health Inventory for Men (SHIM) has been developed and validated, along with a diagnostic classification and an ED severity scale [189]. A recent systematic review of more than 60 studies found the IIEF scale to be highly robust in different ethnic and geographic populations, as well as sensitive to treatment effects across a variety of treatment agents [188].

5) **NORMS**

Numerous normative cut-off scores have been published for the IIEF.

6) **LANGUAGES**

The IIEF has been linguistically validated in 32 languages. Requests for use can be made at www.prolutssh.com. It is also available from the MAPI Institute at: www.mapi-institute.com
7) RATING ON AVAILABLE EVIDENCE:
Grade A and Level 1 evidence

2. PREMATURE EJACULATION MEASURES

Several premature ejaculation measures have been described in the literature [190-192], although only a small number couple have undergone extensive psychometric testing and validation. Currently, there are two questionnaires that meet most of the criteria for test development and validation: The Premature Ejaculation Profile (PEP) and the Index of Premature Ejaculation (IPE). A third brief diagnostic measure (PEDT) has also been developed, and is available for clinical use [191,192].

a) Premature Ejaculation Profile (PEP)

1) DESCRIPTION

A four-item, self-report measure of premature ejaculation have been described by Patrick et al [192]. The PEP is comprised of single-item constructs of: (1) perceived control over ejaculation; (2) satisfaction with sexual intercourse; (3) personal distress related to ejaculation, and (4) interpersonal difficulty related to ejaculation. Each of the four individual items is assessed on a 5-point scale, which are averaged to provide an index PE score. The measure has been used in observational studies and clinical trials of premature ejaculation [193]. It has also been recommended for clinical use in evaluating the subjective components of the disorder. Validation studies have been performed in comparison to stop-watch measures of intravaginal latency and other PRO measures of sexual function and distress [192].

2) ADMINISTRATION TIME

The four-item PEP scale takes less than 5 minutes to complete.

3) TARGET POPULATION

Men aged 21 and older with premature ejaculation.

4) RELIABILITY AND VALIDITY

Psychometric evaluation was conducted in both large-scale observational studies and clinical trials conducted for dapoxetine (a centrally acting agent for treatment of PE). Test retest reliability was reported as Intra Class Correlations (ICC), which ranged from 0.66 for perceived control to 0.80 for the overall PE index score in the US observational study. The measure showed adequate known groups validity in comparing men with PE to non-PE controls. As predicted, men with IELT of 0-2 mins showed significantly poorer scale scores than men above 2 mins (p < .001). Sensitivity to change analyses were also conducted.

5) NORMS

Norms have not been established for the measure.

6) LANGUAGES

Official translations are not available. Available on request.

7) RATING ON AVAILABLE EVIDENCE:
Grade C, Level 3 evidence

b) Index of Premature Ejaculation (IPE)

1) DESCRIPTION

The Index of Premature Ejaculation (IPE) was developed by Althof et al [190]. It is a 10 item self-administered questionnaire designed to evaluate sexual satisfaction, control and distress in men with premature ejaculation. It was developed using four stages: item pool development, initial psychometric analyses, patient interviews, and final psychometric analyses. It is currently being used in Phase III clinical trials.

2) ADMINISTRATION TIME

Five minutes

3) TARGET POPULATION

Heterosexual men from the community.

4) RELIABILITY AND VALIDITY

The IPE contains three factor analytically derived domains: control, sexual satisfaction and distress. All three domains have shown excellent internal consistency and reliability, as well as showing good known groups validity between men with and without PE. Convergent validity against IELT was also strong for all three domains (control (r=0.75); sexual satisfaction (r=0.60) and distress (r=0.68)). Treatment sensitivity has yet to be determined.

5) NORMS

Initial understanding of normative scoring is available.

6) LANGUAGES

It has been linguistically translated into several other languages and can be requested at the following web-site: www.prolutssh.com.

7) RATING ON AVAILABLE EVIDENCE:
Grade C and Level 4 evidence.

c) Premature Ejaculation Diagnostic Tool (PEDT).

1) DESCRIPTION

The previous two measures (PEP, IPE) are available for use as treatment change or outcome measures of PE treatment. The PEDT was developed and is available only in the form of a screening questionnaire
This questionnaire is a brief, 5-item measure used to screen men for potential presence of PE based on DSM-IV-TR criteria of lack of control, frequency, minimal stimulation, distress and interpersonal difficulty.

2) **Adminstration Time**

1 minute

3) **Target Population**

Heterosexual men from the community.

4) **Reliability and Validity**

Internal consistency (cronbach alpha = 0.71) and reliability (ICC = 0.73) were good. Importantly known-groups validity was strong when comparing men with time-defined PE (IELTs <2 minutes in 70% of coital attempts) and those with self-reported no PE. A score of >11 would suggest presence of PE and men scoring 9 or 10 are likely to have PE and are recommended for further assessment. This scoring system has shown good convergent validity with clinical expert diagnosis of PE (k-statistic=0.80).

5) **Norms**

Norms are available

6) **Languages**

The PEDT has been linguistically translated into several other languages and has additionally been psychometrically tested in Turkish [194]. Language versions can be requested at the following web-address: www.prolutssh.com

7) **Rating on Available Evidence:**

Grade C and Level 4.

5. DELAYED EJACULATION SCALES

a) **Male Sexual Health Questionnaire (MSHQ).**

1) **Description**

The MSHQ was developed by Rosen et al. [195]. It is a 25-item validated questionnaire to measure specific aspects of ejaculation in older men. The MSHQ, which includes independent domains for ejaculation (7 items), erection (3 items), and sexual satisfaction (6 items), provides a more in-depth assessment of ejaculatory function and sexual satisfaction than the IIEF. The ejaculation domain of the MSHQ assesses loss of ejaculation, delayed ejaculation, the force of the ejaculation, the amount of semen ejaculated, pleasure associated with ejaculation, pain/discomfort during ejaculation, and the bother associated with ejaculation. A 4-item MSHQ-EjD Short Form, with 3 ejaculatory function items and 1 bother item, has also been psychometrically validated for the assessment of EjD in clinical and research settings [196].

2) **Adminstration Time**

The 25-item MSHQ takes approximately 20 to 30 minutes to complete. The 4-item MSHQ-EjD Short Form takes approximately 5 minutes to complete.

3) **Target Population**

Older men from the community and medical populations

4) **Reliability and Validity**

In psychometric validation studies, the 3 domains of the 25-item MSHQ demonstrated a high degree of internal consistency (.81 to .90), rest-retest reliability (.86 to .88), and construct validity, together with the ability to differentiate between men with LUTS and sexual dysfunction and healthy men [195]. The 3 ejaculatory function items of the MSHQ-EjD Short Form maintain reliability and construct validity for assessing EjD in heterosexual, bisexual, and gay men [196].

5) **Norms**

Analyses to establish normative cut-off scores for the MSHQ are on-going.

6) **Languages**

The MSHQ has been linguistically validated in 16 languages and is available from the MAPI Institute at: www.mapi-institute.com

7) **Rating on Available Evidence:**

Grade B and Level 3 evidence

6. OUTCOME MEASURES AND QUALITY OF LIFE-RELATED SCALES (SEE TABLE 21)

a) **Treatment Satisfaction Scale (TSS)**

1) **Description of Measure**

The Treatment Satisfaction Scale (TSS) is a sexual quality of life measure developed by Kubin et al. [197]. The scale provides a comprehensive assessment of sexual satisfaction of men with ED, and their partners and to assess sequential measurements over time to evaluate satisfaction with treatment [197, 198]. It is a multi-faceted measure of patients' and partners' satisfaction with their sexual life relating to erectile dysfunction and intended for prospective use.

The TSS has 4 modules: unmedicated patient (12 items), medicated patient (19 items), unmedicated partner (12 items), and medicated partner (18 items). All TSS modules have these domains: spontaneity, quality of erection, quality of ejaculation, quality of orgasm, sexual pleasure, and confidence. The medicated patient and partner modules have these domains: reliability of treatment, convenience, treatment efficacy, conformity to treatment expectations, overall satisfaction and intentions for continued use of the particular drug.

</table>

**SR = Self Report**
In all the modules, respondents answer the questions considering the previous 4 weeks. Item responses are scored on a 5-point scale, ranging from 1 "not at all" over "a little", "somewhat", and "very" to 5 "extremely". Some items have a sixth response "not relevant". The TSS scale scores are computed by taking the mean of each scale's item responses and converting the result to a 0-100 scale, with 0 being the worst possible score and 100 being the best. Higher score indicates greater satisfaction [198].

2) Administration Time
The TSS patient module takes approximately 13 minutes on average to complete, whereas the partners' module takes approximately 7 minutes on average to complete. It is a brief questionnaire and practical to use.

3) Target Population
Men with erectile dysfunction and their partners.

4) Reliability and Validity
The TSS baseline "unmedicated" and "medicated" modules have 63% item-congruence. The medicated patient and partner modules of the TSS comprise 95% identical items and the unmedicated patient and partner modules comprise 100% identical items. This multidimensional scale has good internal consistency, reliability and concurrent validity with the IIEF [197]. Specifically, all multi-item scales (satisfaction with erectile function, sexual confidence and satisfaction with medication) had Cronbach alphas above 0.70 at baseline and follow-up. Furthermore, all patient TSS domains were significantly correlated with three domains of the IIEF (erectile function, intercourse satisfaction and overall satisfaction) and there was a significant correlation between men's IIEF -erectile function results and the six partner TSS domains [198]. The TSS scales were able to discriminate between four ED severity groups, and between responders and non-responders to treatment; all patient and partner TSS scales were responsive (sensitive to change) for the respondents [197].

5) norms
Norms are available.

6) Languages
The TSS was linguistically validated in 20 languages. The TSS is available from the MAPI Institute at: www.mapi-institute.com

7) Rating on Available Evidence:
Grade B and Level 3 evidence

b) Sexual Life Quality Questionnaire (SLQQ)

1) Description of Measure
The Sexual Life Quality Questionnaire (SLQQ) was developed by Woodward et al. [199]. It is a validated, multi-dimensional questionnaire that consists of two domains: (i) sexual quality of life (SQoL) (10 items) and (ii) treatment satisfaction (6 items). The SQoL domain compares the current sexual experience of the subjects or his partner with their individual experience prior to the onset of the subject's erectile dysfunction [199]. Scores on each item can range from -4 to 4, with 0 indicating no change from before the onset of erectile dysfunction, negative numbers denoting worse outcomes, and positive scores indicating better outcome.

2) Administration Time
The SLQQ is easy to administer and takes about 8-10 minutes to complete.

3) Target Population
Men with erectile dysfunction

4) Reliability and Validity
The SLQQ is a good measure of treatment satisfaction as shown by a high correlation with response to a question asking about their likelihood of continuing the treatment (r= 0.89). The SLQQ is also responsive and able to detect changes in sexual quality of life [199]. For the quality of life domain, Cronbach alpha was 0.97 for patients and 0.98 for partners. For the treatment satisfaction domain, Cronbach alpha was 0.85 for patients and 0.87 for partners respectively [199].

5) Norms
Norms are available.

6) Languages
There are at least 7 languages available. The SLQQ is available from the MAPI Institute at: www.mapi-institute.com

7) Rating on Available Evidence:
Grade C and Level 4 evidence

c) Erectile Dysfunction Inventory for Treatment and Satisfaction (EDITS)

1) Description of Measure
The EDITS scale was developed by Althof et al [200]. It is a multi-dimensional scale to assess male treatment satisfaction following ED therapy, and which explores the impact of patient and partner's satisfaction on treatment continuation [200, 201]. The Patient EDITS version consists of 11 items, scored from 0 (no satisfaction or dissatisfaction) to 4 (high satisfaction) and measuring overall satisfaction, degree to which treatment met expectations, likelihood of treatment continuation, ease of use, satisfaction with onset of action, satisfaction with duration of action, impact of treatment on sexual confidence, partner satisfaction with treatment, how the partner felt about
the patient’s continuing with treatment by patient self-report), naturalness of erections and naturalness of erection hardness. The Partner version of the EDITS consists of 5 items assessing overall satisfaction, degree to which treatment met expectations, how treatment affected the partner’s sense of sexual desirability, partner satisfaction with duration of action, and how the partner feels about the patient’s continuing to use the treatment. The EDITS score is calculated by multiplying the mean EDITS score by 25 resulting in a treatment satisfaction range of 0- extremely dissatisfied to 100- extremely satisfied.

2) Administration Time
The questionnaire takes about 5 minutes on the average to administer.

3) Target Population
Men with erectile dysfunction and their partner.

4) Reliability and Validity
Scores on the Patient EDITS and the Partner EDITS were normally distributed with internal consistencies of 0.90 and 0.76 respectively [4]. The Patient EDITS has an internal consistency of 0.90 and a test-retest reliability of 0.98. The Partner EDITS has an internal constancy of 0.76 and a test-retest reliability of 0.83. The EDITS has shown sensitivity to change [201].

5) Norms
Norms are available.

6) Languages
The SEAR is available in 27 languages, which can be requested from www.prolutssh.com

7) Rating on available evidence:
Grade A, Level 2

e) Psychological and Interpersonal Relationship Scale (PAIRS)

1) Description of Measure
The PAIRS scale was developed by Swindle et al [205] to assess broad psychosocial outcomes associated with erectile dysfunction and its treatment. Items were generated based on literature review, focus groups, interviews with patients and partners, market research and consultation with clinicians. Of the 47-items initially developed, 23 were retained to form 3 domains: Sexual Self-Confidence (6-items), Spontaneity (9-items) and Time Concerns (8-items).

2) Administration Time
Approximately 5-10 minutes

3) Target Population
Men with erectile dysfunction

4) Reliability and Validity
Four studies were completed to psychometrically validate the PAIRS [205]. Factor analysis elicited the 3-domain structure and, convergent and divergent
Discriminant validity was also demonstrated with scores across all three domains being statistically significantly different between men with ED and those with no ED. Reliability was assessed using Pearson’s correlation coefficient and showed adequate results: Time concerns (r=0.63); Spontaneity (r=0.66); and Sexual Self-confidence (r=0.77). Additionally, strong internal consistency across the studies and domains was shown (α: 0.73-0.97). Responsiveness of the measure to treatment effect was also shown.

5) Norms
These are reported.

6) Languages
U.S. English only. Available on request from the first author.

7) Rating on available evidence:
Grade B and Level 3

f) Sexual Quality of Life – Male (SQOL-M)

1) Description of Measure
The Sexual Quality of Life measure for Men (SQOL-M) was developed by Abraham et al [206, 207] for or use in men with either premature ejaculation or erectile dysfunction to assess impact of these conditions on men’s self-esteem, relationship and emotional well-being. The item pool was taken from the Sexual Quality of Life measure for Females (SQOL-F – see below) after confirmation from experts, a review of the literature and interviews with men with either ED or PE that the items were applicable to men. Factor analysis and item-total correlations showed that 11-items, as a total score, of the 18-items were most pertinent to men [206].

2) Administration Time
Approximately 5 minutes.

3) Target Population
Men with sexual dysfunction (current validation in PE and ED cohorts).

4) Reliability and Validity
The reliability and validity of the SQOL-M was confirmed in both men with ED and PE. Internal consistency ranged from 0.87-0.93 and test-retest reliability ranged from 0.77-0.79. Convergent validity with the IIEF-Overall satisfaction domain for men with ED and IPE-satisfaction and distress domains for men with PE was confirmed. Highly significant differences were shown between men without sexual dysfunction compared to those with ED or PE, or as a combined sexual dysfunction group.

5) Norms
Norms are reported.

6) Languages
20 language versions are available and can be requested at the following web-site: www.prolutssh.com

7) Rating on available evidence:
Grade B and Level 3

g) Sexual Quality of Life – Female (SQOL-F)

1) Description of Measure
The SQOL-F was developed by Symonds et al [208] to assess the impact of female sexual dysfunction on women’s sexual quality of life, specifically self-esteem, emotional well-being and relationship. Items were developed through interviews with 82 women from 7 countries (United Kingdom, United States, Australia, France, Denmark, Netherlands, Italy). From these interviews 24-items were developed, which were then reduced down to 19-items by a multi-disciplinary clinical panel due to lack of clinical relevance, conceptual relevance, and face validity. Psychometric validation reduced it further to 18-items and confirmed the items formed one domain addressing the overall concept of sexual quality of life [207].

2) Administration Time
Approximately 5 minutes.

3) Target Population
Women with female sexual dysfunction.

4) Reliability and Validity
The reliability and validity of the SQOL-F was conducted in three separate studies (UK study, US Study, and Test-retest reliability study). Results across these three studies demonstrated the SQOL-Fs strong psychometric properties. Internal consistency was very high (α: 0.95), as was test-retest reliability (0.85). Convergent validity was good against both a sexual satisfaction measure and sexual function measures. Additionally, the SQOL-F can distinguish between women with FSD and those without FSD.

5) Norms
Norms are reported.

6) Languages
The SQOL-F is available in 23 languages and can be requested at the following web-site: www.prolutssh.com

7) Rating on available evidence:
Grade C, Level 4
SUMMARY AND RECOMMENDATIONS ON SYMPTOM AND SCALES

This section represents an overview from a clinical perspective of the scales and questionnaires currently available to measure and quantify the status of an individual’s or couple’s sexual functioning. The instruments covered in this section are for the most part, contemporary measures that have been recently developed. The design of these measures tends to emphasize brevity and the self-report modality, which articulate well with the majority of the primary formats for clinical trials. The measurement constructs these inventories and interviews are designed to operationalize tend to be consistent with the acknowledged elements of the sexual response cycle and consequences of problems, and are referenced under the general headings of desire, arousal, orgasm, pain and satisfaction.

It is evident that multiple, validated questionnaires and scales are currently available and recommended for use in practice settings and clinical trials:

1. The field of sexual psychometrics has progressed dramatically during the past decade from one in which there were only a handful of measures available to a field of measurement in which a great deal of activity and new development is taking place.

2. Instrument development is currently an area of high activity with new measures being developed rapidly and previous measures being revised to reflect new knowledge. Consequently the reviews and recommendations incorporated can only reflect the current state of the art.

Despite major advantages of these measures in efficiency and quantification of measurement, several disadvantages should also be noted:

1. First, these measures provide information only on current level of sexual function and cannot substitute for a detailed sexual or medical history. Furthermore, the questionnaires do not provide information regarding specific etiology or comorbid medical or psychiatric conditions.

2. Additionally, some patients experience discomfort or embarrassment while completing questionnaires or symptom scales, or may experience language or comprehension difficulties. Steps should be taken to ensure privacy and confidentiality and to assist the patient with comprehension when indicated.

3. Finally, the use of questionnaires or symptom scales should not be used as an alternative or substitute for direct inquiry or face-to-face clinical interaction with the patient.

As the field continues to evolve and development, new questionnaires will undoubtedly be developed and disseminated. It is incumbent on clinicians and researchers to be aware of these developments in the future.

**APPENDIX 1.**

**BRIEF SEXUAL SYMPTOM CHECKLIST FOR MEN (BSSC-M)**

Please answer the following questions about your overall sexual function.

1. *Are you satisfied with your sexual function?*
   - □ Yes □ No

   If No, please continue.

2. *How long have you been dissatisfied with your sexual function?*
   ...............................................................................................................................................

3a. *The problems with your sexual function is: (mark one or more)*
   1. Problems with little or no interest in sex
   2. Problems with erection
   3. Problems ejaculating too early during sexual activity
   4. Problems taking too long, or not being able to ejaculate or have orgasm
   5. Problems with pain during sex
   6. Problems with penile curvature during erection
   7. Other: ................................................................................................................................

3b. *Which problem is most bothersome (circle)* 1 2 3 4 5

4. *Would you like to talk about it with your doctor?*
   - □ Yes □ No
APPENDIX 2.

BRIEF SEXUAL SYMPTOM CHECKLIST
FOR WOMEN (BSSC-W)

Please answer the following questions about your overall sexual function

1. Are you satisfied with your sexual function?
   - Yes □ No □

   If No, please continue.

2. How long have you been dissatisfied with your sexual function?
   ............................................................................................................................................

3a. The problems with your sexual function is: (mark one or more)
   1 Problems with little or no interest in sex
   2 Problems with decreased genital sensation (feeling)
   3 Problems with decreased vaginal lubrication (dryness)
   4 Problems reaching orgasm
   5 Problems with pain during sex
   6 Other : ................................................................................................................................

APPENDIX 3.
SEXUAL COMPLAINTS SCREENER
FOR MEN (SCS-M)

This screener is a series of questions concerning your sexual experiences during the last 6 months. Each question can be answered by circling the condition that best characterizes your personal experience.

**Sexual activity** includes any kind of activity aimed at experiencing sexual satisfaction and enjoyment. The term sexual activity does not necessarily include sexual intercourse (vaginal or anal penetration).

This screener is a series of questions concerning your sexual experiences during the last 6 months. Each question can be answered by circling the condition that best characterizes your personal experience.

*Sexual activity* includes any activity aimed at experiencing sexual satisfaction and enjoyment. The term sexual activity does not necessarily include sexual intercourse (vaginal or anal penetration).

Understanding human sexual behavior requires balancing the simplicity of DSM-like definitions of normal and abnormal arousal, desire, performance, and orgasm, with the bewildering array of exceptions to those definitions that characterize sexual function and dysfunction in real people. Scientific blinders limit the nature of the questions we ask, the approaches we take, and research is normally constrained by research review committees pressured to enforce “community standards”. There is much that we simply cannot study in humans, either because of ethical concerns, impracticality, or the lack of sufficient technology. These constraints are most obvious when we ask questions about the neurobiology of sexual behavior. Although studies have viewed human brain activation in sexual circumstances and have monitored the sexual responses of individuals following drug treatments, there are significant limitations on what can be studies experimentally in humans. Most people will not knowingly allow themselves to be rendered sexually dysfunctional by some experimental manipulation, and few would allow monitoring of their copulatory behavior firsthand, even if review boards would allow such research. Lastly, there is the problem of self-selection of human subjects where those willing to allow detailed recording of their sexual interests and responses may represent a very special subset of people and may well not represent the general population.

Despite these constraints, we have made real progress in the past decade in elucidating neuroanatomical and neurochemical mechanisms of erection, ejaculation, and other sexual responses, and in the design of rational pharmacological treatments for certain sexual dysfunctions. We have begun to examine the mechanisms that underlie sexual desire, and how sexual stimulation and reward influence attractiveness and mate choice. Progress in these areas could not have been made without the help of animal models. However, appreciation of the importance of animal models is more limited than it needs to be for basic animal research to speed the advance of treatments for human sexual dysfunction.

Although studies of animal sexuality predate empirical studies of human sexuality we arrived at a place by the end of the 20th Century where sexuality research was divided into to camps, clinicians who studied people, and behavioral neuroendocrinologists who studied animals. These camps rarely shared common insights at scientific meetings. After all, human copulatory behavior doesn’t really resemble copulatory behavior in animals. In laboratory animals commonly used to study sexual behavior, such as rodents, gonadal hormones serve two primary functions: to make it physically possible for a male or female to engage in sex, and to motivate them to engage in sex (Wallen, 1990). By contrast, in humans and other anthropoid primates, only the latter function of hormones remains, with hormonal influences on the capability to mate having largely disappeared for evolutionary reasons which are still unclear. Thus unlike in laboratory rodents, there is no human equivalent of the lordosis, which is under tight hormonal regulation and whose execution is necessary for a male to get an intromission with a female. Similarly, although erection is necessary for mating in both rodent and human males, in men erectile capacity is no longer under the control of testicular hormones with castrated or hypogonadal men as responsive to sexual stimuli as are males with fully functioning testes. As Miller (1931) pointed out more than 75 years ago, humans can mate at any time and under any hormonal condition. Although he believed that this continual capacity to engage in sex was unique to humans, we now know that this is a proclivity that we share with most, if not all of our primate cousins, and something which distinguishes us from the laboratory rodents from which we have derived so much of our understanding of the neuro-
chemical and endocrine mechanisms that underlie sexual responding.

At another level of analysis, however, commonalities in sexual responding could be conceived of between animals and humans (Pfaus, 1999). The links started forming around the study of sexual pharmacology. For example, the dopamine receptor agonist apomorphine induces erection in rats and men (Lal et al., 1987; Melis, Argiolas, & Gessa, 1987) whereas the dopamine antagonist haloperidol reduces sexual arousal and desire in rats and men (Petrie, 1985; Pfaus & Phillips, 1991). Such results allowed researchers to make a predictive link between the sexual responses of male rats and men (e.g., Barfield, 1993; Everitt & Bancroft, 1991; Pfaus, 1996), and gave rise to an important theoretical implication that certain brain systems had been conserved in evolution to subserve similar or identical functions among species. This has led to a new understanding of how animal models can help elucidate mechanisms of sexual behavior in humans – provided that researchers can translate human clinical questions into experimental situations appropriate for animals.

1. WHAT MAKES A GOOD ANIMAL MODEL?

Animal models must relate in some predictive way to the human condition. At the simplest level of analysis, it is prudent to recognize that all organisms that engage in sexual behavior share common processes. We must be able to respond to hormonal and neurochemical changes that signal our own sexual desire and arousal. This capacity underlies our moment-to-moment level of sexual arousability (as conceived by Whalen, 1966), and defines a large part of the internal state that is commonly referred to as “sex drive”. The rest requires a complex mix of instinct, learning, and feedback; a neural organization that allows us to interact with external sexual incentives and predict their reactions along with our own responses to those reactions. We must be able to identify external stimuli that predict where potential sex partners can be found, to seek out, solicit, court, or otherwise work to obtain sex partners, distinguish external cues and behavioral patterns of willing sex partners from individuals who are not sexually receptive, and to pursue and execute sexual behavior once sexual contact has been made. Neural mechanisms exist that allow sexual responding to become habitual or automated with practice, and such processes may underlie the ability of sexually experienced animals to be less affected by treatments that disrupt sexual responding in sexually naive animals (e.g., Pfaus & Wilkins, 1995). Similarly, neural mechanisms exist that allow the stimulation received during sexual contact to be perceived as rewarding. Such reward alters subsequent behavior, for example, by contributing to the formation of preferences for salient stimuli associated with positive sexual reinforcement (Pfaus, Kippin, & Coria-Avila, 2003). These aspects of sexual responding go well beyond the traditional focus in animal studies on copulation or penile reflexes and make them particularly applicable to human sexual behavior. Although some appetitive and preparatory responses that animals make prior to copulation are not specific to sexual behavior, they can be considered “sexual” if they are conditioned using sexual reward as the positive reinforcer. This is as true for bar pressing in male rats (e.g., Everitt et al., 1987) as it is for giving flowers and remembering birthdays in men.

For all animals, sexual behavior occurs as a sequence or “cascade” of behavioral events. Beach (1956) recognized the heuristic value of separating sexual behavior into appetitive and consummatory phases. Essentially, this scheme followed from the work of early ethologists like Craig (1918) and experimental psychologists like Woodworth (1918), who defined appetitive (or “preparatory”) behaviors as those which bring an animal from distal to proximal and into contact with goal objects or incentives. In contrast, consummatory behaviors are performed once an animal is in direct contact with the incentive (i.e., to “consummate” the goal). Consummatory sexual behaviors tend to be species-specific, sexually differentiated, and stereotyped, whereas appetitive behaviors are more flexible. Indeed, survival often depends on an animal’s ability to learn a variety of strategies to obtain goals in different appetitive circumstances. We have found it useful heuristically to conceive of appetitive and consummatory behaviors as two overlapping Venn diagrams (e.g., Pfaus, 1996; 1999) in which the behavioral stream moves from appetitive to consummatory incentive sequences (Figure 1). The intersection of the diagrams defines precopulatory behaviors made once animals come into contact with potential sex partners. The diagrams are overlapping, rather than discontinuous, because the division between the two phases is rarely fixed. Some responses, such as solicitation, can be placed into both phases, especially if sexual interaction comes in bouts. We would therefore define solicitation as a precopulatory behavior that acts as a transition from appetitive to consummatory. It is also essential to place the behaviors into a comparative context: are they homologous or analogous to human sexual responses?

a) Homologies versus analogies

Homologies are typically defined in biology as tissues that correspond in evolutionary origin, structure, and function; for example, the flippers of a seal and the arms of a human being. However, homologies come in degrees. We may regard brain dopamine systems among different mammals as homologous because cell bodies originate and axons terminate in similar brain regions (e.g., ventral tegmental area to
nucleus accumbens). In addition, drugs that activate dopamine receptors (e.g., apomorphine) or block the reuptake of dopamine (e.g., amphetamine or cocaine) produce psychomotor stimulation in many mammalian species, thus we may regard the function of this neurochemical system as homologous at that level of analysis. We may also define tissues with different function, such as the labia and scrotum, as homologous structures because they differentiate from the same primordial anlage. Regarding behavior, homologies are usually easy to define because they have the same endpoints and are typically controlled by similar neural systems. Erections in rats and men are a good example: A large number of drugs, situations, and brain lesions, alter the latency to obtain an erection and the duration of erection similarly across species.

Analogies are less straightforward and require a degree of creativity in interpretation, inference, and design. What distinguishes analogies from homologies is the idea that things or events are dissimilar in form, yet may serve the same endpoint. In biology, this is usually taken to mean that the organ or structure is similar in function, but not necessarily in evolutionary origin. For example, the gills of a fish

---

**Figure 1:** Incentive sequences for human and rat sexual behavior (modified from Pfaus, 1996, 1999, and Pfaus et al., 2003). The behavioral stream moves from left to right, through appetitive, precopulatory, and consummatory phases of behavior. This conforms to the movement of animals from distal to proximal to interactive with respect to the sexual incentive. Sexual excitement can manifest itself in learned or unlearned behaviors, whereas preparatory behaviors are learned responses that animals must make in order to acquire the incentive (e.g., operant behaviors, pursuit, preference etc.). Recognizing which responses occupy which parts of the behavioral stream allows researchers to compare behaviors that appear different among different species, but that accomplish a similar motivational endpoint. Such behaviors in one species (e.g., rat) may then serve as models of analogous behaviors in humans. The predictive validity of such models is enhanced when drugs or other treatments modify the behavior of both species the same way, suggesting that a common neural system for those behaviors has been conserved.
and the lungs of a mammal both remove oxygen from water or air, but cannot remove it from both media. However, analogous tissues may have similar neural control. With regard to behavior, something done by an animal may not appear similar to its human counterpart, despite serving a similar endpoint and being dependent on identical neural systems. Solicitation in female rats is a good example. During copulation, female rats control the initiation and pacing of copulation by soliciting mounts from males. Females make a headwise orientation to the male and then run away, forcing the male to chase them if they are interested in sex (e.g., McClintock, 1985). If the male is sluggish or nonresponsive, the female may increase the strength of her solicitations, to the point of kicking the male in the head before the runaway or even mounting the male if he does not respond to previous enticements (Afonso & Pfaus, 2006; Beach, 1969).

Nonhuman primates show a remarkably similar pattern of sexual initiation with female rhesus monkeys doggedly maintaining close contact with males they are sexual interested in until the male is finally induced to engage in sex (Wallen, et al., 1984; Wallen 1990). Male rhesus monkeys manipulate this propensity of female to pursue them by walking away from females who initiate close contact, one supposes, to see whether the female will follow. Indeed rhesus monkey females at peak fertility pursue males through several of these arrivals and departures, whereas females further from peak fertility typically will not initiate contact with the male, or if they do, will not pursue the male if he leaves. Similar approaching and leaving behavior would be seen as sexual solicitation in most human cultures, but the specific form that it would take would be highly culturally defined. Thus a woman walking across a crowded room at a party to stand near a specific man could be an expression of sexual interest, whereas standing the same distance from that man on a crowded subway may not express the same sexual intent. High levels of solicitation in females, or analogous courtship behaviors in males, suggest that the individuals are highly motivated to engage in sex. Whether the solicitations result in sex reflects an increasingly complicated social calculus that takes into account the social context, the specific individuals involved, and their social history and experience. While some components of this social calculus are evident in rodents, it is much more complicated in humans and has a much stronger influence on the likelihood that sex will occur.

At a strictly behavioral level of analysis, it does not matter whether the motivation to sexually initiate is driven by a primary desire for sexual gratification, offspring, conflict resolution, or other social rewards. Contrast solicitation behavior with the lordosis posture, the arching of the back characteristic of sexual receptivity in many mammalian females which elevates and rotates the female’s pelvis making it possible for the male to intromit with the female. As mentioned above, there is no human counterpart to this, as postural control of access to a woman’s genitals in not a spinal reflex as is lordosis and such access is under the woman’s voluntary control, except in cases of forced copulation, something that cannot occur in a nonreceptive female rat. Thus it is solicitation in rats, and not lordosis, which is the “analogous rat model” of behavior expressing sexual desire, such as sexual initiation in women.

b) Three features of a good animal model

Predictive validity: As mentioned previously, the most important requisite of an appropriate animal model is predictive validity. In addition to this, animal models should be simple and practical enough to have “high throughput”, meaning the ability to have experiments conducted relatively quickly. Issues of sample size and ease of testing and analysis are key. For example, testing the sexual effects of alcohol in male dogs may reveal processes similar to those in men (e.g., the ability of low doses of alcohol to increase the ejaculation latency in male dogs that led to the suggestion by Gantt (1952) that a couple of glasses of wine could be used as a quick remedy against premature ejaculation), but such experiments are cumbersome from an experimental testing and animal housing standpoint, and indeed might have a difficult time passing an animal ethics review by today’s standards.

Throughput in numbers: Because testing large animals is simply not practical except in field studies, many researchers utilize smaller animals, such as rats, rabbits, ferrets, gerbils, hamsters, voles, mice, snakes, lizards, or birds, to examine the neural and hormonal control of sexual behavior. These animals can be tested in large numbers at the same time, and do not present a challenge for animal housing in a colony room. Although some, like certain transgenic mice, require constant monitoring, this is not an overriding obstacle to their use as research subjects.

Optimal testing environments: Testing small animals means that suitable chambers and testing environments need to be constructed. Attention has to be paid to the ecological validity of those testing environments. Some animals, like rats, are very social and will copulate under a variety of circumstances regardless of the presence of a human experiment-er (Calhoun, 1962). The testing environment also needs to be optimized for each animal. For example, female rats like to pace the rate of copulation. Providing them with chambers that allow such behavior to occur (e.g., the preference chambers described by Emery, 1986; the pacing chambers described by Erskine, 1989 and Paredes & Alonso, 1987; or the biveral chambers described by Mendelson & Pfaus, 1989, Pfaus, Mendelson, & Phillips, 1990, and Pfaus, Smith & Coopersmith, 1999; shown in Figures 3 and 4), gives researchers the ability to de-
tect certain appetitive behaviors in both female and male rats in an unambiguous manner. Likewise, if the experimenter wishes to study appetitive responses made to acquire a sex partner, then the testing environment should contain some kind of operant apparatus upon which the animal must work to obtain sexual reinforcement (e.g., as described in Everitt et al., 1987). Each experimental question dictates the proper treatments and testing environment, so the rate-limiting factor in generating the appropriate animal model is really the inspired intuition of the experimenter (see Ågmo & Ellingsen, 2003).

A. BEHAVIORAL MODELS

Behavioral models comprise both copulatory and precopulatory responses, in addition to models of hypofunctionality that can be achieved either by hormonal manipulation or learned inhibition. Both copulatory and precopulatory behaviors in animals can be viewed in laboratory circumstances under different conditions. Virtually all animals will learn to copulate in a variety of testing chambers, although such chambers typically alter the acquired baseline behavior of the animals (e.g., the different number of intromissions or ejaculation latencies of male rats trained to copulate in unilevel versus bilevel pacing chambers: Ismail et al., 2008; Figure 2, 3). Likewise, female rats show different patterns of solicitation in unilevel or bilevel pacing chambers (Ismail et al., 2008; Pfau et al., 1999). Once learned, such automated patterns are difficult to retrain, even with extensive experience in different chambers.

It is useful to pattern the discussion of behavioral models after the phases of sexual behavior denoted in the DSM. Thus, animal models exist for sexual arousal, desire, and reward, which reflect analogies and homologies of sexual arousal, desire, and orgasm in humans. Recent work has also been aimed at models of sexual inhibition in animals that can inform both the etiology and treatment of sexual arousal, desire, and orgasm disorders in humans, or the ability of “prosexual” drugs to induce states of sexual disinhibition (e.g., alcohol, cocaine).

I. MODELS OF SEXUAL AROUSAL

Physiological sexual arousal in both humans and other animals can be defined as increased autonomic activation that prepares the body for sexual activity. This includes both parasympathetic blood flow to genital and erectile tissues, in particular the clitoris, labia, vaginal epithelium, and penis, and...
sympathetic blood flow from the heart to striated and smooth muscle that participate in sexual responses. Sexual arousal also includes a central component that increases neural “tone” or preparedness to respond to sexual incentives. This latter concept was defined as “arousability” by Whalen (1966), and may form around an intricate interaction of hormone priming and noradrenergic activity in different regions of the brain. Both peripheral and central arousal may be detected as part of the perception of subjective sexual arousal, and both clearly lead to changes in responsiveness in genital tissues and control certain copulatory responses, such as the latency to orgasm or ejaculation (with shorter latencies indicating an increase in arousal). There is a considerable degree of similarity between male rats and men in terms of the neuroanatomical, neuroendocrine, and neurochemical regulation of penile erection and ejaculation (see Andersson & Wagner, 1995; Meisel & Sachs, 1994; Rosen & Sachs, 2000, for comprehensive reviews). Penile erections in men can be either be “physiological” or “psychogenic” in response to parasympathetic arousal. They can be studied using mercury-in-rubber strain gauges either during the night (to gain an unbiased measure of physiological erectile capability), or in response to different types of erotic or somatosensory stimuli (to measure psychogenic arousal). Latency to erection (tumescence), percentage of full erection, and duration of erection can be studied following the administration of drugs that either enhance or delay parasympathetic arousal. Such studies are important diagnostically in distinguishing psychological from physiological erectile dysfunction, or in determining spared erectile capability in men with spinal cord injury. Ejaculation has been more difficult to study objectively in men, and has thus been the subject of far fewer studies. Typically, subjects masturbate in the presence of different types of erotic stimulation following an experimental treatment. Ejaculation latencies are recorded along with physiological measurements of ejaculate volume, sperm motility, or psychological measurements of orgasm intensity (e.g., Mah & Binik, 2002; Rowland, Strassberg, de Gouveia Brazao, & Slob, 2000). Subjective sexual arousal, or the ability of people to describe or monitor their own sexual arousal, is difficult if not impossible to determine in animals. We must use components of sexual desire, specifically behavioral excitation in response to changes in genital blood flow, to make inferences about subjective arousal in animals.

1. PENILE ERECTIONS

In rats, penile erections can be studied in isolation to obtain measures of physiological arousal (summarized in Meisel & Sachs, 1994) or in response to different types of sexually arousing stimuli (e.g., noncontact erections in response to estrous odors) to obtain measures of psychogenic arousal (Sachs et al., 1994; Sachs, 1995).

2. PENILE REFLEXES

In typical penile reflex tests, male rats are placed supine in a tube with their penile sheaths held back and the penis retracted. The penis then shows a characteristic pattern of tumescence and detumescence accompanied by “quick flips” (quivers following full erection) and “cups” (a flaring of the glans penis thought to be analogous to ejaculation). Latency to erection and the frequency of these different reflexes are counted following an experimental treatment, (e.g., systemic or central drug administration, brain lesions, or lesions of different nerves that innervate the pelvic ganglia). Many treatments that enhance penile erection in men (e.g., sildenafil, apomorphine, prostaglandin E1, oxytocin, α2-adrenergic receptor antagonists like yohimbine, idazoxan and imiloxan, and vasodilators that act through nitric oxide substrates, such as nitroglycerine, sodium nitroprusside, and lindsomine) enhance penile erection in rats (reviewed in McKenna 1999; Meisel & Sachs, 1994). Erectile responses to these drugs are also studied by monitoring intracavernosal pressure with electrodes (e.g., Andersson et al., 1999; Bernabe et al., 1999). Conversely, drugs that reduce sexual arousal in men, e.g., dopamine antagonists such as haloperidol (Crenshaw & Goldberg, 1996), also reduce penile reflexes in rats (Pehek et al., 1988). However, selective activation of different dopamine receptors in the mediopontic area alters autonomic arousal differently, with selective agonist actions on D1 receptors facilitating erections and inhibiting seminal emissions in male rats, and selective actions on D2 receptors having the opposite effect (Hull et al., 1989). This suggests that the erectogenic actions of apomorphine in rats occur through its binding to D2 receptors in this or other brain regions.

3. “PSYCHOGENIC” ERECTIONS

Noncontact erections in rats are studied in the presence of an inaccessible receptive female behind a mesh screen, or behind a series of walls with an air circulation system that brings the estrous odors to the male’s compartment. Erections in response to these salient sexual cues are viewed as a model of psychogenic erection because they do not require direct somatosensory stimulation to be induced. The neurochemical and hormonal mechanisms that control their expression have been studied in detail (e.g., nitric oxide release in the paraventricular hypothalamus, Melis et al., 2000; dopamine in the medial preoptic area, Adachi et al., 2003; peripheral and central actions of androgens, Manzo et al., 1999). Drugs that enhance noncontact erections also induce a “penile erection and yawning syndrome” in rats in the absence of sexual stimulation (Bertolini, Gessa, & Ferrari, 1975; Doherty & Wisler, 1994; Melis & Argiolas, 2002). It remains to be studied whether this “syndrome” is related neurochemically to psychogenic erection in rats, or whether it stems
from a more general activation of the autonomic nervous system. On the other hand, general autonomic activation by drugs or environmental circumstances may be translated into sexual arousal in the presence of a sexual incentive. This is reminiscent of the idea put forth by the ancient Roman poet Ovid, in Ars Amatoria (2 CE/1930; www.sacredtexts.com/cla/ovid/ibook/) that, under the right circumstances and occasion setting, high levels of general arousal can be manipulated into sexual arousal (see below).

Such an effect is also consistent with the notion by Meston and colleagues (Meston, 2000; Meston & Gorzalka, 1996), that sympathetic arousal provides a necessary background for the perception of sexual arousal.

4. COPULATORY RESPONSES IN MALES THAT INDICATE AROUSAL

Ejaculations in rats can be studied much the same way they are studied in humans, with the latency from first mount or intromission to ejaculation being the key variables. Male rats typically ejaculate following several penile intromissions, and can ejaculate several times before becoming sexually exhausted, in which the male no longer responds to estrous odors or female solicitations (Beach & Jordan, 1956). During successive ejaculatory series, the refractory period or postejaculatory interval between each ejaculation and the subsequent resumption of copulation increases progressively (Larsson, 1956). Penile intromission requires erection, and ejaculation typically requires sensory feedback from the penis that accumulates with multiple intromissions. The number of intromissions before ejaculation, the number of ejaculations achieved in a timed test, and the length of the postejaculatory interval, are all dependent on autonomic arousal and can be enhanced or disrupted by drugs that have similar effects on copulatory performance in men (see Bitran & Hull, 1987; Doman & Malsbury, 1989; Meisel & Sachs, 1994; Pfaus & Gorzalka, 1987, for selective reviews). For example, drugs that delay or abolish orgasm in men (e.g., selective serotonin reuptake inhibitors such as fluoxetine), increase the ejaculation latencies and reduce the total number of ejaculations in rats (Frank, Hendricks, & Olson, 2000; Yells et al., 1994). As in men, the reduced ability to ejaculate is more pronounced in rats following long-term daily administration (Cantor, Binik, & Pfaus, 1999). Acute alcohol intoxication also delays ejaculation in men (Malatesta et al., 1979) and in rats (Dewsbury, 1967; Pfaus & Pinel, 1989). Although tolerance to this effect appears to accrue contingently in rats (Pinel, Pfaus, & Christensen, 1991), it is not yet known if contingent or conditional tolerance occurs in humans to alcohol's sexual effects with long-term use.

A short ejaculation latency in rats, ejaculation with fewer than normal preejaculatory intromissions, or an increased number of ejaculations in a timed test or before sexual exhaustion sets in, suggests an enhancement of sympathetic arousal. Although at first glance, faster ejaculation and/or ejaculation with fewer intromissions suggest that the male may be a more "proficient" copulator, such behavior in the wild would be less likely to get a female rat pregnant (e.g., Adler, 1969), and should be considered a disruption of normal copulatory responding. Such behavior is more reminiscent of premature ejaculation in humans, and can be induced by drugs that stimulate sympathetic arousal (e.g., cocaine; Ferrari & Giuliani, 1997) or by experiential conditions that increase sympathetic arousal in sexual circumstances. For example, Larsson (1956) observed that male rats would ejaculate faster, and with fewer intromissions, if the stimulus female was removed from the test chamber for periods up to one minute between successive intromissions. Although Larsson's "Enforced Interval Effect" could constitute a rat analogue model of premature ejaculation, it remains to be seen whether drugs that can counteract premature ejaculation in men, such as alcohol or fluoxetine, can increase the latency of male rats to ejaculate in this condition.

Classically conditioned stimuli are also capable of increasing sexual arousal as reflected by copulatory rate measures. Zamble and his colleagues (Zamble, Hadad, Mitchell, and Cutmore, 1985; Zamble, Mitchell, and Findlay, 1986) used placement of male rats in a holding cage as a conditioned stimulus to signal non-copulatory exposure to a receptive female behind a wire-mesh screen on several training trials. On test trials, they found that placing the males into the holding cage prior to unrestricted copulation resulted in significantly shorter latencies to intromit and ejaculate than if the conditioned stimulus was omitted. Subsequent studies found that second-order conditioned stimuli (e.g., a plastic toy fish found in the holding cage) were effective in enhancing the same measures of arousal (Zamble et al., 1985), and such conditioning in sexually naive or sluggish males could increase the proportion of males that copulate on a subsequent test (Cutmore & Zamble, 1985). Hollis, Cadieux, and Colbert (1985) demonstrated that repeatedly pairing a light with non-contact exposure to a receptive female resulted in conditioning of sexual behavior in male gouramies, a type of Labyrinth fish. They found that males receiving the conditioning treatment displayed significantly lower latencies to initiate copulation and lower levels of aggression towards females when the conditioned stimulus was presented before access to a female. Similar results have been demonstrated Domjan and colleagues in birds, notably Japanese quail. Male quail that received repeated exposure to females following the presentation of a conditioned stimulus light displayed significantly shorter latencies to initiate copulation when the stimulus was present compared to when it was absent (e.g., Domjan, O>Vary, and Greene, 1989). Pfaus, Talianakis,
and Kippin (in preparation) recently found evidence that somatosensory stimuli can be used to condition sexual arousal in male rats. Males that received prior sexual experience with receptive females while wearing a rodent harness jacket displayed slower intromission and ejaculation latencies if tested without the jacket than with it on. A rat model of conditioned sexual arousal would be useful as an analogy of psychogenic copulatory sexual arousal, or perhaps even the development of certain fetishes. However, the ability of conditioned stimuli to “prime” sexual arousal may depend on the association of neutral stimuli with sexual reward in addition to arousal (see below). In fact, pairing stimuli with sexual arousal per se, without sexual reward, may result in counterconditioning, in which males show lower levels of arousal in the presence of such stimuli.

5. FEMALE SEXUAL AROUSAL

Physiological sexual arousal in women has not received nearly the same experimental attention as in men, in part because genital blood flow in women has been assumed to follow the same physiological and psychological rules as in men (Barlow, 1986). Certainly, drugs or stressful circumstances that block erections in men also block vaginal and possibly clitoral blood volume in women. However, clinical results with sildenafil in women with sexual arousal disorders have been inconclusive (Basson et al., 2002; Berman et al., 2001; Rosen, 2000). There may be real differences between men and women in patterns of sexual arousal and in the types of psychogenic stimuli that elicit genital blood flow (e.g., Palace & Gorzalka, 1990; Rosen & Beck, 1988). For example, women are reported to experience cyclic fluctuations in arousability and desire, with peak incidents of female-initiated sexual activity coinciding with ovulation (Wallen, 1995). Indeed, event related potentials (ERPs) that correspond to attention and stimulus processing for working memory (e.g., the P3 amplitude) increase following the presentation of sexually arousing pictures, but not pictures of babies or body care products, to women during the ovulatory phase (Krug, Pihal, Fehm, & Borh, 2000). The same pictures do not activate those ERP components during other phases of the menstrual cycle, or in women taking oral contraceptives (Krug, Pietrowsky, Fehm, & Borh, 1994). Timing may thus be extremely important when studying sexual arousal in women relative to men. Such a relationship has been established for rats and other species. Female rats display sexual “heat” only during the periovulatory period of their estrous cycle, a state that can be induced in ovariectomized rats by sequential administration of estrogens and progesterone (Bolling & Blandau, 1939).

In vivo experimental models of genital arousal in female New Zealand White rabbits have been developed by Traish, Goldstein, and their colleagues (e.g., Kim et al., 2003; Min et al., 2003; Munarriz, et al., 2003; Park et al., 1997; Traish et al., 2002a,b). In these models, electrical stimulation of the pelvic nerve is applied that mimics the type of stimulation normally received by females during vaginal intromission and results in increased vaginal blood flow, vaginal wall pressure, vaginal length, clitoral intra-cavernosal pressure and blood flow, and decreased vaginal luminal pressure. Similar effects have been reported following pelvic nerve stimulation in female rats (Giuliano et al., 2001; Vachon, Simonner, Zahran, & Carrier, 2000). In addition to vaginal and clitoral blood flow responses, vaginal smooth muscle preparations have been developed to examine the ability of different neurotransmitters to induce muscle contraction and relaxation. These studies have shown that ovariectomy diminishes vaginal blood flow, lubrication, and epithelial cell morphology, and that treatment with estradiol restores these measures of vaginal response. Moreover, the nitric oxide-cyclic GMP pathway appears to be critical for vaginal blood flow, as it is for penile blood flow. Treatment with androgens facilitates vaginal nitric oxide synthase activity, along with vaginal smooth muscle relaxation. Although it is not yet known how these vaginal responses are integrated with behavioral responses, Whalen and Lauber (1986) hypothesized that cyclic GMP was a common target for drugs that substitute for progesterone in the facilitation of lordosis in rats. Inhibition of the ability of nitric oxide to stimulate cyclic GMP in the rat brain results in a profound disruption of lordosis (Chu & Etgen, 1997) suggesting that the brain is an important target for nitric oxide/GMP stimulated activation of lordosis. However, it remains an intriguing possibility that increased vaginal blood flow could be perceived by females and help stimulate behavioral measures of sexual arousal. Such a relationship could be examined following inhibition of peripheral nitric oxide-cyclic GMP.

II. MODELS OF SEXUAL DESIRE

Sexual desire seems a straightforward concept, yet there is no agreed-upon definition of what it is or how it manifests itself. In the DSM-IV-TR, the diagnosis of Hypoactive Sexual Desire Disorder (HSDD) is given when “desire for and fantasy about sexual activity are chronically or recurrently deficient or absent.” By converse logic, then, sexual desire is the presence of desire for, and fantasy about, sexual activity. This definition while coherent is circular and provides no objective way in which to identify sexual desire. Many clinicians view desire as distinct from arousal in both animals and humans. This is apparent in the DSM’s categorization of arousal disorders as distinct from desire disorders, a distinction that generally reflects blood flow to the genitals and erectile tissues versus a “psychological” sexual interest in which individuals “want” sex (as defined by Robinson & Berridge, 1992). In practice, however, desire may well be informed or even confirmed by the presence
of autonomic and central responses that define arousal, and there is growing evidence that people regard desire and arousal as parts of one another, despite being given distinct definitions. When an individual expresses sexual desire behaviorally, it follows that attention and behavior focus on obtaining some form of positive sexual reinforcement. This can occur alone in fantasies or together with others in goal-directed social and sexual behaviors. Thus, in addition to subjective appraisals of desire, the concept encompasses the effort, including risk, which individuals engage in to obtain sexual rewards, the excitement displayed in anticipation of such rewards, and the strength of the incentive value ascribed to a particular sexual stimulus.

1. HORMONAL INFLUENCES.

Although the vast majority of studies of hormonal influences on sexual motivation have utilized rodents, their relevance to understanding human sexual desire is more limited than is generally credited. In females, both the behavioral endpoints used and the hormones underlying sexual motivation are markedly different than those thought to operate in primates, including humans. Lordosis has been the primary behavioral evidence of female sexual motivation in rats and is one of the most completely understood behavioral systems in behavioral neuroendocrinology (Pfaff, 1980; Pfaff et al., 1994).

However, as previously described, there is no behavioral equivalent in humans. In addition, although estradiol can induce some expression of lordosis, full expression in rodents requires sequential exposure to estradiol followed by progesterone separated by at least 24 hours. While no study has specifically ruled out the possibility of progesterone synergism with estradiol to produce full sexual receptivity, there is no evidence for a role for progesterone in stimulating sexual behavior in primates. Thus the elegant understanding we have of the hormonal and neural modulation of lordosis is likely to be of little use as an animal model with reference to human sexual desire. Instead, female initiation and pacing (Erskine, Pfau) are analogues much more likely to be valuable. It is the use of female initiation, for example, which produced convincing evidence that bremelanotide, a melanocortin receptor agonist (previously referred to as PT-141), specifically influenced sexual motivation and not the capacity of females to respond to the male’s sexual initiation (Pfaus, et al, 2004). The parallels between rodent female sexual solicitation and that seen in monkeys (McClintock reference; Wallen, et al, 1984) are striking and ovarian estrogens capacity to induce female sexual solicitation is similar in both rodents and primates. However the specific role that progesterone plays in female rat sexual solicitation is unclear. Full sexual receptivity in female rats requires progesterone after a period of estrogen exposure. Though estradiol alone increases the female rats attraction to males, the largest increase in time spent with male rats occurs after a sequential estradiol and progesterone treatment (Pfeiffe and Edwards, 1984) In monkeys in naturalistic social groups, the time females spend near males is strikingly correlated with estradiol levels, increasing as estradiol increases, declining as estradiol declines, and inversely correlated with progesterone levels, declining rapidly as luteal progesterone increases during the ovarian cycle (Wallen, et al., 1984). In naturalistic social groups of monkeys, females initiate more than 90% of all copulatory episodes during the fertile portion of their cycle (Wallen, et al., 1984). They typically initiate sex by approaching and sitting near males where if the male is not responsive they may stimulate him be staccato movements such a suddenly standing up, or slapping the ground to solicit copulation (Wallen, et al, 1984). As shown in Figure 4, the pattern of sexual initiation seen in female rhesus monkeys across the ovarian cycle is strikingly similar to the menstrual cycle variation seen in increased sexual desire reported by women (Stanislaw & Rice, 1988). Additionally, estradiol in ovariectomized female rhesus monkeys reinstates female sexual initiation, even when males are not sexually responsive, strongly supporting that this behavior reflects female sexual desire (Zehr, Maestripieri, and Wallen, 1988).

![Figure 4 Top: The number of women reporting sexual desire for the first time in their ovarian cycle in relation to ovulation (data from Stanislaw and Rice, 1988). Bottom: Mean frequency of female macaque approach (closed circles) and sexual solicitation (open circles) of males in relation to the female’s mid-cycle estradiol peak (data from Wallen et al., 1995).](image-url)
While data in monkeys strongly support the role of estradiol in female sexual motivation, and so far provide no evidence for a facilitating role for progesterone, it is the precursor of estradiol, testosterone, which has gotten the greatest attention in women. Studies from the 1930's and '40s reported that testosterone treatment increased libido (Salmon and Geist, 1943) However, these treatments used massive doses of testosterone resulting in deepening of the women's voices and clitoromegally. While this was seen as a therapeutic treatment, there was no known source for such levels of T in women. This changed in 1959 when Waxenberg Drellich and Sutherland reported that adrenalectomized and ovariectomized women reported significantly less sexual intercourse than did women ovariectomized only and concluded that ovarian hormones were unimportant and that adrenocortical androgens were the source of libido in women. Leaving aside that this study was done in women with terminal cancer, who received adrenocortical androgens were the source of libido in women. When reported changes in sexual desire. When reported changes in sexual desire instead of sexual intercourse were compared, this study actually provided the first evidence for the importance of ovarian hormones in women's sexual desire. When reported changes in sexual desire instead of sexual intercourse were compared, they were significantly reduced following ovariectomy, whereas intercourse frequency was not. This likely reflects the capacity of women to engage in sex whether or not they desire sex, something which is not possible in rats and other laboratory species. Although there was evidence in this study that ovarian hormones influenced female desire, this was unrecognized until Sherwin's landmark studies which definitively demonstrated that ovariectomy dramatically reduces or eliminates female sexual desire (Sherwin, Gelfand, and Brender, 1985; Sherwin and Gelfand, 1987). These studies also seemed to show that testosterone combined with estradiol reinstated women's sexual desire, whereas estradiol alone did not. The notion that in women, T is the libidinal hormone has become well entrenched, leading several pharmaceutical companies to develop potential T therapies for HSDD, though none have received approval for treatment in the US.

A recent survey of all random double blind studies of hormonal therapy in surgically or naturally menopausal women found that T combined with low levels of E was successful in reinstating sexual desire in women, but that E alone was effective in two of the three studies in which women were not hypoestrogenic (Alexander et al., 2004). Because of concerns about the long term consequences of estrogen therapy, few human studies use estradiol levels that would not be considered hypoestrogenic. Thus it is not possible to tell whether the effectiveness of combined estrogen and androgen therapies reflects an aromatization of the testosterone or some sort of synergism. In female rats, testosterone is capable of synergizing with estradiol to induce a full state of female sexual desire and receptivity (Jones et al., in press). This is true in ovariectomized female rats and gonadally intact females over the age of 15 months, after their ovarian steroid output has become acyclic. The exact physiological role of this synergism is still not known.

2. ANTICIPATORY MOTOR RESPONSES.

Male rats in bilevel chambers (Figure 3) display an increase in level changing in anticipation of the arrival of a sexually receptive female (Pfaus, Mendelson, & Phillips, 1990; van Furth & van Ree, 1996a,b). Typically, males are placed into the testing chamber for a 5-min adaptation period prior to the placement of a receptive female. The anticipatory behaviors develop naturally over a few trials but do not develop if the chamber is baited with an ovariectomized (nonreceptive) female or another male. Dopamine receptor antagonists decrease the number of anticipatory level changes displayed by male rats in bilevel chambers at doses that do not alter copulatory responses once receptive females are placed into the chamber (Pfaus & Phillips, 1991). Interestingly, a loss of desire and interest in sex is a common complaint among patients taking these drugs as major tranquilizers (Crenshaw & Goldberg, 1996). Long-term use of the stimulant drug cocaine is also reported to decrease sexual desire in men (MacDonald et al., 1988; Siegel, 1982; Washton & Gold, 1984). We have recently found that long-term administration of cocaine to sexually active male rats decreases conditioned level changes progressively over time (Pfaus et al., in preparation).

III. INSTRUMENTAL RESPONDING FOR PRIMARY OR SECONDARY SEXUAL INCENTIVES

All animals will work to obtain sexual rewards, and such behavior can be viewed as analogous to desire. Sexual rewards may come in the form of primary reinforcers (e.g., orgasm in humans; ejaculation in male rats or pacing in female rats), or secondary reinforcers, such as stimuli associated with sexual gratification (e.g., certain facial features, clothes, or smells in humans; certain odors or place cues in rats). In male rats, those behaviors have included performance in obstruction boxes (Jenkins, 1928; Moss, 1924; Stone, Barker & Tomlin, 1935; Warner 1927), straight-alley running (Beach & Jordan, 1956a; Sheffield, Wulff, & Backer, 1951; Ware, 1968), maze learning (Drewett, 1973; Eliasson & Meyerson, 1975; Hetta & Meyerson, 1978; Kagan, 1955; Meyerson & Lindstrom, 1973; Warner et al., 1991; Whalen, 1961), crossing of electrified grids (Moss, 1924), nose-pokes, and other attempts to “get to” a potential sex partner behind a wire-mesh screen (Damsma et al., 1992; Pfaus et al., 1995; Pfaus et
Some appetitive instrumental sexual responses are expressed easily, without much prior experience (e.g., nose-pokes, digging, obstruction box performance, crossing electrified grids), whereas others require some degree of training (maze learning, bar pressing). Those behaviors can be reduced following castration, indicating that gonadal steroid actions in the brain are necessary for their development and/or maintenance, or following lesions of certain steroid-concentrating brain regions, e.g., basolateral amygdala (Everitt et al., 1987; Nissen 1929). They can also be reduced after a devaluation of the reward offered by the incentive the male is working for (e.g., switching from receptive female to no female, an extinction procedure), or following infusions of dopamine antagonists to the nucleus accumbens (Everitt, 1990; Mendelson & Pfaus, 1989). Restoration of bar pressing in male rats with lesions of the basolateral amygdala can be made following infusions of amphetamine to the nucleus accumbens, indicating that mesolimbic dopamine release is critical for the expression of that behavior, and suggesting that the extensive glutamate projections from basolateral amygdala to the nucleus accumbens modulate dopamine release (Everitt, 1990). Dopamine antagonists administered systemically to male rats reduce running speed in a runway that leads to a goal box containing a sexually receptive female (López & Ettenberg, 2001). Antagonists infused to the medial preoptic area of the hypothalamus disrupt maze learning for sexual reinforcement in male rats (Warner et al., 1991). It is likely that different dopamine terminal regions play a role in different types of unconditioned and conditioned sexual activity. Although many of these paradigms have been in the literature for over 50 years, they have not been mined extensively by sex researchers to study the effects of drugs that activate or inhibit other neurotransmitter systems. Likewise, they have been applied sparingly to females. Bermant (1961) and Bermant and Westbrook, (1966) reported that female rats would bar-press for access to gonadally-intact, sexually active males. More recently, Matthews et al. (1997) reported that access to intromissions from a male that were made contingent on poking a lever with the nose increased the incidents of nose-poking in sexually receptive female rats. Contingent access to male bedding or emulsified preputial gland did not support increases in behavior, indicating that the copulatory stimulation was rewarding. The paradigm used by Matthews et al. ensured that females could control or “pace” the rate of copulation, a characteristic of copulatory interaction that female rats find rewarding (see below). Becker and colleagues (Becker, Rudick, & Jenkins, 2001; Jenkins & Becker, 2003; Mermelstein & Becker, 1995) found increased dopamine release in the striatum and nucleus accumbens of females that had to press a lever to gain access to a male, or run back and forth from behind an opaque barrier, relative to females that did not. Indeed, lesions of the striatum reduced the efficiency of females to pace the copulatory interactions, whereas lesions of the nucleus accumbens resulted in females that avoided sexual contact (Jenkins & Becker, 2001).

1. SEXUAL PREFERENCE PARADIGMS.

Sexual desire can be inferred from the strength of preference made toward particular features of a person or conspecific, or toward a place in which potential sex partners have been found in the past. As with other instrumental responses, preferences are typically displayed prior to sexual interaction so that animals and people can focus their forward trajectories toward sexual incentives. In humans, preferences exist for gender, and within gender for certain individually-defined physical features that people find attractive (shape of face, smile, eye or hair color, body type, etc). Preferences also exist for scents, for certain types of clothing, even for fetish objects. There are likely as many combinations of these as there are people, and the role of such preferences is to focus the attention of individuals on other individuals so that sexual interactions can occur. Some preferences are determined by particular cultures or epochs within a culture, whereas others are learned during a critical period of sexual behavior development, especially during an individual’s first sexual experiences. Some may be genetic. However, what is clear is that the association of particular features with sexual gratification entices people to seek out those features in future sexual interactions, even if those interactions are made at a distance or are part of a rich fantasy life. We would never deny that preferences exist in humans that are conditioned by experience; yet arguments continue to be made that the sexual preferences of animals (and even humans) are hard-wired for ultimate reproductive success and fitness, rather than more proximate rewards, such as sexual pleasure (e.g., Buss, 1994; Symons, 1979). Is this true? Certainly animals do not exist within a social organization that approximates human culture, and therefore are not subject to moral restrictions or the whims of advertising executives. However, recent evidence indicates that animals do show preferences for specific fea-
tures, many of which are learned during experience with sexual reward, rather than driven instinctually to maximize reproductive fitness. This latter dimension represents an exciting new foray into a level of animal behavior that approximates our own.

Some preferences seem instinctual and hard-wired by hormonal influences on the brain. For example, numerous studies have shown that male rats spend more time near sexually receptive compared to nonreceptive females (Edwards & Einhorn, 1986; Hetta & Meyerson, 1978; Merkx, 1984). Likewise, sexually receptive females spend more time near gonadally intact, sexually active males versus castrated, sexually inactive males (Gilman & Westbrook, 1978). Male rats also show unconditioned preferences for the odors of sexually receptive versus nonreceptive females (Bakker, van Ophemert, & Slob, 1996; Carr, Wylie, & Loeb, 1970; Stern 1970). These studies have been conducted in Y-mazes, T-mazes, radial-arm mazes, or open fields, that contain goal boxes baited with feathered receptive versus nonreceptive conspecifics (e.g., Gilman & Westbrook, 1978), different conspecifics behind wire-mesh screens (e.g., Ågmo, 2003a,b; Bakker, van Ophemert, & Slob, 1996), or in which different anesthetized stimulus animals are contained at opposite ends (e.g., Landauer, Wiese, & Carr, 1977). Castration of male rats abolishes their preference to remain near a sexually receptive female, whereas replacement with testosterone restores the preference (Ågmo, 2003a). Moreover, intact, sexually experienced males display significant preferences for sexually receptive females versus nonreceptive females and for sexually receptive females versus males, but not for sexually nonreceptive females versus males. Those data suggest that amount of time spent near the receptive female is based on the intensity of her olfactory cues. Indeed, Ågmo reported that the intensity of preference for a live receptive female could be generated by bedding that contained estrous odors, suggesting that olfactory cues are important sensory determinants of incentive value in the rat. Estrous odors are known to induce dopamine release unconditionally in the nucleus accumbens of intact, sexually inexperienced male rats (Mitchell & Gratton, 1991, 1992; Wenkstern, Pfaus, & Fibiger, 1993), and such odors increase neural activation in several key brain regions known from lesion studies to be critical for male sexual behavior, including the medial preoptic area, bed nucleus of the stria terminalis, medial amygdala, nucleus accumbens, and ventral tegmental area (Bialy & Kaczmarek, 1996; Bressler & Baum, 1996; Kippin, Cain & Pfaus, 2003; Newman et al., 1997; Pfaus & Heeb, 1997, Swann & Fiber, 1997; Veening & Coolen, 1998).

The studies of Mitchell and Gratton (1991, 1992) are of particular interest because they suggest that endogenous opioid release in the ventral tegmental area occurs in response to estrous odor cues, and this release in turn disinhibits ascending mesolimbic dopamine neurons. However, systemic treatment with a dopamine agonist or antagonist (amphetamine, cis-flupenthixol) or opioid agonist or antagonist (morphine, naloxone) did not alter the amount of time sexually experienced males spent near a sexually receptive versus nonreceptive female in an open field, except at higher doses that induced motor deficits (Ågmo, 2003a). Although Ågmo’s data suggest that dopamine and opioid systems are not necessary for the processing of unconditioned incentive cues, infusions of the dopamine antagonist cis-flupenthixol to the ventral tegmental area of male rats decreases the percentage of time spent near a sexually receptive female in an X-maze (Warner et al., 1991), and infusions of the dopamine antagonist haloperidol to the nucleus accumbens or medial preoptic area decreases conditioned level changing in bilevel chambers (Pfaus & Phillips, 1991). It is also known that sexually experienced males are relative resistant to many treatments that disrupt sexual behavior in inexperienced males, including castration, pentile anesthesia, novelty of a testing chamber, olfactory deprivation, and age (Gray, Smith, Dorsa, & Davidson, 1981; Lisk & Heiman, 1980; Lodder, 1975; Pfaus, Kippin, & Centeno, 2001; Pfaus & Wilkins, 1995; Thor & Flannelly, 1977). It is not clear whether experience may have buffered Ågmo’s males from the effects of dopaminergic or opioid drugs.

The kinds of studies outlined above are considered “pure” measures of preference because they are not confounded with copulation. However, that fact leads to the question of what is actually being studied. Meisel and Sachs (1994) note that, in the absence of the opportunity to engage in sexual behavior, the choice to spend time near one conspecific over another could reflect sexual preference, but could also be measuring social affiliation, opportunity to engage in aggression, curiosity, or a reaction to other incentive aspects of the stimulus animal that have nothing to do with sexual behavior. This concern was partially addressed in the study mentioned above by Ågmo (2003a): Sexually experienced males displayed selective preferences for sexually receptive females, but had no preference when the choice was between sexually nonreceptive females and other males. Indeed, although these kind of preferences are displayed by sexually naive males, they are not as strong as those displayed by sexually experienced males (Carr, Loeb & Wylie, 1969), indicating that sexual experience increases the incentive value of sex-related odors in the rat. Repeated exposure to estrous odors are known to sensitize mesolimbic dopamine release (Mitchell & Gratton, 1992), and intermittent exposure to amphetamine, which also sensitizes mesolimbic dopamine release, facilitates copulatory behavior in sexually naive male rats (Fiorino & Phillips, 1999).

Some preferences are not instinctual, in the sense
of being hard-wired, but rather reflect a process of Pavlovian conditioning in which neutral stimuli associated with sexual reward become conditioned sexual incentives. Such conditioned preferences can be assessed along with copulation in sequence. For example, studies by Domjan and colleagues have examined conditioned preferences in the seasonally-monogamous Japanese quail. Male Japanese quail respond differentially to females based on the presence of stimuli previously paired with copulation. Nash and Domjan (1991) allowed male quail to copulate with females of two strains of quail that have different plumage color (brown versus blond). Subsequently, males chose to spend more time in the proximity of females whose color was the same as that of females with whom they had copulated previously. Similarly, males allowed to copulate with females that were adorned with bright orange feathers subsequently spent more time near, and engaged in more sexual activity with, females similarly adorned compared to unadorned females. Moreover, males trained with adorned females attempted to copulate with a taxidermic model of a female quail, but only when it was adorned with the same color feathers (Domjan, O’Vary, & Greene, 1988). Domjan and Hall (1986) also demonstrated that males would stay in the vicinity of a window in their home cage through which they could see a sexually receptive female during a precopulatory period. However, this behavior developed only if the males had the opportunity to copulate with the female after the precopulatory period. A variant of this procedure, similar to that used to study anticipatory motor responding in rats, was used by Balthazart and colleagues to study the role of hormones and brain dopamine systems in conditioned sexual behavior in quail. Male quail were placed into a chamber that contained a window and sliding door at one end through which the male could see a sexually receptive female. After a 10-min period, the sliding door opened, and the animals could interact freely (Balthazart et al., 1995). As in Domjan and Hall (1986) and Mendelson and Pfaus (1989), only males that copulated with the females during this period developed the behavior, in this case, a preference to stay close to the window in the precopulatory period of subsequent tests. Castrated males did not develop this conditioned proximity behavior, nor did males that did not copulate. Castration also reduced the time spent near the window males trained prior to castration, and subsequent replacement with testosterone or estradiol restored the behavior. Subsequently, Castagna, Ball, & Balthazart (1997) reported that nomifensine, a dopamine reuptake inhibitor, decreased the appetitive social proximity response, but increased the frequency of mount attempts. In contrast, amfonelic acid, a compound that enhances dopaminergic tone, increased aspects of both appetitive and consummatory sexual behaviors. Thus, brain dopamine systems in birds and mammals seem to have analogous functions in the control of appetitive or conditioned sexual behaviors.

We have developed a model to examine the role of associative learning on sexual partner preferences in male and female rats during sexual interaction. Kippin et al. (1998) trained male rats to associate a neutral odor (almond or lemon extract) with copulation to ejaculation in either unilevel or bilevel pacing chambers (Figure 2, 3). The odor was dabbed around the back of the female’s neck and anogenital area, two regions that the male reliably places his nose during copulation. Males in several control groups were either not exposed to the odor or had the odor randomly paired with sexually receptive and nonreceptive females. On a final test, each male was presented with two receptive females in a large open field (Figure 5, top).

![Figure 5: Open field partner preference paradigm.](image)

Top: Males are placed into the open field for 5 min, after which two receptive females, one bearing a conditioned cue (e.g., odor) and one without the conditioned cue are presented at opposite corners. Latency and frequency measures for mounts, intromissions, and ejaculations are then calculated for each female during a 30-min test. Choice of female for first mount, intromission, or ejaculation, and the distribution of these measures across the test, are then determined for each male.

Bottom: The same preference test for females. Females are placed into the open field that already contains two sexually vigorous males, one bearing the conditioned cue and one without the cue. Because males tested in pairs with a single female will crawl over one another, they must wear rodent jackets that are tethered to opposite corners of the open field by a spring. Females can then “sample” both males, or display a preference for a single male by staying in his vicinity. Latency and frequency measures for mounts, intromissions, and ejaculations are calculated for each male, along with appetitive measures of solicitation and hops and darts, and defensive responses. Choice of male for first mount, intromission, or ejaculation, and the distribution of these measures across the test, are then determined for each female.
One female was scented with the odor, whereas the other was left unscented. The males were allowed to copulate freely with both females for 30 min. Males in the control groups did not show a preference for either female for first mount, intromission, or ejaculation, or for the total number of mounts, intromissions, or ejaculations displayed throughout the test. In contrast, although males in the paired group did not show a preference of female for mounts or intromissions, they chose the scented female for their first ejaculation, and displayed significantly more ejaculations overall with that female compared to the unscented female.

Thus, a simple odor-conditioning paradigm reversed what is typically considered a hard-wired biological predisposition in the polygamous male rat to prefer a novel partner over a familiar partner (Symons, 1979).

Subsequent studies identified the postejaculatory interval, rather than ejaculation per se, as the critical unconditioned stimulus for the development of this preference (Kippin & Pfau, 2001a). Significant conditioning also occurred after the male’s very first ejaculation, although it was considerably stronger if the males had multiejaculatory trials with the scented female (Kippin et al., 2001). Males were found to become “choosy” during their last few mounts before ejaculation (Kippin & Pfau, 2001b), and males in the paired group were more likely to attempt to mount sexually nonreceptive females scented with the conditioned odor, indicating that the odor acquired conditioned excitatory properties. When presented alone, the conditioned odor activated regions of the brain associated with olfactory processing and reward, including the main olfactory bulb, main olfactory (piriform) cortex, basolateral amygdala, and core of the nucleus accumbens (Kippin, Cain, & Pfau, 2003). Those findings suggest that estrous odors and sexually-conditioned odors are processed by distinct pathways that may converge in the ventral striatum. Finally, males showed greater conditioning in unilevel pacing chambers bisected by 1-hole versus 4-hole dividers (Ismail et al., 2009). Given that males take longer to ejaculate in 1-hole chambers, and require more intromissions prior to ejaculation, those data suggest that sexual reward is greater when it rides on a higher level of arousal.

We have found similar results in female rats (Coria-Avila et al., 2006, 2007). In those studies, the odor was paired with a different unconditioned stimulus: The ability of females to pace the copulatory contact. This was done using a unilevel pacing chamber bisected by a 4-hole divider. During training, females in the paired group received sequential access to scented males on one side of the divider or unscented males with no divider, on alternate testing days. Females in the explicitly unpaired group received the opposite order of experience. On the final test, each female was placed into an open field with two intact, sexually experienced males, both tethered to opposite sides of the open field (Figure 4, bottom). One male was scented and the other was not. Females in both groups were significantly more likely to solicit and receive their first intromissions from the male paired with pacing. However, only females in the paired group showed a significant preference to stay with that male for their first ejaculation; females in the unpaired group did not show a conditioned partner preference. The selective copulation and mating behavior on the part of females in the paired group would be expected to assure paternity (Coria-Avila, et al., 2005). The development of conditioned partner and ejaculatory preferences is disrupted by treatment with the opioid antagonist naloxone during training in both male and female rats (Coria-Avila et al., 2008a; Ismail et al., 2009). In contrast, treatment with the dopamine antagonist flupenthixol disrupts conditioning in females, but not males (Coria Avila et al., 2008b; Ismail et al., 2009).

2. DESIRE IN COPULATORY MEASURES.

Sexual desire can also be inferred from certain unconditioned copulatory measures. For example, the rate at which female rats will solicit and pace their copulatory contact with males, and the willingness of males to chase females, can be considered analogues of desire (and possibly arousal). These measures can be recorded unambiguously in bilevel chambers, pacing chambers, mazes, or choice boxes (e.g., Ågmo, 2003). Solicitations by the female usually result in mounts and intromissions by the male. Following intromission, the female runs away in order to “pace” the rate of copulation. In an open field or in bilevel chambers, the male typically chases her until she stops again and holds a lordosis crouch, allowing him to mount. If the male stops chasing, then she will have to solicit to initiate another bout of copulation. Essentially, pacing refers to the amount of temporal distance the female keeps from the male between bouts of copulatory activity. This measure is inversely related to her degree of sexual interest; for example the timing between intromissions increases with successive intromissions, and increases dramatically following several ejaculations (Pfaus, Smith, & Coopersmith, 1999). Rates of pacing are also much larger in ovariectomized female rats primed with estrogen but no progesterone, relative to females primed with both hormones. To the extent that solicitation and pacing reflect inversely a general desire for sexual contact, then experimental treatments that increase solicitations and/or keep pacing durations low, may increase desire in women. For example, ovariectomized female rats primed with estrogen and progesterone, or estrogen alone, and administered the melanocortin agonist bremetanotide, display a dramatic and selective increase in solicitations (Pfaus et al., 2004). This drug increased vaginal arousal in women viewing a female-centric...
erotic film, and increased the ability of women with lifelong HSDD to initiate sex with their partners (Diamond et al., 2006). This finding was a landmark in that solicitations in female rats had predictive validity as a model of sexual desire in women.

Another feminine copulatory behavior that is taken as a measure of the willingness to have sex is lordosis, the arching of the back displayed by female rats (and other species) that indicates their sexual “receptivity” (Beach, 1976). More is known about the hormonal, neurochemical, and neuroanatomical control of lordosis than any other mammalian sexual behavior (Pfaff, 1980; Pfaff et al., 1994). This reflex is dependent on estrogen, although treating ovariectomized females with estrogen alone produces only a moderate activation of the reflex in response to flank stimulation by the male. Full receptivity depends on additional activation by progesterone. Indeed, so does the full expression of proceptive behaviors like solicitation, and the normally low expression of pacing (Beach 1976; Pfaus, Smith, & Coopersmith, 1999). Drugs that bind to D1 dopamine receptors, α1 adrenergic receptors, oxytocin receptors, 5 opioid receptors, or GABA receptors in certain hypothalamic brain regions can increase lordosis in ovariectomized rats primed with estrogen alone, e.g., (see Kow, Mobbs, & Pfaff, 1994; Pfaff, 2000; for reviews). These substances may work on neurochemical substrates normally activated by progesterone, or could work via cell-signalling cascades that activate progesterone receptors (e.g., as has been described by Mani et al., 1994, for dopamine in the ventromedial hypothalamus). If these drugs also enhance solicitations and delay the increase in pacing normally observed at the beginning of estrus termination, they might stand as suitable candidates for the treatment of HSDD.

In males, the willingness to mount, intromit, and pursue females, can be used as analogues of male desire. Several drugs are known to decrease mount and intromission latencies in sexually naive or sluggish male rats, including the opioid receptor antagonist naloxone, (Gessa et al., 1979; McIntosh et al., 1980; Pfaus & Gorzalka, 1987). Although chasing behavior displayed by male rats in open fields or bivel-level chambers has not been studied in detail, it was noted that dopamine antagonists reduced this behavior in bivel-level chambers at doses that did not alter the initiation of copulation (Pfaus & Phillips, 1991).

IV. MODELS OF SEXUAL REWARD

How do we infer sexual reward in animals? There are at least three ways. The first involves assessments of operant or instrumental responding for a particular sexual reinforcer. Anything an animal must do to get closer to, or obtain, the reward can be assessed in this manner. In rats, this would include behaviors like nose-poking through a wire-mesh screen, navigating obstruction boxes or complex mazes, or bar-pressing for first- or second-order reinforcers. The inference here is simple (albeit circular): if the animal will work for it, it must be reinforcing. But Meisel and Sachs’ caveat for understanding preference without copulation also applies here: without knowing what animals will actually do with the reinforcer once they obtain it, it is difficult to know exactly what the motivation was behind the responding and hence difficult to specify what was rewarding about the stimulus in the first place. Consider male rats with bilateral lesions of the medial preoptic area. Those rats display normal or even elevated rates of anogenital investigation of a receptive female, and will pursue females if solicited (Heimer & Larsson, 1967; Everitt et al., 1987). They will even bar-press at high rates to obtain second-order sexual reinforcers (Everitt & Stacey, 1987). However, they cannot translate that arousal and desire into copulation. The female is clearly a reinforcer, but the males cannot do the one thing required to “prove” that it is sexual.

1. REWARD IN COPULATORY MEASURES.

The second way to infer sexual reward is based on copulatory activity. Indeed, solicitation and pacing in female rats, and courting, chasing, or other copulatory rate measures in male rats, can all be construed as indices of the reward value of the stimulus animal. These behaviors are also operants in the sense that animals must perform them in order to achieve the goal of copulatory interaction/sexual stimulation. Beach (1956) originally proposed that two separate but interactive sexual mechanisms existed in male rats, an Arousal Mechanism (AM) and Copulatory Mechanism (CM). The AM integrated distal olfactory, auditory, and visual cues from receptive females. When the cue strength became sufficiently intense, the AM activated the CM to initiate copulatory responding (mounts and intromissions). The CM then integrated somatosensory stimulation from the penis with each vaginal intromission, leading eventually to ejaculation. Given the fact that sexually naive males can show preferences for receptive females, and that they are responsive to sex odors from receptive females, the first unconditioned reinforcer in the cascade of sexual reinforcers would be sex odors. The goal would be getting to them. In Beach’s terms, this would be the primary function of the AM. But what about copulation? Whalen (1961) asked what the necessary stimulation must be for the development of copulatory behavior. The answer was penile stimulation. Whalen varied whether males achieved mounts without intromission, intromissions without ejaculation, or intromissions with ejaculation, with sexually receptive females. On a final test, males were allowed to copulate to ejaculation with receptive females. Many rats that achieved only mounts during their sexual experience trials did not copulate, whereas rats that achieved intromissions with or without ejaculation were able to copulate to ejaculation normally. Thus, exposure to sex odors alone was not...
sufficient to crystallize patterns of copulation; sensory feedback from penile stimulation was necessary. This makes penile stimulation a second goal or reinforcer in the cascade (and the first of the CM).

Related to penile stimulation is the fact that the male is chasing a moving target: A soliciting and pacing female generates much excitement for the male during copulation. As mentioned above, the female often directs the behavior of the male by forcing him to chase her. Pacing behavior in bilevel chambers typically increases dramatically as the male approaches ejaculation, in a natural expression of Larsson’s “Enforced Interval Effect” (Pfaus, Smith, & Coopersmith, 1999). This increased pacing almost always results in the male ejaculating. Everitt (1990) reported that sexually vigorous male rats given subthreshold neurochemical lesions of the mesolimbic dopamine system initiated copulation normally with sexually receptive and proceptive females. However, if the females were treated with the dopamine receptor antagonist flupenthixol (which has the effect of prolonging the time spent in lordosis and eliminating proceptive solicitation and pacing), the males took significantly longer to initiate copulation.

The next copulatory goal or reinforcer is ejaculation. López, Olster, and Ettenberg (1999) asked whether sexually naive rats would show decreased run times in a straight-arm runway if their prior copulatory experience was intromissions with or without ejaculation. Only rats that achieved ejaculation showed decreased run times. Thus, it would seem that a cascade of reinforcing events, from perception of sex odors to chasing receptive females to penile stimulation during mounting to ejaculation, is necessary for the normal display of appetitive and consummatory sexual responses. However, ejaculation itself may not be the final endpoint in the cascade of copulatory reinforcers for male rats. In the odor-conditioning studies mentioned above, the postejaculatory refractory period was identified as the necessary unconditioned stimulus for the development of the preference in the paired groups (Kippin & Pfaus, 2001a). Ejaculatory preferences developed only if males were allowed to be in close proximity of the odor during the postejaculatory period. If the females were removed immediately after ejaculation, no preference developed. Moreover, if males were allowed to achieve only 5 intromissions without ejaculation prior to the removal of the scented female, they displayed the opposite preference in the final choice test and ejaculated preferentially with the unscented female (despite having never had access to an unscented receptive female before). Finally, a small but significant ejaculatory preference developed if males copulated with an unscented female but had her replaced with a scented female during the postejaculatory refractory period. Thus, ejaculation induces a powerful reward state that occurs during the postejaculatory interval.

Experience with an ejaculatory sexual reward can also alter the incentive properties of an unconditionally aversive odor (cadaverine) applied to the neck and anogenital region of female rats (Pfaus, Kippin & Centeno, 2001). During conditioning trials, male rats copulated with cadaverine-scented females. Subsequently, when males were given a final open-field test with two receptive females, one scented with cadaverine and one unscented, males in the paired group did not show any preference for either female. In contrast, males in the unpaired group copulated exclusively with the unscented female, despite aggressive solicitations and interceptions by the scented female. Indeed, in a final test, males in the paired group would approach and chew on a wooden dowel scented with cadaverine, whereas males in the unpaired group, or in a cadaverine-alone preexposure group, would avoid contact with the dowel, or would bury the dowel in bedding. Pairing an aversive stimulus with drug reward has been shown previously to induce taste preferences for initially nonpreferred flavors (e.g., a bitter taste paired with the consequences of morphine in rats; Zellner et al., 1983). The same basic phenomenon, pairing sexual reward with a highly arousing circumstance -- whether aversive or appetitive, painful or pleasurable -- may underlie human sex behavior preferences or fetishes (see Krafft-Ebbing, 1928).

Conditioned partner and place preference. Contextual factors such as settings are important components of positive sexual experiences for both men and women (e.g., Basson, 2001; Hoon, 1984; Kinsey, Pomeroy, & Martin, 1948; Kinsey, Pomeroy, Martin, & Gebhard, 1953; McCarthy, 1977). Salient cues in the environment or on partners may be associated with sexual reward in such a way that they increase arousal or desire directly in their presence. Accordingly, the third way to infer sexual reward is to examine responses made toward contextual or partner-related cues paired with sexual reward. With animals, this can be done using the conditioned partner or ejaculatory preference or place preference (CPP) paradigms. Animals often display a preference to remain in a context that has been paired consistently with access to a reward (e.g., drugs of abuse, highly palatable foods, a mate) over a context that has not. This type of CPP is typically demonstrated in an apparatus with two distinctive compartments that are connected to either side of a third neutral compartment. During training, the compartments are paired differentially with unconditional stimuli, (e.g., one side is paired with a sex partner, food, or a rewarding drug, and the other side is paired with either nothing or a control manipulation). On the final test, the subject is placed into the neutral compartment with the two doors on either side opened to allow free access to either compartment (Figure 6).

In male rats, sexual CPPs have been established...
The compartment paired with copulation is preferred over the other compartment (e.g., Ågmo & Berenfeld, 1988). A CPP induced by this procedure is referred to as a “postejaculatory CPP”. Demonstrations of postejaculatory CPPs might appear puzzling at first glance because the conditioned stimulus (i.e., the distinctive environment) is presented after the unconditioned stimulus (copulation to ejaculation), in what learning theorists call “backward conditioning” (that would not be expected to yield conditional responding to the environment). However, if the neural reward state induced by ejaculation is the unconditional stimulus, then the pairing of environmental cues with it is simultaneous. Thus postejaculatory CPP can be accounted for by the rules of Pavlovian conditioning.

CPPs have also been demonstrated in female rats and hamsters. Oldenburger et al. (1992) found that when copulation occurred within one of the distinctive compartments of a CPP apparatus, female rats showed only a weak CPP. Conversely, Paredes and Alonso (1997) and Paredes and Vazquez (1999) demonstrated a robust CPP in female rats that depended on whether the females were able to pace the rate of copulation without having to employ defensive behaviors. This was accomplished using unilevel pacing chambers, in a Plexiglas divider bisects the chamber (e.g., Figure 3). The divider contains one or more holes that only the female can pass through. This allows her to pace the rate of copulation by moving freely from side to side. Like males, females acquired a strong preference for a distinctive environment only if they were placed into the CPP box immediately after paced copulation. No preference was found if the copulation was unpaced prior to placement in the CPP box (meaning that it had occurred in the same pacing chamber but without the divider). Thus, for a female rat, CPP develops only if she has been able to control the initiation and rate of copulation freely without having to use defensive behaviors. Although a sexually vigorous male rat is a clear unconditioned stimulus for approach and solicitation in female rats (e.g., Ågmo, 1999), contextual cues associated with pacing elicited a conditioned sexual reward state in those females. However, these results may also indicate the presence of an unconditional aversive state during unpaced copulation. To examine this possibility, Afonso, Woehrling, and Pfaus (2003) allowed female rats to copulate in two paced conditions using Plexiglas dividers that had either 4 holes or 1 hole. This was done to eliminate the possibility of an “aversive” state resulting from unpaced copulation. Trials were conducted sequentially at 4-day intervals, and each pacing condition was paired with one of the distinctive sides of a CPP apparatus, in a counterbalanced fashion. Control groups contrasted the 4-hole condition with no divider, or the 1-hole condition with no divider (as was done by Paredes and colleagues).
Control females developed significant CPP for either the 1-hole or 4-hole condition, relative to unpaced copulation with no divider. Those control data replicate the findings of Paredes and colleagues, and indicate that both the 4-hole and 1-hole condition are rewarding relative to the unpaced (no divider) condition. However, they do not rule out the possibility that the real distinction being made is between an aversive condition (unpaced copulation) and a rewarding condition (paced copulation). This was addressed in the group allowed to contrast the 4-hole versus 1-hole condition. In this group, females developed significant CPP for the 4-hole condition, relative to the 1-hole condition, suggesting strongly that copulatory CPP reflects a true sexual reward state in females. Similarly, Jenkins and Becker (2003) found that female rats developed significant CPP for paced relative to unpaced mating, but also for unpaced mating in which the experimenter removed the male for a period that approximated the female’s imposed inter-intromission interval, relative to unpaced mating in which male removal did not occur. Thus, female rats develop CPP for sex at their own preferred intervals. Taken together with the results of Matthews et al. (1997), these data suggest that reward comes from the sexual stimulation that females receive, namely mounts with intromission, so long as that stimulation occurs at the desired time intervals. Accordingly, artificial stimulation of the vagina and cervix (Meerts and Clark, 2009) or clitoris (Parada et al., 2009) that is distributed in time to approximate a desired or paced interval can also induce a significant CPP in rats.

What about males? Martinez and Paredes (2001) found that males developed significant CPP if they had unrestricted access to females (as occurs in pacing chambers without a barrier). This was the opposite preference to the one developed by females in their studies. Although both copulatory and postejaculatory CPP procedures produce effects of similar magnitude in male rats, there are differences in the underlying neurobiology. The opioid receptor antagonist naloxone disrupts both copulatory and postejaculatory CPPs, but in different ways. Ågmo and Berenfeld (1988) found that the development of postejaculatory CPP was blocked by injections of naloxone prior to each training session. Conversely, the development of a copulatory CPP was unaffected by naloxone prior to each training session (Meharra & Baum, 1990). However, once a copulatory CPP had developed, its expression was blocked by naloxone injections prior to the final test (Hughes et al., 1990; Meharra & Baum, 1990). There is also evidence that the site of action of naloxone is different for these effects. Ågmo and Gomez (1993) found that naloxone’s disruption of the development of postejaculatory CPP occurred following infusions into the medial preoptic area, whereas infusions of naloxone into this brain region did not disrupt the expression of a copulatory CPP (Hughes et al., 1990). In females, naloxone blocked the acquisition of a pacing-related CPP, suggesting that common opioid systems in the brain of male and female rats is activated by sex-related cues (Paredes & Martinez, 2001). As with approach behaviors toward sex-related odors, castration disrupts the expression of a copulatory CPP on the first postoperative test in male rats (Miller & Baum, 1987; Hughes et al., 1990), and acquisition of a copulatory CPP was blocked by naloxone in castrated, but not gonadally-intact, male rats (Meharra & Baum, 1990). Endocrine responses have also been detected in male rats following exposure to contextual stimuli associated with copulation. Kamel et al. (1975) reported that serum testosterone, luteinizing hormone, and prolactin levels were elevated after 45 min of exposure to an arena in which prior copulation occurred. Interestingly, a wintergreen odor paired with copulation to ejaculation was able to elevate serum testosterone and luteinizing hormone levels relative to the same odor not paired with sexual reward (Graham & Desjardins, 1980). Dopamine antagonists have not been reported to alter the development or expression of copulatory CPPs in either male or female rats, or postejaculatory CPPs in male rats (Ågmo & Berenfeld, 1988; Portillo et al., 2001). In contrast, Meisel, Joppa, and Rowe (1996) found that the development of a copulatory CPP in female hamsters was blocked by injections of the D2-receptor antagonists sulpiride or raclopride prior to each training session. To summarize, sexual reward appears to involve the activation of brain opioid systems. In some cases, odor or contextual stimuli associated with sexual reward activate mesolimbic dopamine pathways (either to increase attention or drive goal-directed behaviors). Likewise, stimuli associated with sexual reward also activate pituitary and gonadal hormone release in male rats.

V. MODELS OF SEXUAL INHIBITION

All behaviors have a beginning, middle, and end. The end typically comes with the attainment of reward large enough to activate mechanisms of satiety. In any motivational system, reward is a dynamic function with an inverted U-shaped relationship to ongoing behavior: Low rewards do not generally sustain behavior, moderate to ideal rewards do, and high rewards induce the inhibitory feedback that characterizes satiety (Toates, 1992). With regard to sexual behavior, rewards that sustain sexual arousal and desire might be considered low-to-moderate, whereas high rewards like orgasm might be those that induce a period of sexual refractoriness. Although sexual satiety decreases sexual responding in the short term, the reward associated with it in male and female rats is necessary for the conditioning of sexual preferences in the long term.

The notion of separate (but interactive) neural systems for behavioral excitation and inhibition goes
back to the work of early neuropsychologists like Sechenov, Sherrington, and Pavlov, and more modern psychologists like Jeffrey Gray. It has important implications for motivation in general because it posits that behavior can commence either due to direct excitation or through a process of disinhibition. A “Dual Control Model” of sexual function has been advanced by researchers (Bancroft and Janssen, 2000; Perelman, 2006; Pfau, 2009) that posits excitatory and inhibitory mechanisms in the brain that interact to produce a level of sexual responsivity in all individuals during all phases of the sexual response cycle. This model stresses the adaptive nature of both excitatory and inhibitory processes. For example, the adaptive nature of sexual excitement would drive individuals to seek out sex partners for reproductive or reward purposes. The adaptive nature of sexual inhibition would guard against situations that threaten the individual, including chronically stressful life events. However, too little activation of the excitatory mechanisms, as might occur in hypogonadal individuals, or too much activation of the inhibitory mechanisms, would be expected to lead to decreased sexual motivation. The study of sexual inhibition is also critical if we are to understand how certain events or “prosexual” drugs (e.g., alcohol, cocaine) induce sexual disinhibition.

Sexual inhibition is most likely to occur in the presence of an obvious threat or a conditioned cultural proscription against the activity (complete with the possibility of getting caught). However, this raises some interesting issues regarding the arousing nature of inhibition. As mentioned above, central excitation and inhibition both activate the autonomic nervous system. A small degree of stress or threat (i.e., something “naughty” or even painful) can be arousing, especially for individuals with low levels of arousability. Translated to a sexual situation, such arousal could be “transferred” directed into sexual activity, perhaps to the point in some individuals that it becomes a necessary antecedent. Anger, fear, or even short-lived terror, can be preludes to sex because they “stir passion” or arousal. The stimuli that evoke excitation and inhibition may be different for different individuals and what inhibits one person may actually excite another.

1. PUNISHMENT AND STRESS

Although punishment with shock can suppress a variety of appetitive and consummatory behaviors in rats (Mackintosh, 1974), such punishment has never been reported to induce sexual inhibition in males (Beach & Fowler, 1959; Beach et al., 1956b; Hayward, 1957; Zimbardo, 1958). In fact, shock, short-term pain (e.g., tail-pinches), or neutral stimuli paired with them, actually stimulate mounting in sexually sluggish or inactive male rats (Barfield & Sachs, 1968; Caggiula, 1972; Crowley, Poplaw, & Ward, 1973), and reduce the number of intromissions required for ejaculation in sexually active males (Beach & Fowler, 1959; Sachs & Barfield, 1976). As mentioned above, both male and female rats will readily cross electrified grids to gain access to sexually receptive partners (Moss, 1924). Thus, punishment with shock or pain is not workable. Indeed, arousal is a necessary antecedent to sexual activity in both male and female rats. Drugs that decrease the activity of the sympathetic nervous system (e.g., α2 adrenergic receptor agonists like clonidine) decrease sexual responding in both male and female rats (Clark, Smith & Davidson, 1985; Meston, Moe, & Gorzalka, 1996).

More reliable methods of punishment have been used. Rodents live in a predominantly olfactory world, and pairing estrous odors with gastrointestinal distress (induced by contingent injections of lithium chloride that make animals sick) induces a conditioned odor aversion in males rats and hamsters that translates to avoidance of female vaginal secretions (Zahorik & Johnson, 1976), increased mount and intromission latencies (Johnson et al., 1978), decreased proportion of males that ejaculate (Peters, 1983), or avoidance of copulation altogether (Peters, 1983; however see Lawrence & Keifer, 1987). This effect occurs if conditioning took place when the males were juveniles (Koch & Peters, 1987), and conditioned males utter distress vocalizations in the presence of vaginal secretions (Peters et al., 1988). Lawrence and Keifer (1987) demonstrated robust conditioned odor aversions using a second-order pairing of almond odor with lithium chloride injections. This conditioning paradigm led males to avoid copulation with almond-scented receptive females. That this conditioning was specific to the neutral odor was demonstrated by Ågmo (2002). Conditioned males in that study were allowed to copulate with females scented with capelin oil (a “fishy” smelling oil extracted from capelin, a fatty fish found off the coast of Iceland) to 1 ejaculation, after which they were injected with lithium chloride. Subsequently, those males avoided copulating with capelin-scented females, although they continued to copulate normally with unscented females. Moreover, in subsequent partner preference tests conditioned males avoided being near capelin oil-scented receptive females, indicating that their approach behavior was inhibited. Taken together with the results of our studies on appetitive odor conditioning, these results indicate that neutral odors can become “good” or “bad” depending on their consequences.

When are animals in the wild exposed to circumstances in which they must inhibit their sexual responses? Interestingly, adult male rats in the wild are rarely observed to attempt copulation with sexually nonreceptive females (Calhoun, 1962; Barnett, 1962). This is in marked contrast to most laboratory settings in which males will attempt to copulate with nonreceptive females placed into chambers in which
the males have copulated previously with sexually receptive females. We have shown that training sexually active male rats to differentiate between sexually receptive and nonreceptive females on alternating test trials leads quickly to a substantial reduction in the proportion of males that attempt to copulate with nonreceptive females (Pfaus & Pinel, 1989). The aversive stimuli provided by the nonreceptive females include a thwarting of attempted copulations due to the female’s lack of receptivity, along with aggressive and defensive behaviors (e.g., boxing, biting, kicking) when the male attempts to mount. By virtue of the females being nonreceptive, these behaviors are paired with a lack of estrous odors. Males learn quickly to differentiate the presence of estrous odors with proceptive and receptive behaviors, and the lack of estrous odors with thwarted sexual advances and female aggression (which can be severe). In the wild, such conditioning may occur normally during adolescence. As juveniles, male and female rats mount almost anything, including one another. As the expression of this behavior transitions into adult forms, males likely attempt to mount adult females that are not in heat. Of course, those females teach the males not to try it again.

We have shown that low-to-moderate doses of alcohol can release sexual behavior from inhibition induced by pairing males with sexually nonreceptive females (Pfaus & Pinel, 1989). After learning to suppress their copulatory advances toward sexually nonreceptive females, males were treated with low to moderate doses of alcohol. Low doses of alcohol that increase the mount, intromission, and ejaculation latencies when males are paired with sexually receptive females, increased the proportion of males that attempted to mount the nonreceptive females. Moreover, many of those males ejaculated, despite never gaining vaginal penetration. However, if the alcohol dose was high enough to induce motor disruption, the males did not attempt any copulation with the nonreceptive females. These findings are of interest for several reasons, most notably because alcohol intoxication figures in high-risk sexual activity (Castilla et al., 1999; Lowry et al., 1994; McCusker et al., 1990; Steele & Josephs, 1990; Woody et al., 1999) and is one of the strongest antecedent predictors of men actually carrying out a rape (Rada, 1975; Ranieri-Collins, 1995; Ullman & Brecklin, 2000; Wild, Graham, & Rehm, 1998). In contrast, cocaine intoxication did not release sexual behavior from primary inhibition (Pfaus, Benibgui, & Wilkins, in preparation).

We have also shown that neutral odors can be paired with access to sexually nonreceptive females, or with sexual activity restricted to intromission without ejaculation, can inhibit male choice in male rats (Kippin et al., 1998; Kippin & Pfaus, 2001). Although those conditions were used as controls in our previous studies of appetitive odor conditioning, in both cases males chose to ejaculate preferentially with the unscented, rather than scented, females during the final choice test. This indicates that, despite the presence of estrous odors and vigorous proceptive behaviors of both females during the final choice test, the neutral odor had acquired sufficient aversive properties to deter the male from ejaculating with a receptive female bearing it. We have recently found that alcohol does not alter the expression of this aversive conditioning, but a low dose of cocaine can eliminate the preference for the unscented female (Pfaus, Benibgui, & Wilkins, in preparation). Given the fact that cocaine use is also implicated in uninhibited or risky sexual behavior, these data suggest that alcohol and cocaine disrupt different types of sexual inhibition.

Finally, situational stressors can be used as models of sexual inhibition in male rats. Sexually naive males are extremely sensitive to novel environments, and a high proportion of naive males will not copulate in a novel environment, despite intense proceptive behaviors displayed by receptive females (Pfaus & Wilkins, 1995). In fact, many of these males never copulate, and in the past have been discarded as research subjects by many laboratories. However, in our study, the effect of novelty was attenuated by systemic administration of the opioid receptor antagonist naloxone, or by preexposure of males to the sex chamber. Novel environments are stressors that induce naloxone-reversible analgesia (Izquierdo & McGaugh, 1987). In turn, naloxone-reversible analgesia is taken to indicate the release of endogenous opioids. Thus, the release of endogenous opioids in response to being placed into a novel environment disrupts copulation in sexually naive male rats, as if they had been administered morphine exogenously. Like treatment with naloxone, preexposure to the chamber lessened the novelty effect naturally, allowing males to copulate. However, sexual approach and copulatory behaviors were not disrupted in sexually experienced male rats placed into a novel environment, indicating that the males had acquired sufficient knowledge of the female as an appetitive sexual incentive to offset the induction of opioid release. This paradigm could be used as a model of situational anxiety in sexually naive males.

Refractoriness and sexual satiety: If male rats are allowed to copulate to sexual exhaustion, they display reduced responsiveness to female solicitations and many will not copulate to ejaculation for 24 to 48 hrs (Beach & Jordan, 1956; Larsson, 1956). This inhibition is due to neurochemical events that underlie sexual satiety, and can be partly or fully reversed with several drugs, notably the α2-adrenergic receptor antagonist yohimbine (which increases noradrenergic tone), the 5-HT1A agonist 8-OH-DPAT (which decreases serotonin release), and the opioid receptor antagonists naloxone or naltrexone (which block the binding of endogenous opioids) (Rodriguez-Manzo & Fernandez-Guasti, 1994; 1995a,b). This suggests
that increased release of serotonin and endogenous opioids, and decreased release of noradrenaline, somewhere in the brain underlies the neurochemical state of sexual satiety. Interestingly, the generation of sexual satiety can be delayed by changing the stimulus female for every ejaculatory series (i.e., by inducing a “Coolidge effect”; Rodriguez-Manzo, 1999). As with men, sexual inhibition in women can occur as a result of stress, lack of intimacy, sexual nonreward, or in the refractory state after orgasm that denotes satiety. Sexual inhibition in female rats has been explored rudimentarily in paradigms of estrus termination (in which sexual behavior is inhibited by a large amount of vaginocervical stimulation prior to testing), after subthreshold administration of ovarian hormones to ovariectomized rats (which stimulates a low level of lordosis but no appetitive behaviors), and following sexual nonreward (induced as noted above by naloxone treatment during the females’ early sexual experience). Appetitive sexual behaviors like solicitation are the most sensitive to those treatments. As the intensity of the inhibition progresses, females display increases in pacing and defensive behaviors and a decrease in high-intensity lordosis.

B. PHYSIOLOGICAL PARAMETERS CHARACTERIZING SEXUAL RESPONSES

I. FUNCTIONAL ASSESSMENT OF PENILE ERECTION IN PRECLINICAL RESEARCH

1. INTRODUCTION

Basic research on penile erection using an animal model was started at least in the latter half of the 19th century by Eckhard, who reported the relevant involvement of the pelvic nerve in erection in dogs.[1] Langley introduced the wording “autonomic nervous system” and also coined the term “parasympathetic” in accordance with his insights into the selective stimulatory action on fibers contained in the cranial and sacral outflows.[2] In the 20th century, the discipline of pelvic neuroanatomy investigation had evolved to a consensus of thought regarding the primarily important nerve plexus of the pelvis.[3] In 1968, historical advances enabled the measurement of intracavernous pressure (ICP), which was performed in bulls by Lewis.[4]

Later, to investigate erectile function, several animal models, including the use of monkeys, dogs and rabbits, were developed. In the 1980s Sjöstrand used plethysmography to quantify penile erection in rabbits.[5] and Lue’s and Goldstein’s groups conducted experiments in monkeys, dogs and rabbits to show the hemodynamic events in the penis and the crucial role of cavernosal smooth muscle.[6-8] Epoch-making experiments using commercially available small animals, rats and mice, were conducted in the last decade. Walsh is known as the pioneer of nerve-sparing radical prostatectomy in humans, and his group reported the historical first study on penile erection using rats, which enabled researchers to conduct erectile function studies easily, resulting in significant progress in this research field.[9] More recently, the first experiments that used mice were reported by Burnett’s group.[10] The use of transgenic mice has widened the physiological and pharmacological understanding of erection.[11, 12] The neuroanatomy and physiology of the penis in rats and mice was also gradually elucidated, and contemporary knowledge and techniques on animal experiments have progressed.[13]

Evaluation of erectile response in anesthetized animals

Erection is a hemodynamic event in the penis. It is the consequence of relaxation of the smooth muscle that involves both the central nervous system and local factors. The current basic concepts of erectile physiology were obtained greatly from in vivo and in vitro experiments, mostly with animals.[14, 15] In the flaccid state, the cavernous tissues are contracted by dominant sympathetic control of the arterioles and the cavernous smooth muscles.[14] Following sexual stimulation, parasympathetic nerve activity induces a blood flow increase through the cavernous artery via relaxation of smooth muscle of cavernous tissue. The inflow of a huge amount of blood induces a rapid increase in ICP. In this phase, the reflexogenic contraction of the ischiocavernous and bulbocavernous muscles also enhances the peak pressure, which rises to well above the arterial blood pressure and gives the maximal rigidity to the penis. Simultaneously, the blood outflow from the cavernous system is decreased via passive compression of veins due to sinusoid expansion (venous occlusion).[16]

The gold standard for quantitative measurement of penile erection during experiments conducted in anesthetized and conscious animals is the recording of intracavernous pressure (ICP).[17] ICP can be recorded in freely moving rats by a miniaturized telemetric device (a catheter implanted in the corpus cavernosum that is connected to a pressure transducer located subcutaneously).[18] In anesthetized animals, we have to apply some stimulation to induce erection because direct somatosensory stimulation such as estrous odor is not applicable. The most common technique to induce erection is electrical field stimulation of specific sites in the nervous system responsible for erection. As well as electrical stimulation, chemical stimulation or drug administration in the periphery or within the central nervous system, including the brain and spinal cord, is feasible in anesthetized animals to study their effects on penile erection.[17] When investigating the prorerecile effect of pharmacologic compounds in animals, certain aspects must always be taken into account. These include the dose used, route of administration, pharmacokinetics, half-life, metabolism of the studied compounds, etc.

2. INTRACAVEROUS PRESSURE MONITORING IN RATS

ICP measurement represents a direct investigation of erectile function (Fig.1). It makes the objective evaluation of even subtle erectile responses possible, but also facilitates the physiologic approach and has resulted in a new understanding of penile erection. The most common animal used to evaluate ICP is the rat.[17] The benefit of using the rat as an experimental model is the simple anatomy of the peripheral nervous system. It is easy to identify the cavernous nerve and the major pelvic ganglion (MPG), which is the origin of the cavernous nerve and the center of the pelvic nervous system. The unilateral MPG of rats consists “one ganglion.” In rats, it is not a “plexus” or a “complex of several ganglia”, which are common in other mammals.[19] Moreover, behavioral studies and the other neurophysiological
studies are possible in the same study group,[20] and many pathophysiological erectile dysfunction models are easy to make with rats such as a diabetic model, aging model, castrated model cavernous nerve injured model and so on.[21-24] The analogy of the anatomy and neurophysiology of penile erection between rats and humans is moderate compared with the reproductive organ responsible for ejaculation. Recently, the cavernous nerve distribution in humans was reported to be broad around the prostate rather than the neurovascular bundle,[25] and the importance of the ancillary nerve as well as the main cavernous nerve in rats was also reported,[26] which is one of the analogies between them.

3. SURGICAL PROCEDURE FOR MONITORING ICP IN RATS

One of the basic methods in rats is described below,[27] and the procedure for mice is basically similar to that for rats;[28] however, those in mice are generally difficult because of its size (especially in the part of carotid artery cannulation). Either rats or mice are weighed and lightly anesthetized with intraperitoneal sodium pentobarbital 30-50-mg/kg so that they breathe spontaneously during the experiment.[9, 29] It should be noted that pentobarbital is a relatively poor analgesic and leads to a decrease in blood pressure in animals with significant tachycardia compared with a mixture of ketamine and xylazine.[30]

For continuous systemic blood pressure measurements, a heparinized polyethylene catheter is introduced into the left carotid artery.[29, 31-33] Mills et al. were the first to evaluate the effect of the blood pressure (BP) or maximal arterial pressure (MAP) on ICP.[34] Since BP sometimes fluctuates during cavernous nerve stimulation due to autonomic responses. The change of BP affects the ICP via the change of blood inflow into the cavernosum; high BP leads to high ICP and low BP leads to low ICP. BP is also influenced by the degree of anesthesia. Therefore it is important to monitor the BP simultaneously and ICP should be corrected by BP and represented as normalized ICP/BP or normalized ICP/MAP (mean arterial pressure). Peripheral nerves, such as pelvic nerve, MPG and cavernous nerve stimulation possibly increased BP due to activation of pelvic nerve afferents to induce pressor responses such as that known as the vesico-vascular reflex.[35]

Figure 1 Original recording of intracavernous and arterial blood pressures when stimulating cavernous nerve. 1: flaccid state; 2: latent phase; 3: tumescence phase; 4: maximal tumescence of the corpora cavernosa; 5: detumescence phase. ICP and BP were mean values of intracavernous and arterial blood pressures during full phase. Filling rate of corpora cavernosa is slope of increase of intracavernous pressure during tumescence phase. Slope of dramatic drop of intracavernous pressure after end of stimulation represents corpora cavernosa emptying rate (Giuliano et al).
The bilateral MPG and pelvic nerves are exposed and the incision is extended to the skin around the penis. A needle connected to a polyethylene tube filled with heparinized saline is inserted into the left penile crus through the tunica albuginea and ICP is registered by means of a pressure transducer. Electrostimulation (20 Hz, pulse width 0.5 ms, 10 V) of the pelvic nerve is applied with a bipolar hook electrode and changes of ICP are measured.

4. SITE FOR ELECTRICAL STIMULATION

For in vivo evaluation of erectile function in rats, most researchers employ either an apomorphine-induced erectile response or neural electrical stimulation with or without pharmacologically induced ICP changes. Apomorphine-induced erectile function bioassay involves systemic administration of apomorphine 80 mg/kg, followed by recording of erectile responses in male rats.[36] Every site in the neural system responsible for erection can be used for electrical stimulation, from the central nervous system to the peripheral nervous system, including the medial preoptic area (MPOA) in the hypothalamus, the pelvic nerve, the major pelvic ganglion or the cavernous nerve.[37] Electrical stimulation of the MPOA was first presented by Giuliano.[38] The erection elicited by MPOA stimulation is thought to be the most physiological erection because the MPOA is the most central component for penile erection.[37] This procedure, however, is the most invasive, and requires considerable skill and experience. The basic procedure consists of fixation of a rat to a stereotaxic head holder in the flat skull position and electrode placement in the MPOA. Stereotaxic coordinates for the electrode tip are 0.1 to 0.25 mm posterior, 0.4 to 0.6 mm lateral (right) and 8.6 to 8.8 mm ventral.[39]

The erection elicited by cavernous nerve stimulation was first introduced by Quinlan.[9] The cavernous nerve is the terminal point on the neural pathway of penile erection, and just before the target organ = corpus cavernosum. Cavernous nerves in rats originate from the bilateral MPG and mainly from the posterolateral surface of the prostate toward the corpus cavernosum (Fig. 2). In the radical prostatectomy nerve-injury model, electrical stimulation of the cavernous nerve itself following cavernous nerve injury is technically difficult because it is necessary to stimulate proximal to the injured site. Thus, as stimulation sites, the pelvic ganglia and pelvic nerve located superior to the pelvic ganglia are available.[40]

The normalized ICP/BP in control or sham operated rats are listed in Table 1. Those via several stimulation sites which were done unilaterally seemed to show similar results. The mean ± SD value in peripheral nerve stimulation is 0.632 ± 0.087. Therefore, ideally normalized ICP/BP should be 0.545 at least. If the ICP/BP is far below from this in the normal control model, one should consider some problems in the procedure.

5. CAVERNOUS NERVE (CN) INJURY MODEL

Clinically, nerve-sparing technique in radical prostatectomy dramatically improves the recovery of erectile function; however, it is not sufficient to achieve the full recovery.[41] Thus, the preclinical research in this field still plays an important role.[24]

Various types of CN injury have been done in rodent animal models, especially in rats. These models were stratified by the extent of the injury, which includes crush, freezing, transection, and excision (from less severe to more severe). Table 2 shows the CN injury models, in which functional assessment by ICP was done. The least severe model is considered to be the crush model. Interestingly, however, the only exposure of CN affected the erectile function as well as the crush models.[31] The crush model and the freezing model as the nerve-sparing radical prostatectomy or the cryoablation model, does not disrupt the nerve continuity preserving the nerve sheath. As more severe CN injury models, transection/excision models were used as the non-nerve sparing or nerve construction model with a nerve graft technique.

The timing of the assessment following CN injury seems to be important for the standardization of the CN injury experiment. The time frames were different among the experiments (Table 2). Some of the transection/excision models were used to investigate the immediate effect of the CN injury, but most of these models were used for the cavernous nerve construction with a graft or a conduit. Therefore, it needed relatively longer period (around 3 months). In adulthood, each rat month is roughly equivalent to 2.5 human years, 42 thus, 3 months in adult rats roughly equivalent to 7.5 years in human. For less
severe technique which used as a nerve-sparing model, a relatively less time frame is administered. In the crush model, even animals without proerectile treatment could recover from erectile dysfunction in a long term period over 2 months, thus postoperative assessment within 1 month is generally accepted. One month in rat estimated to be 2.5 years in human. Therefore, it is a reasonable time frame for the nerve-sparing technique assessment.[43]

6. STUDY OF ERECTION IN CONSCIOUS ANIMALS

In conscious rats, penile erections can be studied in isolation to obtain measures of physiologic arousal or in response to different types of sexual arousal stimuli (e.g., noncontact erections in response to estrous odors) to obtain measures of psychogenic arousal. Ex copula reflex erections are thus elicited after 5 to 10 minutes. Ex copula reflex erections are generated by spinal reflex mechanisms and modulated by supraspinal control. These erections are divided into 2 components, lengthening of the penile body and glans erection. The dorsiflexions of the penile body are called “flips” and the intense glans erections with flaring of the glans extremity are called “cups”. [44]

A model of noncontact erections in rats is studied in the presence of an inaccessible receptive female behind a mesh screen, or behind a series of walls with an air circulation system that brings the estrous odors to the male’s compartment.[45] Erections in response to these salient sexual cues are viewed as a model of psychogenic erection because they do not require direct somatosensory stimulation to be induced, which is different from ex copula reflex erections. The oral drug efficacy test should be conducted in the conscious state; thus a noncontact erection model is ideal for this purpose.

7. CONCLUSIONS

Experimental research assessing penile erection quantitatively via ICP has been very productive regarding the physiology, pathophysiology and pharmacology of penile erection. The technique makes it possible to evaluate even subtle erectile responses. The development of the new models using small commercially available animals such as rats and mice has facilitated in vivo investigation. The study of ICP in transgenic animals has opened a new door to research on the mechanism of penile erection from higher neural control down to molecular events within the erectile tissue.

II. PHYSIOLOGICAL INVESTIGATION OF EJACULATION

1. INTRODUCTION

Ejaculation consists in the succession of distinct physiological events that form two distinct although intimately connected phases: emission and expulsion. Closure of the bladder neck, to prevent the flow of semen backward in the bladder, precedes and goes with the emission phase, i.e. secretion of the various components of sperm by seminal vesicles, prostate and ampullary vasa deferentia contents into the prostatic urethra (Bohlen et al., 2000; Gil-Vernet et al., 1994). Forceful expulsion of sperm to the urethral meatus is then caused by rhythmic contractions of pelvic and perineal striated muscles, with a primary role for the bulbospongious muscles (Master and Turek, 2001; Gerstenberg et al., 1990).

Occurrence of ejaculation necessitates the process of somato-sensory and visceral sensory information from the reproductive organs to the spinal cord and the brain. Both sympathetic and parasympathetic tones act in a synergistic fashion to initiate seminal emission by activating respectively smooth muscle contraction and epithelial secretion throughout the seminal tract. The expulsion phase of ejaculation is under the sole control of the somatic nervous system that activates perineal muscles and smooth muscles of the urethra. High coordination of autonomic and somatic systems is required for normal antegrade ejaculation.

From a neural perspective, the ejaculatory process requires somato-sensory afferents and sympathetic, parasympathetic, and somatic systems as efferent pathways. Afferent nerve impulses are driven to the spinal cord via pudendal nerves for the most part (Johnson and Halata, 1991), but also through hypogastric nerve continued by paravertebral sympathetic chain (Baron and Janig, 1991). The sympathetic fibres relay in the paravertebral sympathetic chain and, in the majority of mammalian species, the fibres then proceed whether directly via the splanchnic nerve or after relaying in the coeliac superior mesenteric ganglia via the intermesenteric nerve to the inferior mesenteric ganglia (Owman and Stjernquist, 1988). Emanating from the inferior mesenteric ganglia is the hypogastric nerve that forms, after joining the parasympathetic pelvic nerve, the pelvic plexus from which arise fibres innervating the anatomical structures involved in ejaculation. The parasympathetic fibres travel in the pelvic nerve to reach the pelvic plexus. Efferents of somatic motoneurons proceed via the motor branch of the pudendal nerve to the pelvic floor striated muscles, including bulbospongiousus and ischiocavernous muscles (Schroder, 1985).

Both autonomic and somatic tones are under the influence of sensory genital and/or cerebral erotic stimuli integrated and processed at the spinal cord level. The thoracolumbar sympathetic, lumbosacral parasympathetic, and sacral somatic neurons are the components of the spinal centres of ejaculation. These spinal centres play a pivotal role in ejaculation as they integrate peripheral and cerebral signals and sends outputs to pelvic organs. The conversion of sensory and cerebral information into secretory and motor outputs involves spinal interneurons which have been recently characterized in rats (Truitt and Coolen, 2002). These cells (named lumbar spinothalamic (LST) cells), located in laminae X and VII of the spinal lumbar segments 3 and 4, have been demonstrated as playing a pivotal role in the command of ejaculation and are therefore regarded as a spinal generator of ejaculation. As a centrally integrated and highly coordinated process, ejaculation involves cerebral sensory areas and motor centres which are tightly interconnected, forming a network specifically dedicated to the control of the ejaculatory process (Giuliano and Clement, 2005).

Researches into the physiology and pharmacology of ejaculation have been mostly led using behavioural paradigms. Such a behavioural approach is necessary for studying the ejaculatory process in a 'natural' context and in relation with other components of the male sexual behaviour such as sexual motivation, copulatory activity, and sex-related rewarding. However, the use of ejaculatory models in anaesthetised animals, in addition to accelerate the pace of research, permits to provide deep insight into mechanisms of ejaculation and drugs mode of action. In those models, measures of organs activity regarded as physiological markers can be reliably and readily monitored for the different phases of ejaculation.

2. PHYSIOLOGICAL PARAMETERS OF EJACULATION

As described above, two phases can be distinguished for ejaculation: emission and expulsion phases. Organs and anatomical structures participate specifically to one of those phases, rendering
possible differential investigation of both phases of ejaculation.

a) Emission phase

Organs responsible for the emission phase of ejaculation include accessory sex glands (seminal vesicles, prostate, and bulbo-urethral glands), which manufacture and secrete almost all the volume of the seminal fluid, and testicles, which produce spermatozoa conducted to the urethra via vasa deferentia. All of these entities receive a dual innervation from parasympathetic and sympathetic systems. It is widely accepted that parasympathetic tone controls the glandular epithelium and that sympathetic tone commands the contraction of smooth muscle cells. Epithelial secretory cells are responsible for synthesis of the seminal secretions that are expressed into the ducts of the glands. Smooth muscle cell contractions promote the discharge of gland secretions into the urethra where mixing of the different components of the seminal fluid occurs. In anaesthetised rats, contractile activity of smooth muscle cells can be monitored by recording variations of the pressure into ejaculatory hollow viscera. Interestingly, pressure measurement into seminal vesicle and vas deferens can readily be done in various experimental paradigms in anaesthetised rats.

1) Seminal vesicle pressure

Seminal vesicles are a pair of tubular glands which stroma is composed of smooth muscle layers. They are responsible for the secretion of 50-80% of the entire ejaculatory volume.

Figure 1: Samples of seminal vesicle pressure (SVP) measurement obtained in anaesthetised rats. A; SVP is monitored in rat i.v. injected with the dopamine D2/D3 receptors agonist 7-OH-DPAT. Phasic multi-peaks increases (inset) in SVP are observed in response to 7-OH-DPAT delivery that correspond to seminal vesicle contractions. B; Phasic SVP increase are also observed following systemic administration of the amphetamine derivative p-chloroamphetamine (left trace). Bilateral section of the hypogastric nerves, which drive sympathetic tone to seminal vesicles, results in inhibition of amphetamine-induced seminal vesicle contractions (right trace).
Pressure in one seminal vesicle can be measured using a polyethylene catheter (0.58 mm inner diameter) filled with mineral oil to prevent coagulation and backflow of gland secretions into the catheter. The catheter, with a bevelled tip, is inserted into one seminal vesicle through the apex with no prior incision and slowly advanced into the gland over 0.5-0.8 mm. Catheter is carefully tied on the seminal vesicle to prevent leakage without pressing the tubing. The opposite free end of the catheter is connected to a pressure transducer coupled with an amplifier (gain x1000). An analog-to-digital converter transforms (5 kHz sampling rate) the amplified output signal to numeric data on a computer where the signal can be visualised in real-time and recorded (figure 1). Measurement of seminal vesicle pressure can be performed in several models of ejaculation (Cf pages 40, 41, and 42).

2. Vas deferens pressure

The vas (or ductus) deferens arises from the tail of the epididymis and terminates in the urethra posteriorly to the prostate. The terminal part of the vas is dilated and tortuous, forming the ampulla where spermatozoa can be stored. The vas has a thick wall of outer longitudinal and inner circular smooth muscle that are responsible for intense peristaltic movement carrying out transport of spermatozoa.

To measure intra-luminal vas deferens pressure, the vas is incised before it reaches the prostate and a catheter (0.58 mm inner diameter) is advanced into the lumen over ~1cm in direction to the urethra. Catheter is carefully tied on the vas and basal vas deferens intra-luminal pressure is kept at 15-20 mmHg through continuous isotonic salt perfusion, preventing catheter tip obstruction. Measurement, amplification, and conversion of the pressure changes are performed as described in the previous section (see figure 2 for illustration). Measurement of vas deferens intra-luminal pressure can be performed in several models of ejaculation (Cf pages 40, 41, 42).

b) Expulsion phase

Pelvic floor striated muscles, including ischiocavernosus, levator ani and more particularly bulbospongiosus muscles, have a preponderant role in the expulsion phase of ejaculation by promoting ejection of semen from the urethra. An important role for bladder neck and urethra, more particularly the external urethral sphincter, during expulsion is also reported. The latter structures receive a dual innervation from sympathetic and parasympathetic systems whereas perineal striated muscles are under the sole control of somatic motoneurons. Contractile activity of the perineal muscles during expulsion is characterized by synchronous activation of ischiocavernosus, bulbospongiosus and levator ani muscles, anal and external urethral sphincters that propel semen within the urethra. In addition, energetic contractions of the bladder neck occur that prevent semen reflux into the bladder. In different experimental models in anaesthetised rats, contractile activity of bulbospongiosus muscle and external urethral sphincter can be visualised by recording electromyogram using thin electrodes placed within the tissue of interest.

1. Bulbospongiosus muscle

The bulbospongiosus muscle, a superficial muscle of the perineum, consists of two symmetrical parts that cover the bulb (or base) of the penis. It serves to empty the canal of the urethra but also contributes to erection and feelings of orgasm in male individuals.

Figure 2: Sample of intra-luminal vas deferens pressure (VDP) measurement obtained in anaesthetised rats. VDP is recorded in rat receiving electric stimulation at the level of the spinal generator of ejaculation (SGE). A short lasting single peak increase in VDP is observed immediately after stimulation.
Bulbospongious muscle is exposed via a perineal incision and electromyogram can be monitored by passing a Teflon insulated stainless–steel wire (diameter, 230 µm) laterally throughout the muscles with two 1-2 mm pieces (separated by 1-2 mm) of insulation stripped off. At one end of the wire, a spherical fishing sinker is attached to avoid electrode displacement caused by intense contractions of the muscle. The other end of the wire is connected to an amplifier (gain x1000) where the incoming signal is filtered (low pass 1 KHz; high pass 10 Hz). An analog-to-digital converter transforms the amplified output signal to numeric data on a computer where the signal can be visualised in real-time and recorded (figure 3). Measurement of bulbospongious muscle electromyogram can be performed in several models of ejaculation (Cf pages 40, 41, 42).

2. **EXTERNAL URETHRAL SPHINCTER**

The external urethral sphincter is a striated muscle that envelopes the membranous part of the urethra extending from the prostate to the meatus. Its contractions, commanded by somatic motoneurons, constrict the urethra. In rats, external urethral sphincter is activated during ejaculation contrary to human where it relaxes. The role of these potent rhythmic contractions is unclear but they could contribute to the build up of a pressure chamber facilitating the expulsion of semen which is in the form of a viscous plug in rats.

Perineal incision is performed to reach the part of the external urethral sphincter where the electromyogram is measured. The same recording electrode as described in the previous section is inserted into the muscle of the middle urethra, ~6 mm from the blad-

---

**Figure 3**: Sample of bulbospongious muscle electromyogram obtained in anaesthetised rats. Electromyogram is recorded in rat injected with the dopamine D2/D3 receptors agonist 7-OH-DPAT into the cerebral ventricle (i.c.v.). Several clusters of intense burst of contraction of the bulbospongious muscle are observed following drug delivery. Rhythmic organisation of the bursts is detailed in the inset.

**Figure 4**: Sample of external urethral sphincter electromyogram obtained in anaesthetised rats. Electromyogram is recorded in rat injected with the dopamine D2/D3 receptors agonist 7-OH-DPAT into the cerebral ventricle (i.c.v.). Several clusters of intense burst of contraction of the external urethral sphincter are observed following drug delivery. Rhythmic organisation of the bursts is detailed in the inset.
nder neck. The electric signal from the external urethral sphincter is amplified, filtered, and converted as described in the previous section (see figure 4 for illustration). Measurement of external urethral sphincter electromyogram can be performed in several models of ejaculation ( Cf pages 40, 41, 42).

It is implicit that several physiological parameters can be monitored in the same animal during the same experimental session ( figure 5). This renders possible the investigation of both phases of ejaculation as well as the synchronisation between them, which is important for a normal anterograde ejaculation, in the same experimental conditions.

3. EXPERIMENTAL MODELS OF EJACULATION

The available experimental paradigms to investigate ejaculation in anaesthetised male rats are briefly described.

a) Ejaculation induced by electrical stimulation of the intermesenteric nerves in anaesthetised rat

OBJECTIVE:

To induce a complete ejaculatory response in anaesthetised rat. In this model, physiological markers of the emission and expulsion phases of ejaculation induced by electrical stimulation of the intermesenteric nerves (IMN), which contains both pelviperineal afferents and efferents, can be measured. Contractions of the seminal vesicle and the bulbospongious muscle are regarded as physiological markers of, respectively, emission and expulsion phases of ejaculation ( figure 6).

SUMMARIZED METHODOLOGY:

Rats are anaesthetised with isoflurane and seminal vesicle pressure (SVP) as well as bulbospongious muscle (BS) electrical activity (BS EMG) are monitored. A stimulating electrode is placed on the IMN and electrical stimulation is applied consisting of 5 square wave pulses (1 ms duration, 6 V, 60 Hz) during 30 s.

ENDPOINTS:

Number and latency of ejaculations (corresponding to the expulsion of a seminal plug)

Number, latency, amplitude, duration and area under the curve of SVP increases

Number, latency, frequency and duration of BS contractions

Figure 5: Sample of recording of seminal vesicle pressure (SVP), bulbospongiosus muscle electromyogram (BS EMG), and external urethral sphincter electromyogram (EUS EMG) obtained in anaesthetised rats after i.c.v. delivery of 7-OH-DPAT (10 µg). A magnification of the tracing is displayed to show the temporal organisation. Typically, SVP rise was followed, after 1.0 ± 0.2 s, by EUS rhythmic contractions, then, after 6.8 ± 0.8 s, by BS rhythmic contractions. SVP responses were characterised by multi-peak (2-4) increases lasting 18.0 ± 0.6 s and reaching maximal amplitude of 3.5 ± 0.3 mmHg. BS and EUS responses occurred in the form of intense and rhythmic bursts of contraction lasting 35.7 ± 1.4 and 28.0 ± 1.0 s respectively, and with burst frequency of 0.40 ± 0.01 and 1.71 ± 0.07 s⁻¹ respectively. (from Clement et al., 2009)

Figure 6: Example of seminal vesicle pressure and bulbospongiosus muscle electromyogram (EMG) responses following electrical stimulation (ES) of the intermesenteric nerves.
b) Para-chloroamphetamine-induced ejaculation in anaesthetised rat

OBJECTIVE:
To induce a complete ejaculatory response in anaesthetised rat. In this model, physiological markers of the emission and expulsion phases of ejaculation induced by the amphetamine derivative para-chloroamphetamine (PCA) can be measured. Contractions of the seminal vesicle and the bulbospongiosus muscle are regarded as physiological markers of, respectively, emission and expulsion phases of ejaculation (figure 7).

SUMMARIZED METHODOLOGY:
Under anaesthesia (isoflurane, urethane or pentobarbital), the carotid artery and the right seminal vesicle are catheterized to measure concomitantly arterial pressure (AP) and seminal vesicle pressure (SVP). Electrical activity of the bulbospongious muscle (BS EMG) is also recorded. Physiological markers are monitored before and over 30 min after PCA systemic injection (i.v. or i.p.). Computerized analysis of the recordings is then performed a posteriori using custom-written analysis programs (Sadoc, CNRS, Gif-sur-Yvette, France).

ENDPOINTS:
Number and latency of ejaculations (corresponding to the expulsion of a seminal plug)
Number, latency, amplitude, duration and area under the curve of SVP increases
Number, latency, frequency and duration of BS contractions
Time interval between SVP increase and BS contractions

REMARKS:
PCA triggers ejaculation by releasing serotonin and noradrenalin at the spinal level. Therefore, this model is suitable for studying peripheral and spinal modulations of the ejaculatory process and not recommended for investigating supra-spinal modulation.

c) 7-hydroxy-2-(di-N-propylamino)tetralin-induced ejaculation in anaesthetised rat

OBJECTIVE:
To induce a complete ejaculatory response in anaesthetised rat. In this model, physiological markers of the emission and expulsion phases of ejaculation induced by the dopamine D3 preferring agonist 7-hydroxy-2-(di-N-propylamino)tetralin (7-OH-DPAT) can be measured. Contractions of the seminal vesicle and the bulbospongious muscle are regarded as physiological markers of, respectively, emission and expulsion phases of ejaculation (figure 8).

Figure 7: Example of recording of seminal vesicle pressure (SV-P) and bulbospongious muscle electromyogram (BS-EMG) during ejaculation induced by i.p. p-chloroamphetamine (PCA). On the left panel are illustrated the successive SVP and BS-EMG peaks that occur over the 30 min-period following PCA injection (5 mg/kg). Right panel: a sample response from the left panel shows the time shift (T) between the beginning of the SVP rise and the first consistent BS contraction (Pelvipharm internal data).
SUMMARIZED METHODOLOGY:

Under anaesthesia (isoflurane, urethane or pentobarbital), the carotid artery and the right seminal vesicle are catheterized to measure concomitantly arterial pressure (AP) and seminal vesicle pressure (SVP). Electrical activity of the bulbospongiosus muscle (BS EMG) is also recorded. Physiological markers are monitored before and over 30 min after PCA systemic injection (i.v. or i.p.). Computerized analysis of the recordings is then performed a posteriori using custom-written analysis programs.

ENDPOINTS:

Number and latency of ejaculations (corresponding to the expulsion of a seminal plug)
Number, latency, amplitude, duration and area under the curve of SVP increases
Number, latency, frequency and duration of BS contractions
Time interval between SVP increase and BS contractions

REMARKS:

7-OH-DPAT triggers ejaculation by stimulating dopamine D2/D3 receptors at the brain level. Therefore, this model is suitable for studying peripheral and spinal modulations of the ejaculatory process but also supraspinal modulations that involve dopaminergic system.

d) Ejaculation induced by electrical stimulation of the lumbar spinothalamic cells in anaesthetised rat

OBJECTIVE:

To induce a complete ejaculatory response in the anaesthetised rat. In this model, physiological markers of the emission and expulsion phases of ejaculation induced by electrical microstimulation of the lumbar spinothalamic cells (LSt), the key component of the spinal generator for ejaculation, can be measured. Contractions of the vas deferens and the bulbospongiosus muscle are regarded as physiological markers of, respectively, emission and expulsion phases of ejaculation.

SUMMARIZED METHODOLOGY:

Rats are anaesthetised with urethane or pentobarbital and intraluminal vas deferens (VD) pressure as well as bulbospongiosus muscle (BS) electrical activity...
(BS EMG) are monitored. For LSt microstimulation, an electrode is positioned in laminae VII-X (figure 9). Electrical stimulation protocol is adapted to the aim of the experimental investigation. Analysis of the recordings is performed a posteriori using custom-written routines in Elphy software (Sadoc, CNRS, Gif-sur-Yvette, France).

**ENDPOINTS:**
Latency, amplitude, duration and area under the curve of VD increases
Latency, frequency, duration and area under the curve of BS contractions

Figure 9: The spinal location where microstimulation evokes ejaculation related events corresponds to the LSt neuron area. (a) Strong current injections through the stimulation electrode at the end of the experiment marked the spinal location from which ejaculation and ejaculation related events could be evoked (spinal cord section at L4, cc = central canal). (b) Left: Dp(SV) response (red) in a single rat for various electrode depths, ie vertical distance from the dorsal surface of the spinal cord at L4 level. Green line indicates stimulation period, red numbers stimulation sequence. Middle: corresponding maximal amplitude of Dp(SV) (red dots) vs. electrode depth (vertical axis). The Gaussian function (black) used for data fitting peaks at t1540 mm from the spinal cord’s dorsal surface. Right: summary data for the maximal amplitude of Dp(SV) and electrode depth (n = 9, red) with mean Gaussian fit (black). For each animal, data was normalized by the Dp(SV) maximal amplitude and the peak position of the Gaussian. Microstimulation applied at L2 and L4 evoked the highest maximal amplitude of Dp(SV) (c) and BSM-rEMG (d). Animal numbers indicated for spinal levels. (e) When placing two electrodes spaced 500 mm laterally at L4, significantly larger maximal amplitudes of Dp(SV) (red) and BSM-rEMG (black) were evoked near the spinal cord midline.
III. UROGENITAL REFLEX

Neurophysiologic recordings in both men and women have shown that rhythmic contractions of the genital organs, anal sphincter and pelvic floor muscles occur concomitant with ejaculation and the sensation of orgasm/climax [4,5,16,17,32]. In men, orgasm is closely associated with ejaculation and can be defined as the expulsion of fluids from the urethra, which is facilitated by rhythmic perineal muscle contractions. Therefore, strictly speaking both emission (secretion of seminal fluids) and ejaculatory reflexes (rhythmic perineal muscle contractions) are required for the full ejaculatory pattern in men. However, there is little conclusive evidence that women ejaculate during orgasm [3,22]. In women, pelvic floor, vaginal, uterine and anal sphincter contractions have been reported to be associated with the sensation of orgasm and climax. Therefore, similar physiological responses occur during orgasm in men and women.

The urogenital (UG) reflex is a model developed on the rat that mimics the expulsion phase of ejaculation and the genital changes seen during orgasmic responses in both men and women [7,18,45,57]. Use of this model has provided important information on the physiological, pharmacological and neuroanatomical control of ejaculation. The UG reflex comprises rhythmic contractions of the perineal muscles, (ischio cavernousus and bulbospongious muscles), penile erections and expulsion of the urethral contents [21,45]. The clonic contractions of the perineal muscles seen during the UG reflex strongly resemble that seen during sexual climax in humans. Examination of the UG reflex in female rats demonstrated rhythmic contractions of the pudendal motor nerve, vagina, anal sphincter and uterus which could be elicited by brief urethral distension or pudendal sensory nerve stimulation [7,45,62]. These physiological responses also occur during orgasm in women.

The UG reflex is generated by a spinal pattern generator which involves multiple spinal segments that coordinate somatic, sympathetic and parasympathetic efferents innervating the sexual organs [35,38,45,46,59]. Distension of the urethra or stimulation of the pudendal sensory nerve triggers the UG reflex in the spinally transected, anesthetized rat. The responses are difficult to evoke in the intact fully anesthetized preparation, but can be induced pharmacologically, suggesting a tonic supraspinal inhibition [6,9,21,55,57].

Peripheral nerves relaying the afferent (sensory) and efferent (motor) information during the UG reflex are the pelvic and pudendal nerves, and damage to these nerves during pelvic surgery (e.g. prostatectomy, hysterectomy) can result in orgasmic dysfunction. The pudendal (somatic) nerve relays sensory stimuli from the perineum, penis, clitoris, urethra and the pelvic floor musculature. These sensory signals are essential for activation of the UG reflex 7,45. The pudendal nerve afferents enter the spinal cord through the superficial dorsal horn of segments L6-S1 (human - S2-S4) and travel through the medial dorsal horn to the dorsal gray commissure, which is located in the medial cord [13,46,52,58,61]. Autonomic afferents may also contribute to sensory inputs from the genital organs. Pelvic afferents terminate primarily in spinal segments L6-S1 (sacral cord in humans). The fibers course through the lateral dorsal horn and extend toward the intermediolateral cell column [2,14,48-50]. The efferent fibers of the pudendal nerve provide innervation of the pelvic floor and anal and urethral sphincters which contract rhythmically during the UG reflex. The pudendal motoneurons are located in the ventral horn of the lumbar spinal cord in Onuf’s nucleus, which in the rat is divided anatomically into the dorsomedial and dorsolateral nuclei [46]. Therefore, spinal pathways regulating the UG reflex are located in the lower lumbar-sacral spinal cord. However, there is some evidence that the sensation of orgasm in women may be perceived through higher spinal (hypogastric pathways) and brain (vaginal) circuits [29-31]. A spinal pattern generator for the UG reflex has been proposed and evidence from several sources suggests it includes...
neurons in the medial gray of spinal segments L3-L4 [6,45,59]. Some of these neurons have been identified (LSt cells) which project to the thalamus and contain galanin and NK1 receptors; these neurons are activated with ejaculatory behavior and with the UG reflex in males but not in females [35,38,59,60]. Further elucidation of the spinal generator mediating female genital responses is required.

Neuroanatomical tract tracing studies using the neurotrophic virus, pseudorabies virus (PRV), have been used to identify the spinal and brain neurons innervating the pelvic organs that contribute to the UG reflex [33,36,43,44,63]. Injection of PRV into the pelvic organs (penis, clitoris and perineal muscles) resulted in labeling of postganglionic neurons in the major pelvic ganglia (penis and clitoris) and pudendal motor neurons (perineal muscles). Sympathetic and parasympathetic preganglionic neurons of the hypogastric and pelvic nerve, respectively, were also labeled. Spinal interneurons were located in and around the intermediolateral cell column and in the medial gray forming a column of neurons through segments T13-S1. These studies suggest that spinal interneurons involved in the UG reflex course through the lower thoracic lumbosacral cord in the lateral and medial gray. These cells may be important in the integration of multiple pelvic responses seen during sexual behavior.

Activation of c-fos, an immediate early gene, has been used to identify spinal neurons that are activated during the UG reflex [35,38]. Activation of the UG reflex resulted in increased c-fos expression in lower thoracic-lumbosacral spinal segments. The spinal circuits involve an afferent arc via the pudendal nerve and efferent outputs via the parasympathetic and sympathetic nerves (pelvic and hypogastric). In addition, c-fos positive nuclei were found in the dorsal horn suggesting that the dorsal horn neurons form connections within the superficial laminae and these cells may be important in coordinating intraspinal and supraspinal information. Spinal interneurons in the lateral, intermediate and medial gray were also activated with the UG reflex; these cells include components of the spinal pattern generator that regulates the UG reflex.

The brain exerts an inhibitory and facilitatory influence on the lumbosacral pathways involved in the UG reflex. Physiological and pharmacological studies demonstrated that the UG reflex was tonically inhibited by neurons in the ventral medullary reticular formation (the nucleus paragigantocellularis, nPGi) [40,41]. Further studies confirmed that lesions of this region facilitated ex copula sexual reflexes in males and improved ejaculatory performance [39,64]. Neuroanatomical tract tracing studies confirmed that the nPGi projects to and receives inputs from the penis, clitoris, perineal muscles and pelvic efferent neurons and interneurons in the lumbosacral spinal cord that modulate pelvic reflexes. Excitatory and inhibitory neurons in the nPGi respond to genital stimulation in the female rat and to manipulations of the pelvic, pudendal nerves and dorsal nerve of the penis in the male [23-25,27,28]. These studies provide evidence that the nPGi tonically inhibits somato-motor output that is associated with the UG reflex and receives sensory information related to sexual function. It is well established that the medial preoptic area (MPOA) plays an important role in sexual behavior [15,20,26,42,51]. Stimulation of the MPOA induces rhythmic contractions of the pudendal motor nerve.

![Responses to urethral distension in the spinalized, anesthetized female rat (38)](image_url)
and the bulbospongiosus muscle [42]. The MPOA does not directly innervate spinal circuits involved in sexual reflexes and physiological and neuroanatomical studies have shown that the midbrain peri-aqueductal gray (PAG) and the ventrolateral medulla (VLM) are important relay sites for these mediated by the MPOA responses [34,37,53,54].

Research efforts continue to examine the pharmacological control of the UG reflex. Currently a number of neurotransmitters acting on specific receptors have been shown to activate or inhibit the UG reflex [1,8,10-12,19,21,41,56,57,67,68]. Briefly, compounds that inhibit the UG reflex include serotonin and opioid agonists, while muscarinic agonists and dopamine activate/ facilitate the UG reflex. Adrenergic systems are also involved [47,65,66,68]. In addition, to specific neurotransmitters, universal compounds that can activate general excitatory receptors (glutamate) or inhibitory receptors (GABA) are involved.

REFERENCES

**IV. PARAMETERS OF PERIPHERAL FEMALE SEXUAL RESPONSE**

Physiological responses that are associated with female sexual behavior, as well as animal models, are not as clear as those that mimic male sexual behavior. One difficulty in developing animal models of female sexual responses has been the historical lack of studies in women and the lack of sensitive equipment to measure women’s sexual responses. However, over the past 20 yrs developments have been made allowing further understanding of women’s sexual responses [1-10]. Female sexual behavior and the integrity of the female genital organs are dependent on gonadal steroid hormones (estrogen and progesterone) [11-14]. However, sexual behavior can occur in conditions of suboptimal or very low...
levels of these hormones, suggesting that sexual behavior/responses can be triggered with adequate stimulation from the genitals or from the brain.

Sexual responses in women include desire, arousal and orgasm, while these sensory responses are perceived by the brain, there are associated peripheral autonomic and somatic changes that occur in the genital organs that are indicative of female sexual responses. Genital arousal responses include vasocongestion and neuromuscular changes of the clitoris and vagina and vaginal lubrication [7,15-19]. Phasic contractions of the striated and smooth muscles of the pelvic floor, perivaginal muscles, vagina and uterus occur during sexual excitement and often during orgasm [2,8,20-23]. The peripheral models of female sexual responses involve monitoring changes in vaginal and clitoral blood flow and temperature and vaginal secretions as well as monitoring smooth and striated muscle contractions of the vagina, uterus, anal sphincter and pelvic floor muscles. Examination of tissue responses (in vitro studies) also provides information of the neural and local neurotransmitters involved.

1. NEURAL PATHWAYS

The genitalia and pelvic floor muscles are regulated by the sympathetic and parasympathetic nervous system (pelvic nerves, hypogastric nerve, paravertebral sympathetic chains) and by somatic nerves (pudendal nerve). Evidence has also been published suggesting a role for the vagus nerve in genital sexual responses. The peripheral innervation of the pelvic organs has been reviewed by several authors [24-26]. These nerves convey impulses from the brain and spinal cord to control motor, secretory and vascular functions, or mediate pleasurable or painful sensations [24,27-31]. The autonomic nerves regulate blood flow and the involuntary smooth muscle contractions that may accompany arousal while the somatic nerves control the voluntary or striated muscle responses that often occur during climax / orgasm. In addition, there is some evidence that clitoral erection is mediated by local mechanisms that are similar to that of penile erection [32-34]. Sensory inputs from the genitalia or brain can facilitate arousal and climactic responses and are mediated by both the somatic and autonomic systems.

2. VAGINAL RESPONSES

Genital arousal in females is associated with increased blood flow to the vagina and clitoris which results in clitoral erection, vaginal engorgement, changes in vaginal luminal diameter and vaginal lubrication. Studies have been published investigating the physiological changes that occur in the vagina and clitoris [15,32-39], and these studies provide a working model for genital arousal in females. The first studies examining female genital function were focused on the estrous cycle and its relationship to pregnancy [40-43]. Techniques developed during

Effect of repeated electrical stimulations (6V, 10Hz, 1 ms) of the pelvic nerve on vaginal parameters including blood flow in anesthetized female rat (15).
these studies included monitoring vaginal blood flow and temperature in multiple species and provided the tools that were translated to monitoring changes of the genital organs during sexual responses.

The majority of these studies have used stimulation of the pelvic nerve in the anesthetized model and monitored changes in vaginal and/or clitoral blood flow [15,32,34,35,38,39,44,45]. Stimulation of the pelvic nerve in the rabbit resulted in increases in vaginal length, pressure and blood flow, and clitoral blood flow. Similar changes in vaginal and clitoral hemodynamics were elicited by pelvic nerve stimulation in the rat and dog (i.e. increases in vaginal blood flow, increases in vaginal wall tension and stimulation of the dorsal clitoral nerve elicited increased clitoral blood flow).

A more recent study reported that stimulation of the somatosensory afferents could also elicit increases in vaginal blood flow [38]. Stimulus intensities required to increase vaginal blood flow were significantly lower than those evoking rhythmic firing of the pudendal motor nerve or contraction of the vaginal smooth muscle. The increase in vaginal blood flow induced by activation of pudendal nerve afferents was abolished by pelvic nerve cuts, suggesting that sensory stimulation can increase vaginal blood flow (genital arousal) through spinal pathways that activate parasympathetic (pelvic nerve) efferent output.

The effects of gonadal steroid hormones on genital blood flow have been examined and they confirm that ovariectomy changes vaginal tissue morphology and reduces blood flow response to pelvic nerve stimulation [32,36,46]. However, other studies showed consistent pelvic nerve induced increases in blood flow to the vagina and clitoris, although evidence for larger responses was reported with the addition of estradiol [15,35,45,46]. A number of studies have shown that the hypogastric and pelvic nerves are sensitive to the levels of circulating gonadal steroid hormones and this altered sensitivity changes vaginal arousal [28,47,48]. Further studies are required to understand the role of gonadal steroid hormones in sexual responses as well as changes that occur with and post menopause.

More research is also required to understand the pharmacological control of genital arousal responses. Only a few studies have been published. Intravenous administration of low doses of apomorphine caused an increase in pelvic nerve stimulation-induced peak clitoral intracavernosal and vaginal wall blood flow in rabbits [49]. In rats, atropine failed to affect the pelvic nerve induced increase in vaginal blood flow, but did block the vaginal contraction, suggesting acetylcholine may not play a major role in vaginal engorgement during sexual arousal [15]. Several studies have documented that nitric oxide mechanisms are involved in mediating increases in vaginal blood flow and lubrication [34,39,50]. Local administration of papaverine hydrochloride and phentolamine increased vaginal wall pressure and vaginal blood flow in rabbits [32]. Further studies are required to understand the role of these neurotransmitters as well as examining the role of specific adrenergic receptors and neuropeptides in the regulation of genital arousal.

Other models of genital arousal include monitoring the appearance of external genitalia in conscious rats after apomorphine treatment in which engorgement of the tissue surrounding the vagina and increased introitus diameter occurred (lasted 2-3sec) [19]. However, these response are very infrequent (1-4 every 30min) and thus studies confirming these usefulness of this model are required [19]. Changes in vaginal temperature have been monitored in animal models; however, the reproducibility of detecting temperature changes in small animals is questionable.

Little research has been conducted on the brain mechanism regulating female genital arousal responses; however one study demonstrated an increase in vaginal blood flow upon electrical stimulation of the medial preoptic area [15].

3. ORGASMIC-LIKE RESPONSES

Contractions of the pelvic muscles, anal sphincter and vagina frequently occur during orgasm or climax in women and these responses have been used as a model to further understand the CNS control of orgasmic responses in females [38,51,52]. Some of the physiological components are neurologically similar to those that occur during ejaculation/ orgasm in men (see urethrogenital (UG) reflex section). Rhythmic contractions of the pudendal motor nerve, vagina, anal sphincter and uterus were elicited by brief urethral distension or pudendal sensory nerve stimulation [38,51,52].

Brain and spinal pathways regulating the UG reflex in female rats appear similar to that reported in male rats. However, the spinal pattern generator thought to mediate ejaculatory reflexes in males does not appear to be activated during the UG reflex in females [52,53]. Further elucidation of the spinal generator mediating female genital responses is required.

V. REFERENCES

Cardiovascular disease, hypertension or related risk-factors that cause endothelial dysfunction and progressive vascular structural changes are linked to male and female sexual dysfunctions (Kirby et al 2005, Esposito et al 2008, Shabsigh et al 2008, Veronelli et al 2009). The microcirculation is proposed to be of particular interest and at risk for functional and structural alterations during the development of cardiovascular and metabolic diseases (Gates et al 2009). Sexual symptoms are reported often to proceed the onset of signs of coronary artery disease and undiagnosed hyperglycemia in men with erectile dysfunction and it has been proposed that the small-diameter penile resistance arteries due to a smaller diameter / wall ratio less favourably tolerate lumen narrowing and vascular wall remodelling and plaque formation (Montorsi et al 2005, Grover et al 2006). Altered clitoral or vaginal hemodynamics have been described in preclinical female models for vascular disease but although some postmenopausal patients with genital arousal disorder are reported to exhibit lower vaginal vasocongestive responses to erotic stimuli, the relations to cardiovascular disease, human genital vascular dysfunction and peripheral arousal disorder are unclear (Min et al 2002, Park et al 2002, Basson and Brotto 2003, Kim et al 2006). Furthermore, clitoral and vulvar swelling and lubrication has been proposed to rather be an automatic reflex that may not well correlate to the subjective arousal in women which in turn reflects a need for well defined endpoints and interpretations of results in relation to sexual function or health risk factors in studies of female genital vascular responses in animal models (Basson 2008).

Below follows an overview of findings on the male and female genital responses in models for lifespan parameters (ageing, hormones), disease processes (hypertension, diabetes), or lifestyle factors (diet, smoking, recreational drugs). When convenient, molecular biological information, functional activities of isolated tissues, and in vivo genital responses are described for various mammals in relation to findings in humans.

II. MODELS FOR LIFESPAN FACTORS

1. AGEING

The structure and function of arteries change throughout a lifetime. In general, changes in arterial function and structure with increasing age are similar across species (human, monkey, rodents) with respect to many parameters such as e.g. stiffness (decreased elastin; increased collagen), endothelial dysfunction, intimal thickening and medial dysfunction, increased levels of inflammatory chemokines, reduced availability of nitric oxide (NO) and vascular endothelial growth factor, and increased activity of

C. VASCULAR ASPECTS & MODELS OF DISEASE

I. BACKGROUND

Improved understanding of the pathophysiological mechanisms and significance of peripheral vascular disease in sexual dysfunctions are of interest not only to identify novel therapeutic approaches in sexual medicine but also to define relations to common health risk factors and to at earlier stages detect and prevent progression of systemic metabolic and vascular diseases.

transforming growth factor-β1 and the Angiotensin II–signaling cascade (Najar et al 2005).

Reduction in the smooth muscle content of clitoral erectile tissue from human cadavers have been described correlated with increase in age and that presence of cardiovascular mortality increased progression of fibrosis (Tarcan et al 1999). Little information is available on structural or functional changes of female genital responses in preclinical models of aging. One study investigated the affect of aging on apomorphine-induced genital vasocongestive arousal (GVA) recorded by visual inspection and defined as significant engorgement of tissue surrounding the vagina as well as an increase in the dimensions of the introitus that lasted for 2–3 seconds. Compared to young rats (225 – 250 gr), only 40% of 18-month old female rats responded to apomorphine and exhibited an approximately 50% reduction of the number GVA responses during a 30-minute observation period. In comparison in a small study of 48 women, when analyzed by age, older women (ages 55 - 67 y) had significantly lower basal clitoral, labial, urethral and vaginal blood velocities than younger women (ages 25 - 54 y), whereas following sexual stimulation using a erotic video, no differences in genital blood velocities were recorded (Berman et al 1999).

2. SEX HORMONES

Contrasting results on the effects of testosterone on female genital vascular responses in ovariecetomized animals have been reported. In a castrate rat model, testosterone-treatment (5.5-55 microgram/day; 2 weeks) was described to increase vaginal blood-flow recorded with laser Doppler flowmetry (Traish et al 2007). In contrast, testosterone (100 microg/day) failed to improve genital blood-flow (laser oximeter recordings) or vaginal lubrication in ovariecetomized rabbits (Min et al 2002). Further studies are necessary to understand if these findings reflect differences between species or in methodological approach.

The effects of antiandrogens or estrogens on erectile responses have received little attention. One study describe that a single dose of flutamide, a clinically available androgen receptor antagonist, significantly decreased apomorphine-induced erections to less than 50% over 12 hours with recovery of erectile response within 48 hours. In comparison, a single dose of p,p-DDE, a DDT-metabolite and environmental pollutant acting as an androgen receptor antagonist, decreased apomorphine-induced erections for at least two weeks (Brien et al 2000). A phytoestrogen,
daidzen (100 mg/kg daily), was shown to decrease apomorphine-induced erections from the 30th day of treatment without differences compared with a synthetic estrogen (Pan et al 2007). In isolated corpus cavernosum tissue, chronic treatment with estradiol or daidzein decreased smooth muscle cell and elastic fiber content of the erectile tissue, reduced relaxant responses to acetylcholine, nitroglycerin, or activation of nerves and potentiated noradrenaline-induced contraction (Srilatha and Adaikan 2004, Huang et al 2008).

### III. MODELS FOR DISEASE PROCESSES

#### 1. HYPERTENSION

Several investigations have shown that hypertensive animals exhibit altered structure and function of the erectile tissue. Specifically, corporal tissue from SHR exhibit smooth muscle remodelling and increased fibrosis, reduced elastin content, subcellular alterations to mitochondria, endoplasmic reticulum and Schwann cells, reduced levels of endothelial NOS, reduced relaxant responses to acetylcholine or activation of nerves, reduced cGMP levels, increased superoxide dismutase activity, and increased Rho-kinase associated protein activity (Toblli et al 2000, 2007a, Chitaley et al 2001, Ushiyama et al 2004, Jiang et al 2005, Mazza et al 2006, Fibbi et al 2008). These findings correspond well to reduced erectile responses in vivo to activation of the cavernous nerve or after administration of apomorphine in SHR and compared to controls (Dorrance et al 2002, Bhr-Roussel et al 2003, Mayoux et al 2004, Hannan et al 2006). Interestingly, in a longitudinal study by Bhr-Roussel et al (2005), the onset of erectile dysfunction was detectable before the onset of hypertension in the SHR. Decreased erectile responses upon electrical stimulation of the major pelvic ganglion has also been recorded in doxycorticosterone-salt and stroke prone-spontaneously hypertensive rats (Chitaley et al 2001). Numerous studies have also evaluated pharmacotherapy for erectile dysfunction or hypertension on erectile function or structure and function of the erectile tissue in hypertensive rat models (Dorrance et al 2002, Tong 2000, Hale et al 2002, Toblli et al 2004ab, 2006ab, 2007a, Bhr-Roussel et al 2005, Mazza et al 2006, Hannan et al 2006, Shamloul and Wang 2006, Ushiyama et al 2006, 2008, Fibbi et al 2008).

Hypertensive models have not been extensively used to study female genital structure and function. Spontaneously hypertensive rats have been described to exhibit smooth muscle proliferation and increased levels of TGF-β1 in clitoral vasculature, higher arterial wall/lumen ratio and increased interstitial fibrosis in both the vagina and clitoris (Bechara et al 2003). Treatment with ramipril was reported to counteract these changes and to increase the expression of clitoral endothelial NOS in comparison to untreated SHR (Toblli et al 2007b). To our knowledge, functional in vivo data on female genital blood flow in hypertensive models is lacking.

#### 2. DIABETES

In animal models for diabetes, insulin-treatment is reported to improve erectile function (Abdelbaky et al 1998, Rehman et al 1997, Escrig A et al 2002, Pu et al 2007). The majority of studies of diabetic erectile dysfunction have been conducted in animals with type 1 diabetes mellitus induced by streptozotocin or alloxan and describe reduced erectile responses recorded as intracavernous pressures to stimulation of the cavernous nerve, intracorporal administration of vasoactive drugs or systemic administration of...
apomorphine (Italiano et al 1993, Yamaguchi and Kobayashi 1994, Rehman et al 1997, Yildirim et al 1999, Bivalacqua et al 2004b, Zhang et al 2006, Morelli et al 2009, Shukla et al 2009). Rats that spontaneously develop type 1 diabetes (BB / WOR) which is proposed to parallel findings in the human insulin-dependent disease have been shown to exhibit reduced NOS activity of the erectile tissue and diminished erectile reflex responses but no change in nerve-induced intracavernous pressure profiles (Murray et al 1992, Vernet et al 1995, Garban et al 1997, Whalen et al 2001). Information is scarce on the impact of type 2 diabetes on erectile function in preclinical models. Penile reflexes are reported reduced in the BBZ/WORdp rat, and recently, intracavernous pressure responses to activation of the cavernous nerve were shown to be significantly reduced in obese-diabetic Zucker rat, a strain which may provide a valuable animal model for studying type 2 diabetes because of an impaired glucose tolerance associated with obesity (Vernet et al 1995, Wingard et al 2007). Interestingly, erectile tissue from the Zucker obese rat exhibited also changes in the activities of PKC and Rho-kinase, enhanced vasoconstrictive responses, and reduced relaxations to a NO-donor, whereas no changes in NOS activities were observed (Wingard et al 2007).

For the study of female genital tissue structure and function, only animals with type 1 diabetes have been used. In these investigations, histological and functional studies of isolated vaginal and clitoral tissues in diabetic rats, rabbits and mice have reported reduced epithelial thickness and atrophy of the muscularis layer, fibrosis and increased amounts of TGF-β1, reduced vaginal levels of eNOS and arginine, reduced neuronal NOS-activity, elevated levels of PKG, signs of oxidative stress, reduction in estrogen receptor activities, and altered sensitivities to activation of angiotensin receptors (Giraldi et al 2001, Park et al 2001b, 2002, 2005, Kim et al 2006, Ferrini et al 2006, Cushman et al 2009). In vivo, the vaginal blood flow response to pelvic nerve stimulation was significantly reduced in diabetic rats and mean baseline flaccid and peak clitoral cavernous blood flow was significantly decreased in the diabetic rabbits compared with the control groups (Park et al 2002, Kim et al 2006). In comparison, premenopausal women with insulin-treated diabetes have been shown to exhibit lower baseline clitoral blood flow compared to controls (Caruso et al 2006).

### IV. MODELS FOR LIFE-STYLE FACTORS

#### 1. HYPERCHOLESTEROLEMIA AND ATHEROSCLEROSIS

Fat cell lesions, loss of intercellular connections, decreased levels of elastin, decreased content of smooth muscle and endothelial cells, reduced levels of vascular endothelial growth factor (VEGF), diminished endothelium-dependent relaxation and endothelial NOS levels, altered adrenergic tonus-generating capacity, and increased Rho-kinase activity are reported findings in isolated corpus cavernosum tissue from diet-induced hypercholesterolemic rats and rabbits (Junemann et al 1991, Srilatha et al 1999, Byrne et al 2001, Yesilli et al 2001, Xie et al 2005a, Ruy et al 2006a). Similar to findings in diabetic erectile tissue, varying responses to NO-donors have been described for isolated corpus cavernosum from hypercholesterolemic animals, but it is not clear if this is related to progression of disease (Azadzoi and Saenz de Tejada 1991, Byrne et al 2001, Firooz et al 2005). Studying temporal changes in the erectile tissue from rabbits with hypercholesterolemia, Xie et al (2005b) reported that alterations in corporeal VEGF levels occurred before abnormalities in vasoreactivity. A study by Behr-Roussel et al (2002) showed that the atherosclerotic changes related to erectile dysfunction were distinct from ageing-related processes in cholesterol-fed rabbits.

Angiographically verified luminal narrowing and atherosclerotic lesions of pelvic arteries of hypercholesterolemic rabbits may be considered to correspond to findings using angiography or duplex ultrasonography in men with erectile dysfunction due to peripheral arterial disease and vascular riskfactors (Gray 1982, Vicari et al 2006).

In vivo, erectile responses to activation of the cavernous nerve or to intracorporeal administration of vasoactive agents have been shown to be reduced in rats, rabbits or monkeys with diet-induced hypercholesterolemia (Azadzoi et al 1996, Behr-Roussel et al 2002, Park et al 2006, Christ et al 2009). In the hypercholesterolemic atherosclerotic apolipoprotein E knock-out mouse, erectile responses to cavernous nerve stimulation have also been described to be reduced (Behr-Roussel et al 2006).

Various pharmacotherapies, protein therapies or gene transfer procedures have been investigated in diet-induced arterial disease of rats, rabbits, and monkeys to overcome erectile dysfunction (Byrne et al 2001, Firooz et al 2005, Kang et al 2006, Ruy et al 2006b, Christ et al 2009).

No information is available on the effects of a high cholesterol diet alone on female genital vascular responses. In a rabbit model combining a cholesterol
diet and ballon-injury of the aorto-iliac arteries, vaginal and clitoral hemodynamic insufficiency in response to pelvic nerve stimulation have been described (Park et al 1997). Histological examination of the clitoris and vagina in these animals revealed atherosclerotic changes of pelvic and clitoral arteries, reduced smooth muscle content and fibrosis (Park et al 1997, 2000).

Kim et al (2002) reported significantly increased plasma cholesterol levels, increased levels of LDL and reduced endothelium-dependent relaxations of clitoral cavernosal tissue from ovariectomised rabbits and proposed chronic estrogen deficiency-induced hypercholesterolemia as a risk factor for female endothelial dysfunction.

2. RECREATIONAL SUBSTANCES

Epidemiological data link cigarette smoking and erectile dysfunction and it is shown that tobacco smoke in general has negative effects on endothelial cells, decreased eNOS activity, impair endothelium-dependent vasorelaxation, impair regulation of thrombosis and reduce responses to VEGF (Gocmen et al 2005, Tostes et al 2008). In preclinical investigations, the effect of smoking on peripheral genital responses has only been studied in models for erectile function and dysfunction. In rats, irrespective of age, daily passive smoking for 8 wks (enclosed cage, 1 hour, 5 days per week) reduced penile neuronal NOS activity, whereas no reduction in the amount of endothelial NOS was observed (Xie et al 1997). In vivo, the authors did not find reduced erectile functions in response to activation of the cavernous nerve in smoke exposed rats compared to controls (Xie et al 1997). In contrast, Bivalacqua et al (2009) reported reduced erectile responses in vivo to cavernous nerve stimulation in mice exposed to 3 weeks of secondhand smoke (enclosed cage, 5 hours, 5 days per week). Mice that were exposed to smoke also exhibited impaired endothelium dependent erectile responses to Ach and the erectile tissue from these animals showed increased superoxide anion activity, decreased constitutive nitric oxide synthase activity, and increased inducible nitric oxide synthase activity, reactive oxygen species generation and nitrotyrosine formation (Bivalacqua et al 2009).

No studies are available that have investigated the effect of alcohol on cavernous nerve-induced erectile responses or endothelium-dependent erectile function in vivo. Dose-dependent negative effects of acute administration of ethanol on apomorphine-induced rat erections have been reported (Heaton and Varrin 1991). In isolated corpus cavernosum tissue, acute exposure to ethanol or its main metabolite decreased nerve-mediated and bethanecol-induced relaxations in isolated precontracted corpus cavernosum from rabbits (Saito et al 1994a, Kim et al 2000). Surprisingly, after chronic ethanol consumption (5% in drinking water for 6 weeks) corpus cavernosum tissue from rabbits exhibited increased relaxations induced by field stimulation or bethanecol, whereas relaxations to sodium nitroprusside were not changed (Saito et al 1994ab). In contrast, in a more recent investigation using continuous ethanol vapor by inhalation for 14 days, isolated corpus cavernosum exhibited abolished endothelium-dependent relaxations whereas the relaxation to EFS and NO were unaltered (Aydinoglu et al 2008). In support of a role for ethanol under the current experimental condition as a risk factor for penile corpus cavernosum endothelial damage, electron microscopy of the erectile tissue from the above mice described nuclear endothelial cell alterations such as reorganisation of heterochromatin, appearance of deep nuclear indentations and a decrease in the number of pinocytic vesicles (Aydinoglu et al 2008).

Central effect of cocaine on sexual behavior and erectile function has been documented (Chang et al 2000). Chronic cocaine abuse is associated with serious cardiovascular complications, including endothelial dysfunction, and atherosclerosis, and recently peripheral mechanisms of erectile function in a rat model of triple-binge cocaine administration were evaluated (Kendrici et al 2007). Decreased erectile responses as measured by intracavernous pressure changes in vivo were observed after cocaine-treatment. Animals exhibited increased plasma levels of big-endothelin-1, and the erectile tissue was shown to contain increased expression of endothelin-A receptors and myeloperoxidase, decreased eNOS expression and NO production, and also to exhibit reduced endothelium-dependent relaxant responses and nerve-induced relaxations (Kendrici et al 2007).

V. CONCLUDING REMARKS

Overall, good evidence of the role for ageing, hypertension, testosterone, type 1 diabetes or hypercholesterolemia / atherosclerosis on erectile function is available in several strains or species, and contain information from molecular biological analyses, functional responses of isolated tissue and in vivo models. Additional studies in models for type 2 diabetes and models for the use of recreational drugs seem important for penile erection and erectile dysfunction.

Information on the role for estrogens, type 1 diabetes or hypercholesterolemia / atherosclerosis on the female genital vascular responses is found in at least one strain or species, and contain data from in vivo models and from molecular biological or functional investigations of isolated tissues. Information of vascular aspects of the female genital response is scarce or absent in the other currently reported models of disease.
Human cardiovascular disease is of multifactorial origin and even if preclinical models to evaluate the impact of vascular risk factors on sexual dysfunction may not depend upon simultaneous presence of known and unknown causative components, these models are important steps to evaluate mechanisms and targets of disease (Faxon et al 2004). Analyses at genetic and molecular biological levels, in isolated tissues and in vivo systems, as well as comparative investigations in human tissues and clinical trials are important to evidence and identify common pathophysiological pathways and putative novel targets of therapy. In extended studies, models that consider combinations of lifespan parameters, disease processes, or lifestyle factors probably serve the purpose better as they mimic the actual clinical condition (Singh et al 2009).

D. CELLULAR AND MOLECULAR STUDIES IN SEXUAL MEDICINE

Over the years, three-dimensional cultures of tissues or dispersed cells have been developed under well-maintained physiological conditions with the purpose of elucidating the intracellular biochemical reactions, ion or signal transfer pathways and others. These in vitro systems do provide useful information on the in vivo interactions and modulations in the presence or absence of chemical, biological, vascular, neurologic, endocrine and genetic inputs. The limitations have included the possible changes in the tissue/cellular integrity due to stages of processing and some intricate differences attributable to the in vivo cellular responses in a physiological milieu. Technically too, there are needs for stringent levels of expertise and control in order to achieve the anticipated results. However, these methods do replace the need for elaborate functional studies or expensive animal models and also provide much useful information at the biochemical enzymatic levels. In the area of sexual medicine, researchers have grown animal and human corpus cavernosal smooth muscle (CCSM) cells as explant cultures in the pure form as characterized by their morphologic appearance and positive immunolucultures in the pure form as characterized by their cavernosal smooth muscle (CCSM) cells as explant research has grown animal and human corpus and genetic levels. In the area of sexual medicine, useful information at the biochemical enzymatic expensive animal models and also provide much replace the need for elaborate functional studies or other methods do not replace the need for elaborate functional studies or expensive animal models and also provide much useful information at the biochemical enzymatic levels. In the area of sexual medicine, researchers have grown animal and human corpus cavernosal smooth muscle (CCSM) cells as explant cultures in the pure form as characterized by their morphologic appearance and positive immunofluorescent staining. As such, the spindle-shaped CCSM cells can well grow into an overlapping confluence and immunostain positively for alpha-smooth muscle actin, which has known specificity for the smooth muscle and non-reactivity towards skeletal or cardiac muscles and fibroblasts (Kershen RT et al., 2002; Chen B et al., 2004). Meeting standards of structural and functional integrity, successfully cultured CCSM has been a useful tool for the understanding of the cellular mechanisms relating to the neurotransmitter- and neuromodulator-mediated responses in the normal erectile process and also provides for an understanding of the changes in ED. Furthermore, the in vitro culture systems can be used for the primary evaluation of newer drugs or agents for their therapeutic potentials in male and female sexual medicine.

In many respects, breakthrough information was provided by way of advanced cell culture techniques when Christ and others delineated the physiological signals in the inter- and intra-cellular erectile pathways (Christ & Brink, 1999; Serels S et al., 1998). Various ion channels, vasoactive agents and second messenger systems were also evaluated (Christ et al., 1999; Kim et al., 2000) in such in vitro physiological environments, albeit with finite life spans. In these studies, several enzymatic, morphological and immunochemical methods were superimposed to characterize the pathophysiological changes in the confluences of human and animal genital tissues (Sadeghi-Nejad H et al., 1998; Traish A et al., 1999; Munarri R et al., 2003). Of noteworthy mention to this evidence-based approach is the finding that the endothelium rather than the interstitium of the corpus cavernosum is more sensitive to the long term side-effects of the age-old intracavernous injection therapy (Pilatz et al., 2005). Presently, as part of our learning from the human cell constructs, there seems little doubt that a daily administration of PDE5 inhibitors is unlikely to upregulate PDE5 expression or decrease cGMP levels (Vernet D et al., 2006). These and other findings illustrate the usefulness of studies at the cellular and molecular level and their possible contribution to our ultimate objective of the restoration of erectile health (Burnett AL, 2008).

Over the decades, standard biochemical principles have been used in all branches of clinical sciences and sexual medicine research is no exception. Several time-tested methods have established that while androgen-priming upregulated nNOS, arginase, PDE5 gene and protein levels (Chamness S L et al., 1995; Traish AM et al., 2002; Morelli et al., 2004), estrogen downregulated both nNOS and eNOS expressions (Al-Hijji J et al., 2000; Yoon HN et al., 2001). Such in vitro experience also showed that exogenously administered testosterone can increase both androgen and estrogen receptor (AR and ER) proteins (Traish AM et al., 2007) and advantageously help to upregulate the responsiveness to PDE5 inhibitor(s) (Zhang XH et al., 2004). Towards a greater molecular understanding of the three types of NOS isoforms, some variation seems to exist in the genetic makeup of nNOS although biochemically, binding of the excitatory amino acids to the postsynaptic N-methyl-D-aspartate receptor triggered it to release NO (Magee T et al., 1996; Gonzalez-Cadavid NF et al., 2000). On the other hand, iNOS could be induced in response to bacterial lipopolysaccharide (Hung A et al., 1995) and the iNOS-cDNA may be able to mitigate age-related changes in erectile function (Garban H, 1997). With the current awareness of lifestyle modification, attempts at calorie restriction and exercise seemed to instigate molecular prevention, seen as limited interaction of eNOS with caveolin-1 (Musicki B et al., 2008).

What more can be said about the value of molecular and biochemical techniques? In diseased animal models, classical western blot studies were able to show that diabetes-related ED was associated with low levels of eNOS and arginase, reductions in ERalpha and AR and a downregulation of cGMP-dependent protein kinase-1 (cGKI) (Waldkirch E et al., 2008). On the other hand, there may be an iNOS induction and NO-ROS interaction indicative of the coexistent oxidative stress (Kim NN et al., 2006; Ferrini MG et al., 2006). Some groups have also reported down-regulation of mRNA transcript and alternative splicing of Slo gene (encoding the BK or Maxi-K
channel alpha-subunit) and a down-regulated variable coding sequence protein A1 (Vcsa1 - hSMR3A) in this organic ED (Autieri MV et al., 1996; Davies KP et al., 2007; Tong Y et al., 2007); the latter predicament has led to an experimental trial with gene transfer of plasmids expressing Vcsa1.

Over the decades, the unique structure of the CCSM has been recognized as a fundamental functional requirement and as described by DiSanto et al., its myosin isofrom is of an intermediate subtype between the vascular and visceral smooth muscles, made up of low (noninserted) and high (inserted) actin-mediated ATPase activities. This seems to also explain the state of "high resting tone but an inherent ability to relax instantly" (DiSanto ME et al., 1998). As for its toxicity, in addition to the well-known adrenergic system, mRNA transcripts for muscarinic acetylcholine receptor (mAChR) m1, m2, m3 and m4 subtypes have been identified in the past through RNase protection assays to account for their balancing role in the smooth muscle tone (Traish AM et al., 1995). Recent studies point to the effect of GTPase RhoA and Rho-kinase as additional factors leading to impaired erectile function with aging and specific co-morbid states. Incidentally, the increased RhoA/Rho-kinase signaling with Rho- guanine nucleotide exchange factors (GEFs) observed in these conditions indicates the prospect of selective GEF inhibitors as novel molecular targets for ED therapy (Linder AE et al., 2005; Jin L et al., 2006). Along these lines, intrinsic biochemical and molecular studies have also characterized some other modulators such as aquaporins (Gannon BJ et al., 2000), hydrogen sulphide (Srilatha B et al., 2007) and the kalikrein system (Wang T et al., 2005) in the male corpus cavernosum. It would be interesting to find out what the future holds for these moieties by way of translational application.

In the specific evaluation of ED therapy, an older binding assay found that the PGE1 receptor density was significantly lower in ED patients (Aboseif S et al., 1993) indicating thereby, the importance of being aware of the possibility of reduced therapeutic responsiveness to intracavernosal PGE1 in such situations. Pursuing the success of PDEIs, several groups showed that these drugs effectively inhibited cGMP hydrolysis in the presence of NO in the intact cells of the human penile and clitoral cavernosum (Kim NN et al., 2001; Park K et al., 1998) and as a proof of concept, new drug discovery is being based on the distribution pattern of the PDE isoenzymes (Qiu Y et al., 2000; Küthe A et al., 2000). It is interesting to note that PDE5A1 and A2 are expressed in a tissue-specific manner although the latter is more dominant (Lin CS et al., 2003). To exemplify the developments in ion channels, the ability of ATP sensitive K+ channel subtype to play a key role in cavernosal relaxation has opened avenues for specific modulators/openers as molecular targets (Venkateswarlu K et al., 2002). Even the purported aphrodisiac mechanism of action of some plant androgens are being tested with the help of these in vitro systems and true enough, Jiang and others found that icariin for instance, worked through increasing cGMP levels and advantageously inhibiting PDE5 mRNA expression (Jiang Z et al., 2006).

As potential markers for La Peyronie's, in depth molecular and biochemical studies using DNA-based chip arrays and ionization mass spectrometry detected 3 upregulated and 2 downregulated proteins and a higher expression level of monocyte chemotactrant protein 1 (MCP-1) and transforming growth factor beta (TGF-beta 1-3). In addition, mRNA transcripts for TGF alpha, insulin like growth factor (IGF) and nerve growth factor (NGF) were also expressed in the tested specimens (Dahiya R et al., 1999; Gonzalez-Cadavid NF et al., 2002; Qian A et al., 2004; Lin GT et al., 2005; Hassoba H et al., 2005). In an advancing pathology, the identified activity of osteogenic progenitor stem cells may explain the calcification of fibroed plaque (Vernet D et al., 2005) and timely attempts at gene transfer using plasmid-expressing INOS indicate that endogenous iNOS induction may be protective or even preventive (Davila HH et al., 2004). The other areas of clinical interest where some of the above mentioned and additional factors come into play include increases in apolipoprotein D (ApoD) and IGF-1, 3, and 5 binding proteins in ischemic (Lin CS et al., 2001) and TGF-beta1, hypoxia inducible factor-1 alpha (HIF-1alpha) and collagen III in neurogenic ED states (Leungwattanakij S et al., 2003). Furthermore, in this era of proteomics, researchers have identified defective expression of several important proteins in some cases of neurogenic ED (Liu, X et al., 2007). Although analysis and interpretation of such protein modifications still present formidable challenges, these advanced techniques do provide fundamental insights into some of the key dysfunctional changes.

Moving from the cell-based gene therapy with endothelial cells, adeno-myoblasts and others (Wessells H et al., 1999; Tirney S et al., 2001), the day is not far when skeletal muscle-derived stem cells, which eventually convert into smooth muscle cells when implanted in the cavernosum (Nolazco G et al., 2008), may provide yet another viable cellular option in the area of stem and molecular therapy. Although there may still be limitations, the already successful attempt of gene therapy using naked DNA as the vector with maxi-K gene / alpha subunit of the human Maxi-K channel (hSlo) for ED is continuing to be focused on providing a practically restorative approach with adequate assurance of clinical safety (Melman A et al., 2008). If this exciting modality answers queries and stands the test of time, it will quietly succeed and overtake the other forms of ED management as the primary option for the future generation.
Not lagging far behind, molecular genetic studies using female genital tissues have investigated the principles of woman's sexual functioning. Although the complexities are yet to be completely unraveled, there are surely a number of advancements. In the context of extrapolating the available oral pharmacotherapy to the female disorders, there were some disappointments in spite of the fact that PDEIs are very successful in men. The low expression states of PDE5 in the human clitoral, labial and vaginal tissue, as shown by Uckert's group might be an answer to this limitation (Uckert S et al., 2007a). However, since both PDE3 and PDE4 are also present in the clitoris (Oelke M et al., 2006) and there is a widespread distribution of several cAMP- and cGMP-PDE isoenzymes (PDE3, PDE4, PDE5, PDE10 and PDE11) in the labia minora (Uckert S et al., 2007b), there are more avenues for therapeutic developments for FSD. Similarly, since all three NOS subtypes viz., nNOS, eNOS and iNOS (Park JK et al., 2002) are also present in the female genital tract, more studies are needed to delineate their roles in the functional outcome regulation.

Looking at the neuromodulators, in addition to functional adrenergic alpha-1 and -2 receptor subtypes (Kim NN et al., 2002), molecular characterization has further identified the expressions of angiotensin I (AT1a and AT1b) and II receptor mRNA; the regulation of the smooth muscle tone is probably through cross-talks with NO (Park JK et al., 1997; 2000). Classical cell culture studies have confirmed the modulatory roles of VIP, NO, PGE1 and others in this context and in further studies, tissue oxygen and hemoglobin contents were mentioned as additional tools to aid in the hemodynamic evaluation of sexual functioning (Min K et al., 2001a; 2001b). There is no doubt that these advances bear significance to our continuing quest for efficient pharmacological treatment of female sexual disorders.

Anatomically, regional differences exist with particular reference to vagina. The higher expression of myosin heavy chain isoform in the proximal vagina may contribute to its phasic contractile characteristics compared to the tonic type in the distal vagina (Basha M et al., 2006). In times of estrogen deprivation, there is an enhanced NO activity in the proximal but not the distal region (Traish AM et al., 2003). The exact impact of such regional variations in the elicited female sexual response is not known at this stage. However, threat to structural integrity is also an important factor in the female. There may be a disproportionate increase in caldesmon relative to myosin in certain situations, with a resultant inhibition of the vaginal smooth muscle contractility (Boreham MK et al., 2001) and estrogen-mediated increase in cystatin C may be seen as a compensatory or protective mechanism. As identified by cDNA array, increased vaginal cystatin C expression in the fibroblasts and smooth muscle bundles can help to strengthen the vaginal wall (Slayden OD et al., 2004).

After all, genital tissue reconstruction is now a possibility both in the male and female. We are moving ahead with the successful engineering of three-dimensional male erectile tissue architecture, basically grown from human CCSM and endothelial cell seeds on acellular collagen matrices (Park HJ et al., 1999; Falke G et al., 2003). On the women’s front, similarly seeded polymer scaffolds have notably converted into vascularized vaginal tissue possessing the same phenotypic and functional properties as the normal tissue (De Filippo RE et al., 2003). The clinical advantage of having such transplantable autologous tissue is manifold.

E. EXPERIMENTAL MODELS FOR THERAPEUTICAL DEVELOPMENT

It is clear that animal models exist that can be used to develop treatments for – or to understand the etiology of – various sexual disorders. What is key in this analysis is the baseline of the animal. It is fine to study normative sexual function in animals, but “ceil-ing effects” may well prevent the ability to observe a facilitation of sexual function. To have a model of dysfunction, one must use animals that are hypofunctional. For example, albino male rats do not readily show psychogenic erections, whereas pigmented males do. The serotonin synthesis inhibitor parachlorophenylalanine (PCPA) had no effect on the number of psychogenic erections in pigmented Long-Evans males, but facilitated erections in albino Wistar males. Likewise, the stimulation of spontaneous erections by bre melanotid was always observed consistently in albino Sprague-Dawley rats, but not consistently in pigmented rats (A. Shadiack, personal communication). Because of their unique physiology that may well suppress erection due to higher than normal serotonin turnover, albino rats provide a lower baseline of erection that allows for an easier treatment effect.

Determining the “right” hormone baseline has been an issue for a long time in the female literature, as most of the doses used to induce sexual receptivity in female rats are maximal. Even repeated administration of low doses of estradiol to female rats (e.g., at 4-day intervals) results in a progressive upward drift in the number of solicitations and high-intensity lordoses (Farrell et al., in preparation). It is instructive to understand that in the natural world, although female rats are capable of estrous cycles every 4 or 5 days, they rarely do because they are either pregnant or pseudopregnant, which results in a far longer period of sexual nonreceptivity and suppression of the estrous (cycling) hormonal profile. Indeed, the induction of estrus termination by high amounts of distributed vaginocervical stimulation is masked by estradiol priming at 4- or 7-day intervals, but not by 14- or 28-day intervals (Pfaus et al., 2000). This indicates that the timing and dose of hormone priming is critical in generating a reliably low baseline upon which facilitative effects of a drug or treatment can be observed. This is also true of males, and will depend critically on the level of sexual experience and the amount of time since castration has occurred.

For sexual arousal, both behavioral and vascular models exist to examine mechanisms of erection, ejaculation, and vaginal/clitoral blood flow. Those models can be employed to study drug effects or molecular interactions, and to examine how peripheral actions are integrated in the brain, both in terms of sensory awareness and descending influences. For example, behavioral models of premature ejaculation exist in rats (Chan et al., 2008; Pattij et al., 2005) and those animals can be used as models for treatment paradigms or studied with regard to the neurochemical and neurophysiological mechanisms that underlie their rapid ejaculation.

For sexual desire and reward, it is vitally important to use models that have predictive validity. In copulatory circumstances, solicitations perhaps the display of high-intensity lordoses, are augmented by drugs (dopamine or melanocortin agonists) or conditioned cues associated with sexual reward. Conversely, pacing and defensive behaviors are diminished by those pharmacological or sensory primes. Likewise, conditioned partner or place preferences can be used to infer reward states that feed back positively on desire. The lack of reward, induced by early sexual experience that is not accompanied by opioid transmission, diminishes the desire of female rats to initiate sexual activity, and abolishes conditioned place and partner preferences in both male and female rats. A similar effect is observed in long-term castrated rats given subthreshold hormone priming. In both male and female rats, precopulatory operant or anticipatory locomotor paradigms, or responses made to unconditioned sexual incentives (e.g., sexually active vs. castrated conspecifics) or conditioned cues paired with reward, are useful to elucidate the basic neurochemical systems associated with their display. Castration, nonreward, and satiety diminish the display of those responses, and thus those paradigms provide a means to examine treatments that might stimulate sexual desire directly.

Sexual inhibition paradigms, either unconditional (in which the animals are presented with sexually non-receptive or unresponsive partners), or conditional (in which the animals are presented with stimuli on sexually responsive partners that was paired previously with sexually nonresponsive partners, or with a lack of sexual reward induced by concurrent treatment with naloxone), are likely to increase in use. Many premenopausal women with HSDD do not possess low hormone levels, thus it is likely that experiential factors have played a role in the etiology of the disorder. The appropriate animal model for such a clinical situation may well be one of low desire induced by sexual nonreward. Again, the most important requirement of the preclinical model will be predictive validity.
F. CONCLUSION - PERSPECTIVES

Animals possess appetitive and consummatory aspects of sexual behavior that are homologous and analogous to our own and that are controlled by similar or identical neurochemical and hormonal systems. They experience sexual arousal, desire, reward, and inhibition. Males are excited by females that require some form of courtship or pursuit, and will work hard to obtain even small sexual rewards. Females like to control the initiation and rate of sexual contact. Sexual behavior in males is strengthened with experience, making them less vulnerable to treatments that disrupt sexual responding. The same may occur in females. From an evolutionary perspective, sexual behavior appears to have similar processes and endpoints for all mammalian species, and perhaps for all species that engage in it. This makes the study of sexual behavior in animals, and the use of animals as models of sexual dysfunction.

If the process and endpoints of sexual response are the same (even if the outward expression of appetitive behaviors or copulation is species-specific), then animals can indeed be used as models of human sexual response provided the homology or analogy is specified unambiguously, and that treatments or experiences have similar effects between the species, giving the animal model predictive validity. This requires that we understand the particular behaviors of both species as best we can, which in turn requires that we be careful and creative in how we ask our scientific questions. For example, it was once believed that male rats lack the cognitive capacity and sophisticated cultural conditioning for sexual inhibition, thereby making them unsuitable models for the disinhibitory effects of alcohol (e.g., Wilson, 1977). Yet they clearly learn not to attempt copulation with sexually nonreceptive females, and show disinhibition under the influence of low doses of alcohol. It was also believed that female rats didn’t “enjoy” copulation because it took them longer to return to a male following intromission or ejaculation, relative to precopulatory interaction or mounts without intromission. However, Paredes and colleagues provided an important glimpse of what female rats really like about sex: their ability to control its occurrence and rate. If they have control over the initiation and rate of sexual interaction, then female rats will develop copulatory CPPs; if not, then CPPs do not develop despite the fact that females still copulate and are sexually receptive. For male rats, the reward state induced by ejaculation and/or its aftermath is critical for the development of CPP and partner preference. Larsson (1956) reported that some enforced intervals between intromissions were optimal for ejaculation whereas others that were too long (e.g., greater than 5 min) led to an inhibition of sexual activity. It may be that male rats also require a form of "control" with regard to female accessibility (as suggested by Martinez and Paredes, 2001). This can be expressed naturally in chasing or pursuit, or in other behaviors that maximize the desired rate of genital contact and stimulation. Control is an important aspect of sexual function in both men and women, and problems with locus of control may form an important part of the etiology of different sexual disorders (McCullough & Fine, 1999). Female rats display preceptive and receptive sexual behaviors only during their periovulatory period, or if they are ovariectomized and given appropriate replacement with estrogen and progesterone. Although female primates, including humans, can have sex throughout their ovulatory cycles, they display increased female-initiated solicitation and sexual activity during their periovulatory periods (Wallen, 1982, 1995). Making the conceptual connection between animal and human sexual behaviors is the primary challenge for researchers. Subsequent testing of those connections is easier, but equally important.

We believe that animal models will continue to be indispensable for studies of the neurobiology of sexual behavior. We need the knowledge that lesion and drug studies, neurochemical and neuroanatomical analyses, and molecular approaches, provide in animals to guide our emerging work in the neuroanatomy of sexual responding in humans using functional magnetic resonance imaging or positron emission tomography. We need animal models to further understand the hormonal processes that lead to changes in sexual arousability (e.g., following hormone replacement therapy in postmenopausal or hypogonadal individuals). The kind of invasive and direct studies of brain or organ function in animals simply cannot be conducted in human subjects.

Although studies of human and animal sexual behavior have advanced independently, their convergence is long overdue. More and more animal models of human sexual response are being used productively by clinical sex researchers and neuroendocrinologists to study the neuroanatomy, neurochemistry, and pharmacology of sexual behavior. The cross-fertilization of these two fields can only lead to a greater understanding of sexual behavior in general, and provide more scientific sophistication to understand its unique -- and common -- expression in all species.
G. RECOMMENDATIONS FROM THE COMMITTEE FOR THE STUDY OF MALE AND FEMALE SEXUAL FUNCTION AND DYSFUNCTION

This committee notes the continuing development of animal models of behavioral, physiological, and pathophysiological conditions in humans. Although the committee recognizes that human sexual behavior and its disruption by organic or psychological conditions is best studied in humans, the committee notes the ethical and practical considerations that make it difficult—if not impossible—to do this on a wide scale. The committee also notes that animal studies provide crucial information from a basic science point of view that both informs treatment strategies and provides sexual medicine with the ability to identify mechanisms in the central nervous system and periphery that can be targets for physiological, pharmacological, behavioral and surgical interventions. It is difficult to make many specific recommendations, other than to strongly endorse the continuing creative development of ethologically-and clinically-relevant animal models.

1. WHAT MAKES A GOOD ANIMAL MODEL FOR THE STUDY OF THE SEXUAL FUNCTION?

Predictive validity is the most important requisite of an appropriate animal model. In addition to this, animal models should be simple and practical enough to have “high throughput”, meaning the ability to have experiments conducted relatively quickly. Issues of sample size and ease of testing and analysis are key factors. The validity of any homologous or analogous animal model can only be determined in situations that test whether a treatment that modifies behavior and/or sexual function in the animal does so in humans.

Rats continue to be the most frequently-used animals in the study of sexual functions and behavior. Rats resemble humans in many analogous and homologous ways.

2. PENILE ERECTION

From a physiological perspective, it appears that there is a close similarity between local mechanisms of penile erection between non-human mammals and humans except for the role of striated muscles which are less important in humans compared to various animal species.

Although care must always be taken before extrapolating quickly from experimental data to the clinical situation, there is a high degree of predictability from rat models to men. Nature appears to have conserved mechanisms of erection in mammalian males.

Behavioral paradigms that assess penile erection in rats include both spontaneous and noncontact erections. The latter is stimulated predominantly by olfactory stimuli (either unconditioned estrous odors from a female, or conditioned odors (e.g. almond) associated with ejaculation) and thus appears to analogous to “psychogenic” erection in men stimulated in response to erotic visual cues.

3. ERECTILE DYSFUNCTION

A non-exhaustive list of pathophysiological models of ED comprises hypertensive rats, atherosclerotic rabbits, diabetic type I and II rats and rabbits, rats with metabolic syndrome, aged rats, castrated rats, cavernous nerve-injured rats... The question of extrapolation to humans using of these various experimental conditions must always be asked before drawing conclusions regarding applicability. It is noteworthy that there is no established standard in this domain and no standardization paradigms between laboratories. Both are critical in particular for diabetes and cavernous nerve injury, therefore we propose that the endpoints must be analogous or homologous (e.g., the restoration of erectile capability sufficient for copulation). Overall there is a high degree of predictability from rat models to men.

Transgenic or knock-out mice have contributed to our understanding of the physiological mechanisms of erectile function as well as various pathophysiological processes occurring during ED.

Cellular and molecular investigation techniques are available including cavernosal smooth muscle cell culture, 2nd messenger pathway: cGMP, cAMP, qRTPCR ...

Tissue engineering and stem cell research is also well established using erectile tissue, pelvic plexus, cavernosal nerve.

4. GENE THERAPY

The apparent preclinical success of most, if not all, gene-based strategies for the treatment of erectile dysfunction is consistent with the multifactorial regulatory mechanisms governing the erectile process.

5. LAPEYRONIE’S DISEASE

An experimental model of transforming growth factor-beta 1 (TGF-β1) induced Lapeyronie’s like condition in the rat has been proposed.

6. PRIAPISM

A transgenic sickle-cell mouse model to study the pathophysiology of priapism has been recently established.
7. EJACULATION

In behavioral experiments, ejaculations in rats can be studied much the same way they are studied in humans, with the latency from first mount or intromission to ejaculation being the key variables. A variety of paradigms have been developed in anesthetized rats, most of them recently:

- Urethrogenital reflex in spinalized rat may be considered as mimicking an orgasm-like response.
- Electrical stimulation of the hypogastric nerve elicits a rise in seminal vesicle and bladder neck pressures partly mimicking emission.
- Pudendal motoneuron reflex discharge is thought to be an experimental model representing what occurs in human during sexual intercourse and that culminate with expulsion of sperm.
- Complete ejaculation can be elicited by electrical stimulation of intermesenteric nerves or more reliably by microstimulation of the lumbar spinothalamic neurons
- Pharmacologically-induced ejaculation can be elicited by para-chloroamphetamine, 8 or 7-OH DPAT.

8. MALE SEXUAL DESIRE

The willingness to mount, intromit, and pursue females, can be used as analogues of male desire. Desire can be also inferred from certain appetitive responses that occur during copulation such as chasing behavior in males. Appetitive responses that occur prior to sexual activity, especially conditioned appetitive responses, may have the most direct applicability to human sexual desire.

9. FEMALE SEXUAL RESPONSE

In anesthetized female rabbit or rat, peripheral neural electrical stimulation elicits vaginal and clitoral vascular response.

10. FEMALE ORGASM

The paradigm of the uro-genital reflex allows the investigation of a female orgasm-like response.

11. FEMALE SEXUAL DESIRE

Psychological arousal or desire in women is likely to be very close to appetitive and precopulatory behaviours, such as solicitations. Accordingly the study of appetitive behaviors and precopulatory behaviours is relevant to any preclinical investigation of potential of compounds for the treatment of female sexual disorders or dysfunctions.

12. SEXUAL REWARD MODELS

Several recent studies have linked the state induced by ejaculation in male rats and by paced mating in female rats with the induction of sexual reward. Paradigms include both conditioned place and partner preferences. Interestingly, the induction of behaviors indicative of sexual desire in both male and female rats are strongly related to the reward state that induce place and partner preferences. Therefore the committee recommends continued development of those paradigms and further basic research into the neuroanatomical and neurochemical support mechanisms that underlie those reward states.

13. MODELS OF SEXUAL INHIBITION

There is a need for the development of animal models of hypoactive sexual desire in both males and females. Such models may include hypogonadal conditions following removal of the gonads and replacement with sub-optimal hormone priming (e.g., estradiol-alone in females or subthreshold testosterone in males), sexual non reward paradigms in which the induction of reward is blunted pharmacologically (e.g., using the opioid receptor antagonist naloxone), or the induction of sexual satiety or estrus termination that leads to inhibition of sexual desire, arousal and copulation.

There is a need for the development of sexually-related pain models of both behavior and neurphysiology.

I. INTRODUCTION

1. SIZE OF THE PROBLEM

Erectile dysfunction (ED) is a common worldwide clinical problem[1]. It is estimated that 150 million men worldwide currently experience ED to a variable degree and by 2025 the prevalence is predicted to rise to over 300 million men[2]. In the Massachusetts Male Aging Study (MMAS), a large population-based random sample of 1290 healthy men aged 40 to 70 years, 52% and 70% of men aged 40–70 or >70 years of age, respectively had some degree of sexual dysfunction. ED was related to age, number of risk factors and concomitant heart diseases [3].

2. ROLE OF RISK FACTORS: “OVERLAP OF RISK FACTORS”

The risk factors for coronary artery disease (CAD) and ED leading to endothelial damage and vascular obstruction are similar, including age, dyslipidaemia, hypertension, diabetes, smoking, sedentary lifestyle, obesity and depression. As a consequence men with ED have a higher incidence of concomitant (silent or manifest) CAD or peripheral vascular disease than non-ED. In addition men with a common vascular disorder, mainly CAD, have an increased incidence of concomitant (not declared) ED or peripheral vascular disease than non-ED. In addition men with a common vascular disorder, mainly CAD, have an increased incidence of concomitant (not declared) ED. Most patients with ED are known to have at least one significant cardiovascular risk factor[4-8]. Seftel et al[9] found that in a general ED population the prevalence of 4 major risk factors - hypertension, diabetes, hyperlipidemia and depression - were 41.6%, 42%, 20% and 11%, respectively. Prevalence was age-related with at least one risk factor found in 85% over 75 years of age. Overall, ED men have a much higher prevalence of risk factors than non-ED men after adjusting for age[10]. In addition, the number of risk factors has been found to be correlated with the likelihood of having abnormal penile blood flow hemodynamics as assessed by penile duplex Doppler ultrasound [11,12]. Interestingly, in many patients with a first diagnosis of ED, underlying, undiagnosed cardiovascular co-morbidities can be detected. For example, both Seftel et al[9] and Sun et al[13] reported 40% undetected hypertension in ED patients. Any form of underlying glucose intolerance or true diabetes was found in up to 17% of ED subjects[14].

a) Hypertension

A significant number of hypertensive patients are likely to have ED. In the MMAS the age-adjusted probability of complete ED was 15% in treated hypertensives compared to 9.6% of the whole population[3]. In another study, ED was reported in 17% of men with untreated hypertension in comparison with 25% of men who were receiving current antihypertensive treatment; a finding which suggests that certain treatments can induce significant deleterious effect on erectile mechanisms. Furthermore, these data indicate that there needs to be careful assessment of the impact of antihypertensive medications in the analysis of hypertension-associated ED. Burkardt et al mailed the International Index of Erectile Function (IIEF) questionnaire to 476 male patients with hypertension[15]. One hundred and four patients (mean age 62.2 years) completed the questionnaire. of these, 68.3% had some degree of ED. ED was mild in 7.7%, moderate in 15.4% and severe in 45.2%. Compared to the general population of ED cases, patients with hypertension had more severe ED (45.2% in hypertensives versus ~10% in a general population as reported by the MMAS). The authors concluded that ED was more prevalent in patients with hypertension than in age-matched controls and that the degree of ED was more severe in patients with hypertension than the general male population. In a survey of 7689 patients (mean age 59 years) using the Sexual Health Inventory in Men (SHIM) questionnaire, Giuliano et al[16] reported an ED rate of 67% in 3906 men with isolated hypertension, 71% in 2377 men with isolated diabetes and 77% when the combination of hypertension and dia-
b) Smoking

In the original MMAS[1] smoking increased the age-adjusted probability of complete ED in men with treated heart disease. Moreover, it doubled the chance of developing ED over an eight-year follow-up period in those who were free from ED at study entry[3]. Smoking is well known as a risk factor for endothelial damage and vascular disease. Although cessation of smoking later in life may still be of some benefit to the 3-4 mm coronary arteries, it may be too late to reverse damage to the small (1-2 mm) penile arteries[17].

c) Lipid abnormalities

A study by Wei et al[18] followed-up for almost two years 3250 men with dyslipidemia and no ED. They showed that a cholesterol value >240 mg/dL (6.2 mmol/L) increased the risk of ED by 1.8 times compared to men with a <180 mg/dL (4.78 mmol/L) level. A high density lipoprotein level >60 mg/dL (1.55 mmol/L) was associated with a lower (0.3 times) risk of ED as compared to <30 mg/dL (0.78 mmol/L) level. Every 1 mmol/L increase in total cholesterol level was associated with a 1.32 times risk of ED whereas a similar increase in HDL-cholesterol was associated with a 0.38 decrease of ED. In contrast to what might be expected, lipid-lowering therapy may not benefit ED and in some cases can actually cause or exacerbate ED, possibly due to a central action secondary to blood-brain barrier penetration, though additional multiple risk factors may also be causative[19].

d) Diabetes

Diabetics suffer from both endothelial/vascular and neurological ED, with ED prevalence as high as 80% in those over 60 years of age[20]. As compared to non diabetics, ED occurs at an earlier age and is strongly influenced by the duration of the metabolic alteration. It is possible that early and vigorous glucose control might be preventative. In addition, the early use of statins and perhaps prophylactic PDE-5 inhibitors as daily therapy theoretically could preserve endothelial function[21].

e) Lifestyle issues

Recent epidemiologic studies have investigated in a longitudinal assessment the role of different risk factors on the development and progression of ED[22]. The long-term extension of the original MMAS study investigated whether cigarette smoking, heavy drinking, sedentary lifestyle, and obesity were associated with an increased risk of developing moderate-to-severe ED in a population of men who were initially potent or mildly impotent, and were followed for an average of 8 years. Results revealed a low risk of ED among men who maintained a physical activity level of at least 200 kcal per day. In addition, the ED risk was high among men who exhibited sedentary activity levels at both baseline and follow up. Most importantly, the risk of ED was significantly reduced among men who were sedentary at baseline and became physically active during the course of the study.

3. CARDIOVASCULAR RESPONSE TO SEXUAL ACTIVITIES

The cardiovascular response to sexual activity is the combination of mild-to-moderate physical activity and a state of arousal (so-called sexual arousal). Opposite to what is commonly thought, sexual arousal is the major determinant of the cardiovascular response to sex. The fundamental paper by Bohlen et al[23] evaluated the hemodynamic and metabolic response to sexual activity in 10 healthy men (mean age 33 yr). Four different types of sexual activity (self stimulation, partner stimulation, orgasm with men on top and with woman on top) were tested. The response was compared with that of a symptom-limited treadmill test. During sexual activity, the heart rate progressively increased with a peak value during orgasm greater with men on top than with woman on top (127±23 bpm vs. 110±24 bpm, p<0.02). During orgasm, the heart rate increase varied to 54-67% of the peak heart rate achieved during the treadmill, with little difference between the four types of sexual activity. Similar results were obtained for oxygen consumption (VO2), expressed as the metabolic equivalent of the task (MET) where 1 MET is equivalent to the VO2 consumption in a resting state, was calculated. During orgasm, the VO2 consumption varied by 11-22% of that obtained at peak treadmill test. The mean METs value was 3.3 for coitus with man on top. Thus, sexual activity poses little cost to the heart and is similar to ordinary daily activities and much less than maximal exercise. Sexual arousal more than exertion is the major determinant of VO2 consumption.

The cardiovascular responses during sexual activity in patients with CAD elicit qualitative changes similar to normals (Table 1). In a study of 30 men and 5 women with stable angina patients assessed by 24 hour ECG monitoring, the heart rate response averaged 122 beats/minute (range:102-137 beats/min) during intercourse compared to a maximum of 124 beats/minute during the rest of the day[24].

Some general considerations should be kept in mind. Firstly, the cost of intercourse is lower (3-4 METs) for couples in a long standing relationship than for extramarital intercourse with an unfamiliar partner. In this setting, the higher heart rate achieved during the sexual intercourse, mainly due to an high degree of sexual arousal, performance anxiety, ingestion of alcohol and food, social disapproval, accounts for the higher cardiac workload and the risk of an
acute cardiac event[25]. Secondly, younger couples may be more vigorous in their sexual activity than older ones expending up to 5-6 METs. Finally, the concomitant use of cardiovascular medication such as beta-blockers and/or calcium-antagonist, may lower sexual activity cost even in CAD patient with reduced coronary reserve, limiting the risk of effort-induced acute coronary events.

Thus, exercise stress test is the most indicated tool to check functional reserve before sex. Drory et al[26] assessed the cardiovascular response to sex by exercise testing and Holter monitoring in 88 CAD patients with stable angina when off-therapy. In the 34 patients with negative exercise testing none had ischemia with Holter monitoring whereas positive exercise testing was associated with ischemic changes by Holter monitoring during sex in 50% of patients. Thus, CAD patients should be always asked to perform an exercise stress test before initiating or resuming sexual activity. If they can exercise up to 3-6 METs without evidence of myocardial ischemia, they can generally engage in sexual activity without experiencing cardiac symptoms.

In an asymptomatic subject, tolerance to sexual activity may be assessed by simple everyday guidelines. If he/she can tolerate walking 1 mile (1.5km) briskly on the level in 20 minutes (3-4 METs) or climb two flights of stairs without limiting symptoms (6 METs), it is highly probable that sexual activity can be tolerated without cardiac symptoms. (Table 2)

However, because there may be a significant variation in the physiologic response to sexual activity, it is important to individualize the advice. If sexual activity leads to angina pectoris because of a disproportionate myocardial oxygen demand relative to the supply, the effect of exercise training can decrease the myocardial oxygen demand for the same amount of total body work and should decrease or obviate the occurrence of angina pectoris.

5. POST-MI SEXUAL DYSFUNCTION AND COITAL DEATH

At least half of the patients who have suffered a MI never regain their earlier frequency of sexual activity. In one of the earliest studies of post-MI sexual dysfunction, 39 men were evaluated one year after MI. One-third of them had intercourse only half as often, and another one-third, only one-quarter as frequently as they did before their MI[32].

There is considerable variation in the incidence of post-MI symptoms, which occur in 8 to 57% of patients, depending on the time after MI at which they are evaluated, how carefully they are questioned about their symptoms, and whether they participate in an exercise rehabilitation program[33]. The relative risk of triggering the onset of MI among patients with a history of prior angina or prior MI was not greater than that observed in those without prior cardiac disease.

Hence, it is safe for the recovering MI patient who is in stable condition and not suffering from congestive heart failure, unstable angina, or arrhythmia not responding to treatment, to resume sexual activity.

4. SEXUAL ACTIVITY AS A RISK FACTOR

Overall, the risk of myocardial infarction during sexual activity is negligible[27]. Although maintaining sexual activity has been reported to have potential health benefits, it can trigger myocardial infarction (MI), arrhythmia or sudden death in a very small minority of patients[28,29]. The Myocardial Infarction Onset Study (MIoS) enrolled 1712 patients with a first episode of myocardial infarction (MI)[30]. Sexual activity was the potential trigger for myocardial infarction in 1.5% of cases. Among 858 sexually active in the year before MI, 70 (9%) reported sexual activity in the 24 hours preceding the acute coronary event, and 27 (3%) in the two hours preceding the onset of symptoms. The relative risk of MI was assessed by “case-crossover” methodology.

Table 3 shows the figures for different categories of patients developing MI during sexual activity. Overall, the relative risk of MI was increase by 2-3 times and was confined to the 2 hours after sexual activity. After correcting for chance occurrence, 0.9% of cases could be attributed to sexual activity within the 2-hour period before MI onset. Of paramount importance was the observation that the risk decreased to none if the subject engaged in regular physical activity (at least 3 times/week) at moderate workload (5-6 METs).

A more important concept is the absolute risk of MI during sex. In other words: “How much does sexual activity increase an individual’s risk of MI above their baseline risk?”. We know from the Framingham Heart Study that the baseline risk of MI for a 50-year-old non-smoking, non-diabetic man is 1% per year or 1 chance in a million per hour. As sexual activity increases the relative risk by 2-3 times, this subject will have a 1.01% per year (or 2-3 chances in a million, only for a 2-hour period). In patients who have had a previous MI, the baseline risk of reinfarction or death is: 10% per year or 10 chance in a million per hour increasing to 10.1% per year or 20 chance in a million for a 2-hour period after sexual activity. Once again, the risk decreased to <3% if the patient could exercise >7 METs.

Coital sudden death is very rare. In three large studies death related to sexual activity was 0.6% in Japan, 0.18% in Frankfurt, and 1.7% in Berlin[31]. Extramarital sex was responsible for 75%, 75% and 77% respectively, and the victims were men in 82%, 94% and 93% of cases respectively. The partnership of an older man with a younger woman was the most common setting. Excessive drinking and sex too close to a large meal were frequently associated.

The association between cardiovascular disease and ED may be related to increased catecholamine loading during sexual performance, especially in patients with ED. Factors such as fear of failure, performance anxiety, anger, shame, and embarrassment may lead to release of systemic norepinephrine. Catecholamine loading during sexual performance may also be related to physiologic and psychologically mediated sexual-related pain, such as Peyronie’s disease, prostatitis, epididymitis, or nongenital pain (e.g. headache). In addition, a physiologically induced catecholamine load may be related to sexual performance itself.
Studies of post-MI patients have shown that heart rate, blood pressure, and ST segment changes recorded during intercourse are within the limits of many other ordinary daily activities[34].

6. CAUSES OF POST-MI SEXUAL DYSFUNCTION

a) Psychological factors

Patients with angina are likely to experience a conflict between the desire for intercourse and the fear of anginal pain and its implication for the heart[35]. Psychogenic factors, rather than physical distress or medication side effects, are the most common cause of post-MI sexual dysfunction. Patients may react psychologically to the MI with fear, denial, manipulation or acceptance. Each of these reactions may affect their sexual function[36].

b) Physical distress

Patients may develop chest pain, palpitations, shortness of breath, or fatigue, which often creates fear and thereby affects the frequency and quality of sexual encounters[33]. Patients with CAD may report chest pain during sexual activity. A patient who had such symptoms before he developed acute coronary event is likely to be even more fearful and anxious upon resuming a normal sex life after recovery. When pain originates “in the heart” the individual feels especially vulnerable, since from childhood on, the heart is understood to be at the centre of life itself. Therefore, the individual who is subjected to attacks of angina tends to try to avoid any activity that could provoke an attack.

c) Drugs

Some cardiovascular drugs, such as diuretics, digoxis, beta-blockers, central-acting antihypertensives drugs, antiarrhythmics, lipid lowering agents, may affect patient’s sexuality. Psychotropic drugs may also have negative effects. All these drugs may affect libido, erection, ejaculation or orgasm (Table 4) [37].

d) Prior sexual problems

Prior abnormal sexual function such as, ED or ejaculatory disorders will continue or be exaggerated after a heart attack. Some patients use their illness as a source of power to manipulate or control those around them in order to obtain their desires. Such behaviors commonly include demands for or abstinence from sexual activity, especially in those relationships where sex has always been used to reward or punish[36].

e) Spouse fear and anxiety

Spouses are most often concerned that sex may be too stressful or unsafe for a cardiac patient. Such fears ultimately will affect their desire to resume sexual relations. Many wives of post-MI patients expressed concerns about risks of sexual activity and the negative effects of this situation on the couple’s emotional relationship[34].

7. ASSESSING THE RISK OF SEX IN ED PATIENTS: THE PRINCETON CONSensus CONFERENCE

The first Princeton Consensus Conference (Princeton I) in 1999 addressed the evidence linking sexual activity and cardiac risk and developed guidelines for safe management of cardiac patients regarding sexual activity and the treatment of ED. The second conference (Princeton II) updated the recommendations based on the expanding knowledge base and new treatments available[38,39].

Princeton I has proved to be a useful clinical guide to evaluating ED and sexual activity in cardiac patients and those at cardiac risk. The importance of ED as a risk marker in men with no cardiac symptoms is highlighted in Princeton II as is the value of lifestyle

changes. The concept of “physically fit = sexually fit” is emphasized. The categories of low-, intermediate- or indeterminate-, and high-risk patients are maintained but updated (Table 5) and the algorithm changed to emphasize the importance of CAD and general vascular disease risk assessment (Figure 1).

The Second Princeton Consensus Conference recommendations addressed this topic more specifically in patients with sexual dysfunction and heart disease [39]. According to the number of conventional risk factors (if asymptomatic) or the presence

Intermediate or indeterminate risk: evaluate to reclassify as high/low risk

Asymptomatic and ≥3CAD risk factors (excluding gender)
Increased risk for acute MI and death ETT may be appropriate, particularly in sedentary patients

Moderate, stable angina pectoris
ETT may clarify risk

MI >2 weeks but < 6 weeks
Increased risk of ischaemia, reinfarction, reinfarction, and malignant arrhythmias ETT may clarify risk

LVD/congestive heart failure (CHF) (NYHA class II)
Moderate risk of increased symptoms Cardiovascular evaluation and rehabilitation may permit reclassification as low risk

Non-cardiac atherosclerotic sequelae (peripheral arterial disease, history of stroke or transient ischaemic attacks)
Increased risk of MI Cardiological evaluation should be considered

High risk: defer resumption of sexual activity until cardiological assessment and treatment

Unstable or refractory angina
Increased risk of MI

Uncontrolled hypertension
Increased risk of acute cardiac and vascular events (e.g. stroke)

CHF (NYHA class III, IV)
Increased risk of cardiac decompensation

Recent MI <2 weeks
Increased risk of reinfarction, cardiac rupture or arrhythmias, but impact of complete revascularization on risk is unknown

High risk arrhythmias
Rarely malignant arrhythmias during sexual activity may cause sudden death Risk is decreased by an implanted defibrillator or pacemaker

Obstructive hypertrophic cardiomyopathies
Cardiovascular risks of sexual activity are poorly defined Cardiological evaluation (ETT and echocardiography) may guide patient management

Moderate to severe valve disease
Use vasoactive drugs with caution

Adapted from Kostis et al [39]
CAD – coronary artery disease; CHF – congestive heart failure; CV – cardiovascular; CVA – cerebrovascular accident; ED – erectile dysfunction; ETT – exercise tolerance test; LVD – left ventricular dysfunction; MI – myocardial infarction; NYHA – New York Heart Association
and the severity of common heart diseases, subjects are divided into three risk categories: low, intermediate- or indeterminate and high risk. Low-risk patients should be reassured and retested in about 5 years. Medications for ED can be prescribed without need for additional tests. High risk patients, mainly those with severe heart diseases, should undergo further cardiologic assessment and should receive aggressive treatment of their risk factors. In this group of patients, treatment for ED should be deferred until a full cardiologic assessment is performed. Men at intermediate- or indeterminate risk, may benefit from additional non-invasive tests aimed to better define the presence and the extension of subclinical coronary atherosclerosis and be re-allocated patients into low or high categories[40,41].

8. ASSESSING THE RISK OF SEX IN ED PATIENTS AT INTERMEDIATE- OR INDETERMINATE RISK: ROLE OF NON-INVASIVE TESTING

An exercise treadmill stress test is performed for the detection of CAD and for assessment of cardiovascular efficacy during exercise and risk stratification of patients. Stress echocardiography, a feasible and accurate technique for the identification and localization of CAD[42], has been added to the investigation profile to increase the sensitivity for the detection of CAD. Men with ED who have a negative stress echocardiography study are at low risk for cardiac death for two years following the stress study[43]. If at least one of these tests was positive, the patients should be referred for coronary angiography for documentation and assessment of the severity of possible CAD.

Some tests address obstructive atherosclerosis by directly assessing coronary flow reserve (e.g. standard exercise stress test, rest/stress myocardial scintigraphy or echocardiography). Other tests are general measures of atherosclerosis burden (not necessarily obstructive) either in the coronary circulation (e.g. coronary calcium score by electron-beam computed tomography [EBCT]), or in extracoronary vessels (e.g. ankle brachial index [ABI], carotid intima-media thickness [IMT] by B-mode ultrasound) as surrogate markers of CAD[44-46]. Although a systematic use of these measures of non-obstructive atherosclerosis burden has not yet been recommended in the guidelines for coronary risk assessment, their use is progressively being extended from the research area to clinical practice[47].

Efforts to identify diagnostic tools that might improve the prediction of acute coronary events beyond the role of classical risk factors continue. These tools include measures of atherosclerosis burden and indexes of vascular function (endothelial dysfunction) or vascular inflammation (high-sensitivity C-reactive protein [hsCRP])[48].

Nineteen percent of patients with ED of vascular origin have angiographically documented silent CAD. According to these studies, the prevalence of CAD determined angiographically in coronary asymptomatic patients ranges from 1.34 to 4.5%[49,50]. Although an exercise ECG is advocated to identify patients at increased cardiovascular risk, this method will identify only those people with obstructive flow-limiting CAD. Wherever possible, intermediate and high-risk patients should be considered for elective computed tomography coronary angiography to identify the presence of non-flow limiting lipid plaques that are potentially vulnerable to rupture[51]. By implementing these measures, it should be possible to initiate early aggressive cardiovascular risk reduction in 'at-risk' patients, thereby taking advantage of
the 2-5 year window of opportunity between the development of symptomatic ED and CAD[52,53].

II. VASCULOGENIC ERECTILE DYSFUNCTION

Vascular erectile dysfunction consists of arteriogenic ED (cavernosal artery insufficiency) and veno-occlusive ED (dysfunction of penile venous system)[54]. Although frequently discussed separately, in reality these two mechanisms often coexist in the same patient, and may reflect two stages of the same pathological process.

Erectile rigidity depends upon the rate and volume of blood flow into the corpora cavernosa of the penis via cavernosal arteries as well as passive veno-occlusion, which maintains rigidity[55]. It is estimated that 70% of all ED is the result of changes related to both the intrapenile and pre-penile vasculature either through diminished inflow or excessive outflow[56].

1. PATHOPHYSIOLOGY OF VASCULAR ERECTILE DYSFUNCTION

Vascular erectile dysfunction is the result of a combination of functional as well as structural changes of the penile vascular bed. In the presence of vascular risk factors functional vascular erectile dysfunction takes place, at least in part, due to endothelial dysfunction resulting from a reduced bioavailability of vasodilators. In particular, a deficit in nitric oxide

Figure 2: Development and progression of vascular erectile dysfunction.
(NO) action and the associated reduction in vasodilation of penile vessels is likely to be a key component of inadequate erectile responses because of the resultant decrease in arterial inflow and the attenuated cavernosal smooth muscle relaxation required for engaging sufficiently the veno-occlusive mechanism. This early stage of functional erectile dysfunction is characterized clinically by inability to maintain a rigid erection and the treatment of risk factors and vascular conditions associated with endothelial dysfunction (e.g., hypertension, hypercholesterolemia, obesity, physical inactivity) has been shown, in some studies, to improve erectile function[57, 58]. Over time, structural erectile dysfunction takes place in the form of atherosclerosis of penile blood vessels leading to arterial stenosis with reduced blood inflow and smooth muscle atrophy and fibrosis leading to increased blood out flow. This late stage of structural erectile dysfunction is currently considered to be irreversible (Figure 2).

Occlusive disease of the pudendal-cavernosal-helicine arterial tree is primarily caused by the development of atherosclerotic lesions leading to narrowing of the hypogastric-pudendal arterial bed and diminished arterial perfusion pressure which decreases arterial inflow to the lacunar spaces of the corpora cavernosa[59-61]. Arterial insufficiency also triggers a cascade of ischaemic/hypoxic cytotoxic events impairing the erectile tissue endothelium, smooth muscle, nerves, and microvessels[59, 62, 63].

2. ENDOTHELIAL DYSFUNCTION

The vascular endothelium of the penis has an important role in mediating vascular tone and blood flow into the penis in response to humoral, neural and mechanical stimuli[55, 64]. Endothelial cells lining the internal surface of penile arteries and sinusoids of the cavernosal tissue affect the tone of adjacent smooth muscle cells through the release of relaxing factors (such as nitric oxide, prostaglandin-E2 and C-type natriuretic peptide) and vasoconstrictive agents (such as endothelin-1 and angiotensin-II)[65-67]. In vasculogenic ED, the regulatory role of the endothelium is hindered, resulting in decreased bioavailability of and/or responsiveness to vasodilatory mediators; this may also be combined with increased levels and/or sensitivity to vasoconstricting agents[55]. Even a subtle alteration in the balance between the factors favoring corporal relaxation and contributing to contraction may result in ED[68].

The nitric oxide (NO) pathway is of critical importance in the normal induction and maintenance of erections[69, 70]. NO induces vasodilatation through increase in cGMP and counter balances RhoA/Rho-kinase-mediated vasoconstriction[71]. Apart from the neurally derived NO, the endothelial NO is also an important mediator of vascular responses in the penis[72, 73]. The neuronal NO synthase (nNOS) and the constitutive endothelial NO synthase (eNOS) isoforms are tightly regulated and produce physiologically relevant levels of NO in autonomic nerve endings and endothelial cells of the penis. In vasculogenic ED, dysfunctional endothelial cells lining the penile arterial system and the corpus cavernosum produce less NO. Hence, phosphodiesterase type 5 (PDE-5), abundant in perivascular smooth muscle cells, can rapidly degrade the reduced quantities of cyclic guanosine monophosphate (cGMP), thus limiting duration of vasodilation, an effect which will negatively impact on the ability to initiate and sustain an erection[69]. Impaired bioavailability of NO may result from impaired eNOS regulatory function through various mechanisms including asymmetric dimethyl arginine -mediated eNOS uncoupling[69, 71] and disturbance in systemic or local secretion or degradation of angiotensin II[65]. The angiotensin II component is not just a result of direct vasoconstrictor activity but also because of the increased tissue generation of reactive oxygen species that decreases NO activity[64].

Another important mechanism in endothelial cell dysfunction is the imbalance between endothelium-dependent relaxation due primarily to NO, and endothelium-dependent constriction due primarily to endothelin-1. Numerous conditions characterized by an impaired availability of NO have been found to be associated with enhanced synthesis of endothelin-1, and vice versa, suggesting that these two factors have a reciprocal regulation[74]. Experimental studies provided evidence that endothelin-1 may influence NO production and that NO can inhibit endothelin-1 synthesis[75].

3. EXCESSIVE SMOOTH MUSCLE CONTRACTION

Chronic ischaemia increases the contractile reactivity of the cavernosal smooth muscle. Ischaemia selectively enhances neurogenic contractile reactivity to electrical-field stimulation while having no effect on contraction to noradrenaline[76]. Indomethacin, a cyclooxygenase inhibitor, decreases neurogenic contraction of ischaemic tissues. These changes are associated with significant increases in the production of constrictor eicosanoids such as PGF-2α and thromboxane. Increased constrictor eicosanoids, in addition to direct interference with smooth muscle tone that favours contraction, also produce adverse effects on the inhibitory role of NO pathway in cavernosal tissue and indirectly augment contraction[76]. High levels of eicosanoids interfere with the expression of NOS proteins and down-regulate NOS expression[77].

4. SMOOTH MUSCLE ATROPHY AND FIBROSIS

Prolonged exposure to ischaemia results in loss of
smooth muscle and increased collagen fibers[60,78]. A close relationship between cavernosal smooth muscle degeneration and the development of corporal veno-occlusive dysfunction has often been reported[63]. Smooth muscle content, normally 42–50% of cavernosal tissue, can decrease to as low as 13% in some men with ED[78]. Thus degenerative changes in the cavernosal smooth muscle are associated with impaired veno-occlusive function. Another consistent finding in patients with ED seems to be a loss of elastic fibers, which is also associated with a pathological increase in collagen accumulation[63,78].

III. THE METABOLIC SYNDROME

1. INTRODUCTION

Metabolic syndrome (MS) refers to the clustering of several cardiometabolic risk factors, including abdominal obesity, hyperglycemia, dyslipidemia and elevated blood pressure, that are likely linked to insulin resistance[79]. The clinical relevance of MS is that it identifies people who are at increased long-term risk of cardiovascular disease and type 2 diabetes, thus providing an opportunity for preventive lifestyle interventions. Insulin resistance is also associated with a wide spectrum of clinical disorders, including polycystic ovary syndrome, non-alcoholic fatty liver disease, sleep-disordered breathing, chronic kidney disease and certain cancers[80]. In men, insulin resistance is associated with erectile dysfunction, with endothelial dysfunction likely to be one of the underlying mechanisms[81]. Increased visceral fat mass is also associated with hypogonadism[82].

2. ORIGIN OF THE SYNDROME

The association between hypertension, hyperglycemia and hyperuricemia was first reported over 80 years ago[83]. Subsequently, this cluster was expanded to include upper body ("android") adiposity[84] and dyslipidemia, and was observed to be linked to atherosclerosis. Hanefeld and Leonhardt in 1981 were the first to coin the term metabolic syndrome. Because that report was published in German and behind the "Iron Curtain," it remained unnoticed by many scientists and clinicians[85]. The authors stated that MS represented the common prevalence of obesity, hyperlipoproteinemia, dyslipoproteinemia, maturity onset diabetes (type 2), gout, and hypertension, associated with increased incidence of atherosclerotic vascular disease, fatty liver, and gallstones, that develops from genetic susceptibility combined with overnutrition and physical inactivity. In 1988, Reaven described a set of metabolic abnormalities (hypertension, hypertriglyceridemia, low high-density lipoprotein (HDL)-cholesterol level and hyperinsulinemia) associated with increased cardiovascular risk, which he termed “Syndrome X”, and postulated that impaired insulin action was the underlying pathophysiology[86].

3. CLINICAL DEFINITIONS

The first definition of MS was proposed by the World Health Organization[87], with hyperglycemia and/or insulin resistance as a central feature, associated with two or more related metabolic abnormalities (elevated blood pressure, dyslipidemia, central obesity or microalbuminuria).

The National Cholesterol Education Program (NCEP) definition requires three or more of the following features: abdominal obesity, elevated triglyceride levels, reduced HDL-cholesterol level, elevated blood pressure or elevated fasting glucose level[88].

In 2005, the International Diabetes Federation (IDF) proposed a definition of MS similar to that of the NCEP, but with increased waist circumference as a necessary requirement, emphasizing the central importance of abdominal obesity[89]. Ethnicity-specific cut-off points were proposed for waist measurements.

The definitions of MS (Table 6) provide clear criteria by which subjects can be evaluated by physicians; however, not all clinical studies have used the same definition, making comparisons among such studies difficult. The various definitions usually include the same core criteria of central obesity, hyperglycemia, dyslipidemia and high blood pressure, but differ in the cut-off points for individual criteria, in specific mandatory requirements (e.g. abdominal obesity or insulin resistance) and in the inclusion of additional factors (e.g. microalbuminuria). Hence, they identify broadly similar, but not identical, groups of individuals with MS.

4. PREVALENCE OF METABOLIC SYNDROME

The National Health and Nutrition Examination Survey 1999–2002 estimated the age-adjusted prevalence of MS in US adults aged 20 years and over to be between 34.6% (NCEP) and 39.1% (IDF)[90].

Approximately one-fourth of the adult European population has MS. Prevalence varies somewhat depending on the age group studied, geographic location, or characteristics of the population studied. With NCEP criteria, less than one-fifth of the studied population in Southeast Asia has MS. This lower prevalence, compared with North American and European populations, may be attributable in part to a younger population[91].

MS is more prevalent with increasing age, affecting half of adults aged 60 years and over[90]. It is more common in men when WHO or IDF criteria are used, but there is little difference between the sexes when
the NCEP definition is used[90,92]. Ethnicity also influences MS prevalence[90].

The prevalence of MS is increasing. Ford et al estimated that 50 million Americans had MS in 1990 and 64 million had the syndrome in 2000[93,94]. Two factors appear to account for this increase. One of these is obesity; in 1988 to 1994 the prevalence of obesity was 22.5%, and in 1999 to 2000, it had increased to 30.5%[95]. A second factor is aging of the population. For any level of BMI, the prevalence of MS in the US population rises with increasing age. This effect can be explained largely by age-related rises of blood pressure and glucose[96].

5. THE LINK BETWEEN METABOLIC SYNDROME AND ERECTILE DYSFUNCTION

Men with the metabolic syndrome have an increased prevalence of erectile dysfunction, and reduced endothelial function score. Erectile dysfunction prevalence increases as the number of components of the metabolic syndrome increases, with approximately 20%, 30%, and 35% of patients with ED having 3, 4, or 5 components of MS, respectively. By contrast, there is an inverse relationship between the number of components of the metabolic syndrome and the endothelial function score[97]. Corona et al re-
ported that among 236 patients diagnosed as having MS, 96.5% exhibited ED[98], and Bansal et al also reported that of 154 men with organic ED, 43% displayed MS (general population, 24%), 79.2% displayed insulin resistance (general population, 25%) and 90.9% displayed both insulin resistance and MS[81]. Clearly, ED represents a risk factor and may be a warning signal for MS and insulin resistance, both being clear risk factors of CVD. Interestingly, the largest jump in expression of MS occurred between men with moderate ED and men with severe ED (21.7%–70%). The authors also demonstrate the prevalence of elevated fasting blood sugar (>110 mg/dL: 5.6 mmol/L), a component of MS is associated with increased severity of ED[81].

Shabsigh et al assessed the relationship between the prevalence of comorbidities and ED severity in a cross-national survey on men’s health (ages 20–75). Hypertension and high cholesterol were the most prevalent comorbidities for each degree of ED severity. The authors also found that men between the ages of 70 and 75 were 14 times as likely to develop ED as compared with men between the ages of 20 and 29. This finding is consistent with the observation that as androgen levels decline with ageing, there is a concomitant increase in the prevalence of MS[99].

Zhody et al linked androgen deficiency with ED and MS by analyzing BMI and other factors in 158 obese men[100]. The authors found a significant association between increasing BMI and the following parameters: systolic blood pressure, low serum testosterone (T), penile duplex parameters, triglycerides, HDL, and LDL cholesterol. With increasing BMI, the frequency of hypogonadism and ED increased, whereas total serum T showed a strong negative correlation. To assess the effect of BMI on vasculogenic ED, the authors examined this relationship in the absence of other risk factors and found that for a BMI ≤25, 3 out of 13 men (23.1%) had vasculogenic ED, as compared with 32 out of 54 men (59.3%) with a BMI ≥25.

6. METABOLIC SYNDROME AND ENDOTHELIAL DYSFUNCTION

Endothelial dysfunction is a particularly relevant finding in patients with ED, especially in the early phase of the disease. In a later phase, other factors, such as impaired arterial flow of hypogastric/pudendal arteries, cavernosal fibrosis, and hypoxia, come into play to cause and maintain sexual dysfunction[102] (Figure 3).

Esposito et al. evaluated endothelial function in erectile dysfunction patients with metabolic syndrome versus age- and BMI-matched controls. Compared with controls, patients with the metabolic syndrome had an increased prevalence of erectile dysfunction, reduced endothelial function, and higher circulating concentrations of C-reactive protein. Their results show the prevalence of erectile dysfunction increased linearly with C-reactive protein levels, with impairment of endothelial function, and as the number of components present of the metabolic syndrome increased[97].
7. THE LINK BETWEEN METABOLIC SYNDROME AND HYPOGONADISM

Hypotheses have been offered to explain the deleterious effect of adiposity on circulating testosterone[82,101]. There is high aromatase activity in adipocytes, an enzyme involved in the metabolism of testosterone to estradiol. That is, the greater the number and volume of adipose tissue, the greater is the breakdown of testosterone. Testosterone inhibits lipoprotein lipase, an enzyme on the outer surface of the fat cell that regulates the conversion of free fatty acids into triglyceride[103]. Thus, lower testosterone levels would enhance the enzyme activity, thereby promoting greater uptake of triglyceride into the adipocytes, increasing fat storage and also stimulating the formation of new fat cells from pre-adipocytes. In turn, this would exacerbate insulin resistance and further drive the cycle to lower testosterone levels. Furthermore, the hypothalamic-pituitary axis would detect the falling testosterone level and increase gonadotrophin secretion to stimulate the testis. This response is potentially inhibited by three different mechanisms: (i) estradiol mediated inhibitory action on LH production[104], (ii) the inhibitory actions of inflammatory adipokines, tumour necrosis factor a (TNF-a) and interleukin 6 (IL-6), on LH release and (iii) the development of leptin resistance of the hypothalamic-pituitary axis (normally leptin stimulates LH release and directly inhibits the action of gonadotrophins on the testis, but in human obesity the HP axis becomes leptin resistant)[105,106] (Figure 4).

Increasing abdominal obesity leads to increased activity of the enzyme aromatase, present in adipose tissue, which converts testosterone to estrogen. The resulting low testosterone level increases lipoprotein lipase enzyme activity and triglyceride uptake leading to increased obesity and insulin resistance. This in turn causes further androgen deficiency and visceral fat deposition. Estradiol inhibits gonadotrophin release from the pituitary. Furthermore, testosterone levels are also lowered as a result of leptin resistance at the hypothalamic-pituitary level and the inhibitory effect of leptin on the testicular axis. Proinflammatory adipocytokines such as tumour necrosis a (TNF-a) and interleukin 6 (IL-6) could also potentially inhibit the pituitary axis resulting in low testosterone levels[107].

8. NEGATIVE IMPACT OF METABOLIC SYNDROME ON THE RESPONSIVENESS TO PDE-5 INHIBITORS

Suetomi et al analyzed the impact of MS on the responsiveness to 50-mg sildenafil in Japanese patients with ED. They reported a lower response rate for patients with MS, compared to the overall efficacy in Japanese ED patients (40% versus 70.9% respectively)[101,108]. The IIEF-erectile function score and the response rate for sildenafil decreased as the number of MS components increased. Moreover, the presence of MS was a significant independent risk factor of nonresponse for sildenafil. The hazard ratio for the presence of MS in sildenafil non-responders was 3.30.

IV. ERECTILE DYSFUNCTION AS A SILENT MARKER OF CORONARY ARTERY DISEASE

As cardiovascular disease and erectile dysfunction (ED) overlap in risk factors, prevalence and manifestation, they are thought to share both the etiology of and progression of the disease process. Pathological changes which link these conditions include endothelial dysfunction, inflammation, alterations in androgen levels and blood vessel size (Table 7).

1. ROLE OF ENDOTHELIAL DYSFUNCTION/INFLAMMATION

a) Endothelial dysfunction

Both cardiovascular disease and ED have been linked to endothelial dysfunction. As with conduit and small vessels of the limb, increased flow- and resultant increased shear stress-induced vasodilatation in the penile arteries appears to be mediated largely through nitric oxide (NO). The small diameter of the cavernosal arteries and the relatively high content of endothelium and smooth muscle on a per unit volume tissue basis compared to other organs suggests that the penile vascular bed may be a sensitive indicator of systemic vascular disease. Men with penile vascular dysfunction generally have endothelial dysfunction in other vascular beds as well. Despite differences in the clinical characteristics of the patient populations, including age, risk factors and type of ED, the results have consistently shown blunted endothelium-dependent vasodilation response in patients with ED as compared to controls. Interestingly, in a study of subjects with vasculogenic ED, endothelial dysfunction was found in the small resistance arteries of the forearm in spite of a negative extensive cardiologic work-up[119].

ACE: angiotensin converting enzyme; AMI: acute myocardial infarction; ARB: angiotensin receptor blocker; CAD: coronary artery disease; ED: erectile dysfunction; EST: exercise stress test; LV: left ventricle; PDE-5: phosphodiesterase type-5
together with other evidence, this finding suggests that endothelial damage occurs differentially in various vascular beds and in a time-dependent manner such that dysfunction within the penile endothelium is likely to occur prior to its occurrence in other parts of the circulation.

An association between erectile and endothelial dysfunction has also been found for non-conventional biomarkers of disease. Specifically, increased plasma levels of endothelin-1 and asymmetric dimethylarginine (ADMA), and decreased levels circulating endothelial progenitor cells involved in repair and C-type natriuretic peptide may also mechanistically link ED and endothelial dysfunction.

In addition, circulating microparticles (e.g. membrane vesicle fragments shed from the surface of endothelial cells during activation and injury) have been found to increase in non-diabetic ED patients compared to the amounts found in men without ED[120-123].

**b) Inflammation**

Chronic low-grade inflammation contributes to all stages of atherosclerosis, from the initial phase of increased endothelial permeability to the formation of the mature atherosclerotic plaque and plaque rupture. Increased levels of inflammatory markers have been documented in various settings of CAD, especially in acute coronary syndromes, bearing a strong association with clinical outcome[124].

Endothelial function and inflammation are associated in a bidirectional mode. Normal vascular endothelium has anti-inflammatory properties; on the other hand, endothelial function is impaired in the presence of inflammatory conditions and increased oxidative stress. Several studies have shown that presence and extent of ED are associated with markers and mediators of subclinical inflammation and endothelial activation, such as hsCRP, fibrinogen, von Willebrand factor, interleukins (IL)-1β and 6 and adhesion molecules (ICAM and VCAM). Of those, fibrinogen and IL-6 and their combination appear to have the potential to aid ED diagnosis or exclusion. Recent data also suggest that ED and CAD are similar in terms of the prevalence of inflammatory and endothelial-prothrombotic activation, with ED patients having an incremental burden. (Figure 5)[48,125].

**Figure 5: Unfavorable endothelial and inflammatory state in erectile dysfunction patients with or without coronary artery disease.**

A and B. Box-and-whisker plots of levels of inflammatory and endothelial-prothrombotic markers/mediators according to erectile dysfunction and coronary artery disease. Erectile dysfunction and coronary artery disease appear to confer a similar unfavorable impact on the inflammatory and prothrombotic state, whereas erectile dysfunction adds an incremental activation on top of coronary artery disease. C. Simple biochemical substances such as fibrinogen or interleukin-6 appear to have the potential to aid erectile dysfunction diagnosis or exclusion. Charts showing the diagnostic performance of fibrinogen and interleukin-6 for erectile dysfunction at cut-off values associated with 95% sensitivity. CAD: coronary artery disease, ED: erectile dysfunction; hsCRP: high sensitivity C-reactive protein; IL-6: interleukin 6; PAI-1: plasminogen activator inhibitor-1. With permission from Vlachopoulos C, et al. [126]
Oxidative stress, particularly via reactive oxygen species, is associated with decreased erectile function mediated by increased oxidative catabolism of NO and activation of the proinflammatory nuclear factor kappa B, which in turn induces cellular inflammation and adhesion molecule production. Oxidative modifications of low-density lipoproteins are involved in development of the atherosclerotic lesions. Myeloperoxidase-modified low-density lipoprotein has been found both in atherosclerotic plaques and in the corpus cavernosum of patients with ED of vascular origin[126,127].

Interestingly, the vasculature of the penis may itself generate a pro-inflammatory milieu. The human corpus cavernosum produces in a paracrine fashion angiotensin II, a pro-oxidant and pro-inflammatory substance, and a deletion polymorphism in the gene encoding ACE (DD genotype) has been reported to be more common in men with a diagnosis of organic ED.

2. THE “ARTERY SIZE” HYPOTHESIS

In all tissues and organs, the lumen diameter of the main feeder artery is a key factor controlling the maximum capacity for blood flow. The arteries supplying the penile tissue are inherently limited by having a vessel diameter that is narrower than in other tissues. From this understanding, Montorsi et al.[117] generated the “artery size hypothesis”, a concept which proposed that the differential timing of the onset of signs and symptoms of ED and CVD is caused, at least in part, by the difference between larger vessels and smaller ones (e.g. penile artery) with regard to their ability to tolerate encroachment upon the lumen (Figure 6). Because of the smaller size of the penile vessels, the same level of plaque burden, vascular remodeling and/or endothelial dysfunction would have a greater effect on blood flow through the penile arteries than through the coronary, carotid and femoral arteries. Therefore, the clinical manifestations of penile endothelial dysfunction (ED) and encroachment on the vascular lumen may become evident much earlier than with coronary or peripheral vascular disease. That is, by the time the lumen of the larger arteries become significantly obstructed (>50%) the capacity for penile blood flow will already decreased considerably, a concept which explains why so many men newly diagnosed with CAD are found to already have ED (Figure 6).

Thus on the basis of this hypothesis and the fact that the endothelium is the same throughout the arterial tree, a malfunction in the penile arteries causing ED may be a predictor of silent, subclinical cardiovascular disease (CVD). Furthermore, because an acute coronary syndrome often arises as the result of rupture of an angiographically subcritical plaque, the presence of ED might be an early warning sign of both a “vulnerable” atherosclerotic burden potentially leading to acute coronary events as well as being a manifestation of advanced obstructive CAD leading to chronic inducible ischemia[109].

3. CLINICAL EVIDENCE OF CAD IN ED PATIENTS WITH NO CVD

Insufficiency of the penile vasculature causing ED may be a predictor of silent subclinical cardiovascular disease[51,53,111,128,129]. The rate of underlying CAD was addressed in patients with vasculogenic ED, either new onset or long-standing, who had no clinical evidence of CAD. These patients frequently had one or more traditional risk factors, including diabetes in about 20% of the cases. Coronary reserve was tested by means of standard exercise stress testing or by dobutamine stress echocardiography.
Coronary angiography was carried out in a part of those who have positive non-invasive results. The rate of positive exercise stress test averaged up to 22%, ranging from 8% to 56% (Table 8). As documented in a prospective angiographic study, almost one out of five men without symptoms for CAD, presenting with erectile function abnormalities of vascular origin as their only symptom, do actually have underlying significant coronary artery stenosis. This is a substantially higher proportion than the 4% found in the general population of comparable profile.[50]

Table 9: ED-CAD temporal relationship.

Coronary angiography was carried out in a part of those who have positive non-invasive results. The rate of positive exercise stress test averaged up to 22%, ranging from 8% to 56% (Table 8). As documented in a prospective angiographic study, almost one out of five men without symptoms for CAD, presenting with erectile function abnormalities of vascular origin as their only symptom, do actually have underlying significant coronary artery stenosis. This is a substantially higher proportion than the 4% found in the general population of comparable profile.[50]

4. ERECTILE DYSFUNCTION IN PATIENTS WITH ESTABLISHED CAD

The prevalence of ED in patients with angiographically proven CAD has been assessed in several studies and found to range between 42% and 75%[50,112,118,131-133]. This wide range may be the result of differences in population characteristics, definitions of ED and CAD, sensitivity and specificity of methods used to diagnose both diseases and concomitant effect of drugs that can interfere with sexual function. Nevertheless, age, common risk factors (mainly diabetes) and extent of CAD (assessed by specific score systems) were repeatedly found to be independent predictors of ED. Interestingly, ED symptoms frequently came before either symptoms or non-invasive detection of CAD, confirming the new concept of ED as an early marker of sub-clinical vascular disease (Table 9).

In the study of Montorsi F et al[109], 47/300 (49%) patients with angiographically proven CAD had ED according to the IIEF-EFD questionnaire. Among these patients, 97 (67%) reported ED symptoms...
prior to CAD symptoms by an average of 36 months. The clinical presentation of CAD was acute coronary event (mainly acute myocardial infarction) in 40% and chronic coronary syndrome in the remaining 60%.

In the subsequent Association Between eRectile dysfunction and coronary Artery disease (COBRA) trial, the same authors found that 93% of patients with chronic CAD reported ED symptoms prior to the onset of angina pectoris, with a mean interval of 24 (range 12-36) months[118] fueling the concept of a lead time of at least 2-5 years between the development of ED and symptomatic CAD. Interestingly, the time interval (range) for patient with one-, two-, and three-vessel disease were 12 (9.5-24), 24 (16.5-36) and 33 (21-47) months, respectively. There was a significant trend between the length of the time interval between ED and CAD and the number of the coronary vessel involved (p=0.0016). Moreover, ED rate was different according to the type of clinical presentation: acute vs. chronic coronary syndrome. Patient with AMI and 1-vessel disease – the common clinical presentation of AMI – had an ED rate (22%), similar to those with angiographically no CAD (24%) and significantly lower than patients with AMI and multi-vessel disease (55%) or chronic CAD (65%). The reason for the low ED rate in AMI with 1-vessel disease may be explained by the peculiar pathophysiological background of AMI. In fact, AMI is usually due to abrupt closure of a previous single, non-critical stenosis in an otherwise coronary tree without additional critical lesions (i.e. low atherosclerotic burden pattern). Since atherosclerosis is a systemic disorder, penile circulation might be poorly involved resulting in a low ED rate. (Figure 7).

It should be stressed that although the prevalence of ED in subjects with CAD is quite high, some patients with severe CAD still report normal erectile function as shown by the normal erectile function score and penile Doppler findings. Reasons for this finding are not fully elucidated. Potential mechanisms include age-related hormonal, metabolic and inflammatory changes[118].

Efforts have been put forth in cardiovascular research to identify diagnostic tools that might improve the prediction of acute coronary events beyond the role of classical risk factors. A normal exercise stress testing (ECG treadmill, stress echocardiography, scintigraphy) can be falsely reassuring as it may not detect non-low limiting, vulnerable, lesions that often patients harbor. Thus, diagnostic tools include both measures of atherosclerosis burden (coronary calcium score), measures of vascular damage influencing prognosis (carotid wall thickening or plaque, carotid-femoral pulse wave velocity, ankle-brachial pressure index) and indexes of endothelial activation, inflammation and thrombosis (ICAM-1, hSCR, fibrinogen, von Willebrand factor, IL-6 and IL-18) (Table 10). Studies support the association between ED and non-obstructive CAD, as demonstrated with the relationship between ED and coronary calcium deposition in the walls of the coronary arteries. Importantly, the latter is correlated in a dose-dependent fashion with future risk of cardiovascular events above and beyond that predicted by standard cardiovascular risk factors[51,125,132].

ACS: acute coronary syndrome, CCS: chronic coronary syndrome.
5. CARDIOVASCULAR ASSESSMENT IN THE TYPICAL SUBJECT WITH ED AND NO CVD

As stated in the introduction, a diagnosis of ED should prompt an initial cardiovascular assessment based on the history and clinical examination in order to define the baseline risk according to (i) their likelihood of silent CAD or to the stage of clinically evident CAD; (ii) other cardiovascular conditions either unrelated, or related to ED (e.g. heart failure, peripheral arterial disease). The second Princeton Guidelines offer a comprehensive and practical way of stratifying risk especially for men with sexual dysfunction who already have heart or atherosclerotic disease [39]. Those at low risk can initiate or resume sexual activity, whereas for those at high risk, sexual activity must be deferred until the condition is treated or stabilized. Those belonging in the intermediate/indeterminate category would require additional cardiologic tests for further risk stratification.

Looking for silent obstructive CAD can involve multiple tests of varying degrees of complexity and expense. Evaluating the pretest likelihood of CAD according to the clinical presentation is of utmost importance in the selection of an appropriate diagnostic strategy and interpretation of diagnostic test results.

Depending on the initial clinical presentation, cardiac echocardiography may offer valuable information for left ventricular performance, wall-motion abnormalities and valvular function[133]

Subjects with ED and no overt heart disease – so called “normals” – are those physicians should concentrate on. Those at low risk need lifestyle advice, risk factors addressed and regular monitoring by their primary health care providers (e.g. family doctors). Those at high risk, apart from treatment of risk factors, should definitely undergo further cardiologic assessment. Once again, the intermediate/indeterminate category would require additional cardiologic tests for further risk stratification.
The resting ECG is usually normal, but if it is abnormal, entry into a higher risk category is automatic. As a next step, an exercise ECG is the simplest, most readily available, and least expensive evaluation and is recommended for all men at higher risk. When an exercise ECG is not interpretable (e.g., in the case of a left bundle branch block), or when it is inconclusive, or when it cannot be undertaken due to mobility problems, obtaining a scintigraphy perfusion scan or stress echocardiogram is advised. If the stress tests are abnormal and depending on their exact findings, the option for further evaluation with cardiac angiography emerges[47,133-135].

Ideally, evaluation of patients at increased risk should include determination not only of silent CAD but also of risk for developing future CAD events that may be related to the development of obstructive lesions, but also to the rupture of vulnerable, non-obstructive plaques. Techniques such as aortic stiffness, carotid ultrasound, ankle-brachial index, flow-mediated dilation of the brachial artery, penile Doppler, coronary calcium scoring and inflammatory markers/mediators show great potential and their future implementation is currently evaluated according to their individual predictive ability, easy of use, cost, and safety. At this stage, aortic stiffness, carotid ultrasound (for the determination of intima-media thickness [IMT] and carotid plaque) and ankle-brachial index, which are measures of arterial (target organ) damage, could be advocated as a recommended, where available, test, in the paradigm of the ESC/ESH guidelines for the treatment of arterial hypertension (Table 10)[136].

Special mention should be made for treatment of risk factors. All patients, independently of risk category, should have their risk factors properly addressed, which may seem obvious, but it is surprising how often they are not acted on. Specialist referral, such as a hypertension specialist or diabetologist, may be recommended. This is, first, to ensure effective address of risk factors, and, second, to adopt a more aggressive approach (that may include specific drug therapy), since the ED may be viewed as either a target organ damage or a parameter that re-stratifies the patient to a higher risk category.

Factors other than atherosclerosis and endothelial dysfunction that may cause ED in CAD patients include side-effects of drugs (beta-blockers, diuretics), and hypoperfusion in the setting of low cardiac output following myocardial infarction. Erectile function has been demonstrated to correlate with functional capacity (6-min walk test, Duke treadmill score) in patients with chronic heart failure[134].

Taken together, available data put forth the issue whether ED is a “CAD equivalent”. While accumulating evidence points towards this direction, further research in needed both at the pathophysiological and clinical level.

6. ED AS A PREDICTOR OF CV EVENT: CLINICAL EVIDENCE

ED appears to be associated with a future risk for cardiovascular events[113-115]. In a retrospective cohort study, ED was associated with a 2-fold increased risk for acute myocardial infarction after adjusting for a number of confounding risk factors[114]. Prospective studies have also offered solid information[112,113,115,116,137]. In the first such study, among men enrolled in the Prostate Cancer Prevention Trial (finasteride vs. placebo), 4247 subjects, 55 yr of age or older, had no ED at study entry and were followed up for 5 years. Onset of both ED and CV events was monitored. Over time, 57% of subjects developed ED. After adjusting for all covariates, incident ED was associated with a hazard ratio of 1.25 for developing subsequent cardiovascular events over the follow-up period, while for men with either incident or prevalent erectile dysfunction, the hazard ratio was 1.45[113]. In another interpretation of the findings of the same study, incident ED predicted subsequent acute CAD to a degree equal to or greater than that of cigarette smoking, hyperlipidemia or family history of acute myocardial infarction. Interestingly, in the Krimpen study, reduced and severely reduced erectile rigidity (assessed by a single question) were independent predictors for a combined cardiovascular outcome with hazard ratios of 1.6 and 2.6 respectively[115].

Attention has been directed to diabetic patients. In a cohort of 2,306 diabetic men with no clinical evidence of CAD (27% suffered from ED at baseline), over a median course of 4 years, ED was independent predictor of CAD with a hazard ratio of 1.58 after adjustment for confounding factors[116]. In a study that followed type 2 diabetes with angiographically detected silent CAD the presence of ED had an incremental effect on the already higher risk of major adverse CV events[112]. Interestingly, this study showed that treatment with statins and phosphodiesterase type-5 (PDE-5) inhibitors might reduce the occurrence of major adverse cardiovascular events among CAD diabetic patients with ED.

An issue that has important clinical implications is by how long the clinical manifestation of ED precedes the clinical manifestation of CAD. In men with ED and CAD, erectile function abnormalities became evident prior to the manifestation (or documentation) of CAD by a mean time interval of 2-5 years[52,118,133,13,8,139] (Table 9). This time window offers a unique opportunity for aggressive risk factor intervention and close follow-up of patients with a view of altering the progression of the diffuse vascular disease.

However, ED does not precede CAD in all patients. In the Prostate Cancer Prevention Trial, a quarter
of patients with incident ED, developed sexual dys-
function after CAD[137]. A potential explanation may
be that a patient with single vessel disease and an
acute coronary syndrome (due to the rupture of a
nonstenotic unstable plaque) who has no ED at the
time may progress over the time to diffuse arterial
disease including the penile and (the noninfarcted)
coronary arteries[118].

Given the frequent co-existence of sexual dysfunc-
tion and cardiovascular disease it has become very
clear there are common etiologies and mechanistic
linkages. An extension of this concept is that drugs
used to treat cardiovascular disease may also re-
verse or prevent the progression of underlying dis-
ease that is causally-linked to the progression of
sexual dysfunction. Although chronic therapeutic
approaches are used in conditions such as hyper-
tension and conventional medical management
of ED normally involves acute treatments that en-
hance penile vasodilatory mechanisms, neither one
is designed to particularly target the underlying pa-
thology. That is, while various therapies will lower
blood pressure in hypertensive patients and improve
erectile responses in ED sufferers they have not
been designed specifically to target the particular
causal-mechanisms at the local, neural, vascular,
or endocrine level. In fact, in both conditions, the
causal abnormalities can often progress despite the
ongoing treatments and thereby eventually limit the
effectiveness of the medication being administered.
Further complicating these issues is the knowledge
that certain cardiovascular treatments drugs (e.g.
certain antihypertensive agents) as well as other
medications (antidepressants) actually induce sex-
ual dysfunction even when the patients previously
had normal sexual function[140-142]. Thus, the
common association between ED and other co-
morbidities, combined with considerable failure rates
for current ED treatment, should signal that modifying
lifestyle and intervention-associated risk factors (e.g.
medications, overweight and obesity, inappropriate
diet, smoking, excessive alcohol consumption, and
physical inactivity) should be a fundamental step in
a holistic approach toward the treatment of both ED
and cardiovascular disease

As indicated, the available evidence indicates that
sexual dysfunction can be induced or exacerbated
by certain antihypertensive drugs. It is noteworthy
that reduction of blood pressure per se should not be
considered as the major cause of this drug-induced
effect, since not all agents have the same negative
impact. These data suggest that depressor agents
from disparate classes including centrally acting
sympatholytic drugs, diuretics and beta-adrenocep-
tor blockers are most likely to impact deleteriously
on sexual function. In contrast, the results of vari-
ous clinical and experimental studies suggest newer
therapies that antagonize the renin-angiotensin sys-
tem (ACE inhibitors and AT1 receptor antagonists)
or long acting calcium channel blockers either have
neutral or possibly even beneficial actions with re-
gards to sexual function[142-145]. The mechanisms
proposed to account for the beneficial effects found
in these studies include improved endothelial dys-
function, reduced vascular reactivity to vasocon-
stricior influences, decreased inflammation and nor-
malization of vascular remodeling, effects that have
even been shown to persist after the treatment was
stopped.

7. CONCLUSION

| Endothelial dysfunction and inflammation are common pathophysiological pathways of ED and systemic vascular disease | LOE 1 |
| Endothelial dysfunction is not confined to penile tissue, but is widespread in other vascular beds | LOE 1 |
| Presence and severity of ED are associated with markers and mediators of subclinical inflammation | LOE 1 |
| The presence of ED suggests there is an incremental inflammatory and endothelial-prothrombotic activation on top of that found in patients with CAD | LOE 1 |
| Patients presenting with ED as their initial condition have an increased prevalence of silent CAD | LOE 1 |
| ED can precede an acute coronary event, stressing the need to develop means of detecting nonobstructive, but vulnerable, coronary lesions | LOE 1 |

8. RECOMMENDATIONS

| Emerging noninvasive tests could be integrated as biomarkers to assess the risk for future coronary syndromes | Grade B |
| ED diagnosis should prompt assessment of cardiac risk and meticulous risk factor treatment | Grade A |
| Available risk assessment charts (e.g. Framingham, SCORE) should be used to stratify the risk of CAD events in each patient | Grade A |
| Patients with ED and no clinical CVD who carry an increased risk of CAD events (>10%) should undergo cardiological assessment and noninvasive testing (mainly ECG exercise stress test) to reveal silent CAD and to further stratify risk | Grade A |
| Additional noninvasive tests of arterial damage may aid in the determination of risk for future cardiac events | Grade B |

V. TESTOSTERONE

1. INTRODUCTION: CARDIOVASCULAR EFFECTS OF TESTOSTERONE

Life expectancy for women exceeds that for men,
and one mechanism for this discrepancy may be
speculated as the differences in sex hormone profiles
as a contributor to accelerated atherogenesis in men.
Heart disease prevalence in women lags behind that
in men until postmenopausal age; after that time,
women outpace men[146] leading to speculation
that sex hormone profile differences are contributors to risk. Evidence associates aberrant circulating androgen levels with increased risk for CAD in both genders, but the precise relation remains to be well defined[147].

In men increasing evidence suggest that low androgen levels are associated with all-cause death and, in particular, CVD death[148]. This begs the question: could this be causal or simply coincidence, with testosterone modulating established risk factors? If testosterone is causative, could replacement be beneficial and safe over time? Clearly, age-related decline in androgens has important clinical implications for CVD management.

The relationship between androgens and coronary artery disease has been extensively reviewed. Observational studies show a consistent inverse relationship between endogenous testosterone and adverse cardiovascular events[149-151]. While these studies provide no support for the suggestion that plasma estradiol or testosterone are primary risk factors for IHD, the associations between plasma testosterone and other probable risk markers (triglycerides, insulin, body mass index, and high density lipoprotein cholesterol) indicate the possibility that testosterone may play an indirect role in the pathogenesis of IHD. These findings may be interpreted as suggesting the hypothesis that chronically lowered blood testosterone may increase risk of cardiovascular disease. However, such findings from cross-sectional studies cannot distinguish the direction of causality or exclude a common cause. The opposite interpretation is that blood testosterone is mildly lowered due to heart disease, as occurs for many chronic disorders[152,153]. Longitudinal studies do not support the predictive value of lowered blood testosterone or dihydroepiandrosterone concentration for further cardiovascular events[154,155] which favors the decrease in cross-sectional studies being an effect, rather than a cause. The only definitive test of this important concept is a prospective interventional study of sufficient power and duration of surveillance to estimate or exclude an important protective effect size with use of testosterone and cardiovascular endpoints.

The 2004 analysis, published by the US Institute of Medicine[156] recommends that the National Institutes of Health support small efficacy trials aimed at treatment of androgen deficiency-related clinical conditions, but not a large, randomized trial to elucidate risk: benefit ratios. Although rigorously conducted, this was largely a qualitative review of the literature, and doubts have been expressed about the accompanying recommendations. Limitations of that research prompted subsequent investigations that have attempted to quantify (using objective and reproducible methods) the effects of testosterone. In 2005, two separate meta-analyses[157,158] were published on the 4 major areas in which an adequate number of randomized placebo-controlled trials were available: body composition; bone density; lipid profiles; and sexual function. Another two important meta-analyses published in the Mayo Clinic Proceedings[159] added to the unexpected findings of effects and adverse effects of testosterone[160]. These analyses revealed the following: a 6% reduction in body fat; a 3-4% increase in lean body mass and bone density; a diversified threshold effect on libido and erectile function.

Haddad and others[159] in their well-constructed meta-analysis of testosterone and cardiometabolic risk demonstrated that in men supplementation is relatively safe in terms of cardiovascular health. They noted that testosterone use in men with low testosterone levels led to inconsequential changes in blood pressure, glycemic control and all lipid fractions. Several reports have described consistent improvement in both anginal symptoms and ischemia on stress electrocardiograms in men treated with older injectable testosterone preparations. More recent studies have reported that low blood levels of androgens are associated with osteoporosis, adverse cardiovascular risk factors (including an atherogenic lipid profile), systolic and diastolic hypertension, obesity, insulin resistance and increased fibrinogen levels[161]. Other authors have published a series of articles[162,163] that consistently document that testosterone replacement is beneficial for cardiovascular disease. In addition, testosterone replacement has been demonstrated as having positive effects on numerous metabolic parameters (e.g. insulin sensitivity, glucose control, visceral obesity and hyperlipidemia) in patients with type 2 diabetes and heart failure[164].

Unfortunately, none of the randomized controlled trials were designed to assess the outcome of ‘safety’. Only large randomized placebo-controlled studies expressly designed to investigate the safety of androgen treatment will provide an authoritative answer[165].

2. TESTOSTERONE AND CVD RISK FACTORS

In 2004, Phillips et al[166] reported that low total and free testosterone levels were inversely linked to coronary artery disease, even after adjusting for age and adiposity. This observation still holds true as supported by a study showing that men with angiographically proven coronary artery disease had lower levels of testosterone than those of controls[167]. Also of significance, testosterone was negatively correlated to the degree of coronary involvement. Recently, a prospective population-based study of 794 men, 51 to 91 years of age, in the Rancho Bernardo community, looked at the relationship of testosterone with all-cause death over the subsequent 2 decades[151]. The authors found that men whose total testosterone levels were in the lowest quartile,
defined as <241 ng/dL, were 40% more likely to die than were men with higher androgen levels. These findings were independent of age, adiposity, lipids, adipokines, and lifestyle. In cause-specific analyses, low testosterone predicted increased risk of death due to cardiovascular and respiratory disease. It is thus clear that low testosterone is independently associated with many of the individual risk factors for heart disease. What are these risk factors, and how are they impacted by testosterone?

a) Visceral obesity, body mass index and fat mass

Studies of body fat and low testosterone levels have demonstrated an inverse relationship of testosterone with visceral fat accumulation. The term ‘lean body mass’ is often used synonymously with fat free mass. The description of age-related sarcopenia in the setting of the decline in serum testosterone in older men, and the knowledge that testosterone replacement increases fat-free mass and muscle volume has led to the hypothesis that testosterone therapy in older men will increase lean body mass and skeletal muscle, thereby improving quality of life increasing strength and stability. The largest placebo-controlled trial to date to test this hypothesis found that over 36 months of treatment, an increase in serum testosterone from 12.7 to 21.7 nM led to a 1.9 kg (3.5%) increase in lean mass. A linear regression analysis showed an inverse relationship to pretreatment testosterone levels[168] in parallel with the decrease in lean body mass seen in hypogonadal men, there is also an increase in fat mass. In a study of men aged 22-69 years (mean age 53 years), hypogonadal subjects had 26% body fat, compared to 19% in eugonadal men[169]. Quantitative CT analysis of hypogonadal men (mean age 52 years) has shown that they have a greater subcutaneous fat area and a trend towards an increased visceral fat area when compared to age-matched eugonadal men[170]. Testosterone replacement, in addition to decreasing fat mass, decreased subcutaneous fat by 12% and visceral fat by 6%[169]. Thereby, as fat mass (obesity) independently predicts cardiovascular risk, the likelihood that testosterone replacement can regulate this risk is equally appealing.

b) Carbohydrate metabolism: the association between low testosterone and glucose intolerance and type 2 diabetes.

Epidemiological studies show that low testosterone levels are independently associated with type 2 diabetes mellitus after adjusting for potential confounders[171]. In fact, lower concentrations of free and bioavailable testosterone even in the normal range are associated with diabetes, independent of adiposity[172]. Men in the lowest tertile of free testosterone were 4 times more likely to have diabetes compared to men in the highest tertile. Furthermore, low testosterone levels independently predict the development of the metabolic syndrome in middle-aged men[173].

Basaria and Dobs have postulated a clinical model that further establishes the role of testosterone in the mediation of glucose metabolism in their series of articles on testosterone and cardiovascular disease in men with prostate cancer. They note that in men undergoing androgen deprivation for prostate cancer, insulin resistance develops within a few months of initiation of the androgen-deprivation therapy[174,175]. In addition, when men who undergo long-term androgen-deprivation therapy are studied, in addition to hyperinsulinemia, they have a higher prevalence of hyperglycemia and metabolic syndrome[175,176]. This relationship between hypogonadism and hyperglycemia persists even after adjustment for age and body mass index, and the degree of hyperglycemia is directly related to the duration of sex hormone suppression[177]. Thus, hypogonadism appears to be an early marker for disturbances in insulin and glucose metabolism and may contribute to the pathogenesis of metabolic syndrome and type 2 diabetes, thus again contributing to the overall cardiometabolic risk.

c) Vasomotor regulation, vascular effects and coronary calcium

As previously mentioned, a clinical trial showed that transdermal testosterone improved exercise-induced myocardial ischemia (measured as time to ST depression) during an exercise stress test in men with stable angina[162]. These vasodilatory effects of testosterone on coronary and other vasculature are confirmed by the findings that men undergoing androgen-deprivation therapy for prostate cancer experience an increase in central arterial pressure (reflecting stiffening of large arteries)[174]. Similarly, in population studies, systolic and diastolic blood pressures have been shown to be inversely correlated with testosterone level[178].

In a study of 106 middle-aged men free testosterone was inversely correlated with intima-media thickness (IMT) of the common carotid artery and vascular adhesion molecule-1 (VCAM-1)[179]. The initial steps in the formation of an atherosclerotic lesion involve the adherence of circulating monocytes to dysfunctional endothelium and transmigration into the arterial intima, so the expression of vascular cell adhesion molecule-1 might be a key regulatory point in controlling the atherosclerotic process. Endothelial cells produce VCAM-1, therefore endothelial cell dysfunction or inflammation may signal an increase noted.

Testosterone has a direct effect on vascular smooth muscle by an action on either calcium or potassium channels[180] (Figure 8). In animal models using isolated coronary, pulmonary, and femoral arteries, a dose-dependent vasodilatory effect exists that is
independent of the endothelium[181]. Experimental studies in animals have demonstrated coronary dilation after acute testosterone administration.

Lastly, testosterone levels appear to be inversely related to arterial calcification. In the Rotterdam Study, the association between total and bioavailable testosterone with aortic atherosclerosis was evaluated in 504 nonsmoking men > 55 years of age[182]. Compared with men with levels of total and bioavailable testosterone in the lowest tertile, men in the highest tertile had a risk reduction of 60% to 80% of severe aortic atherosclerosis. Given that this was assessed by radiographic detection of calcification in the abdominal aorta, it is likely that subclinical atherosclerosis was not detected in this study. Another prospective study of elderly men (mean age 77 years) showed free testosterone concentration to be inversely related to the progression of intima-media thickness of the common carotid artery (CIMT) after adjustment for age and other risk factors[183]. The Tromso study also demonstrated an inverse association between total testosterone levels and intima-media thickness of carotid artery that is present even after exclusion of men with established cardiovascular disease[184].

Therefore, it appears that arterial stiffening, endothelial dysfunction, and increased atherosclerosis are means by which male hypogonadism may contribute to a higher risk of death.

d) The association of androgens with lipids, abnormalities of coagulation and inflammatory cytokines

Epidemiological data suggest that testosterone levels are associated with a beneficial lipid profile, with negative correlations with total cholesterol, LDL-cholesterol, and triglycerides, and a positive association with HDL-cholesterol[185]. Other various cross-sectional studies in men have reported a positive correlation of testosterone levels with HDL-C[186,187] and a negative correlation with total cholesterol, LDL-C and triglycerides[188,189] thereby suggesting that hypogonadal men have a pro-atherogenic lipid profile. There are also inverse associations between inflammatory cytokines and testosterone[190]. An inverse relationship between testosterone and interleukin-6 and C-reactive protein suggests a role for replacement, modifying the inflammatory response to CRP and cytokines, a theory that needs to be supported by further randomized trials. These associations are further validated by clinical trials showing improvement in lipid profile and reduction in inflammatory cytokines with testosterone replacement[191]. Additionally, inverse associations between testosterone and plasminogen activator inhibitor I, fibrinogen, and factor VII have been reported in men[182].

In summary, testosterone may influence cardiovascular disease via multiple mechanisms including changes in body composition, fat metabolism, glucose regulation, vascular mechanisms, and clotting.

Figure 8: Sites of androgen action on the vasculature, including sites where androgens have been shown to interact with the vessel wall and bloodstream components to initiate early stages of atherosclerosis, to propagate and enlarge the lesions, and to modify the late stage of plaque rupture.
3. TESTOSTERONE AND CARDIOVASCULAR OUTCOMES AND ALL-CAUSE MORTALITY

Several studies have evaluated the link between testosterone levels in men and the development of cardiovascular disease[149,150,192]. A prospective study of 794 men aged 50-91 years, in the Rancho Bernardo area of California evaluated the relationship between testosterone and all-cause mortality over approximately 20 years[151]. They found that men with testosterone levels <241 ng/dL i.e. in the lowest quartile, were 40% more likely to die than those with higher levels of testosterone. These findings held true regardless of age, lipid levels and other variables. Furthermore, low testosterone levels were associated with death from cardiovascular disease (HR, 1.98, 95% CI, 1.02-1.85) and respiratory disease (HR, 2.29: 95% CI, 1.25-4.20), but were not associated significantly with cancer-related deaths (HR, 1.34, 95% CI, 0.89-2.00).

A study conducted in Seattle by Shores and colleagues[149] evaluated whether low testosterone levels were associated with an increased risk of mortality in male veterans. This retrospective study included men older than 40 years without a diagnosis of prostate cancer. Men classified as having a low testosterone level- approximately 20% of the overall study population- had an increased mortality (HR 1.88; 95% CI, 1.34-2.63) after adjustment for clinical covariables, compared with those men with equivalent or normal levels. This suggests an increased mortality of 12%.

A third study, the largest study of testosterone levels and mortality ever conducted, called the European Prospective Investigation in Cancer in Norfolk (EPIC-Norfolk) Study[150] examined the relationship between testosterone levels and mortality due to all causes, cardiovascular disease, and cancer. The authors conducted a nested case-control study to determine the association of endogenous testosterone with all-cause mortality. They compared 825 men, who did not have any cardiovascular disease or cancer at baseline but died during the course of follow-up (entry between 1993-1997 through follow-up in 2003), with the 1489 men who were still alive. The cases and controls were matched for age and date of baseline visit. The authors found that the baseline testosterone levels were inversely related to deaths due to all causes, cardiovascular disease and malignancy, after controlling for the usual confounders (plus dehydroepiandrosterone and sex hormone-binding globulin).

The protective effect of testosterone increased with increasing quartiles, such that men in the highest quartile had a 30% lower risk of death than that of those in the lowest quartile. Even after excluding for deaths during the first 2 years of follow-up, this inverse relationship was maintained. Indeed, every 6-nmol/L (173 ng/dL) increase in serum testosterone decreased the death rate by 14%, and this benefit was irrespective of a patient’s age (above or below 65 years of age).

The study has limitations, though it is well conducted. It included on a single testosterone measurement, and thus did not control for any measures of transient variation in testosterone secretion. Second, the authors did not measure or calculate the free or bioavailable testosterone, the moiety that binds most closely to the androgen receptor. These measures are more accurate than total testosterone, especially in subjects with obesity or diabetes or older age because of the changes in sex hormone-binding globulin levels expected in these patient populations. Lastly, the authors did not measure estradiol levels, and it would be of interest to know if the beneficial effects of testosterone are mediated solely by testosterone or the aromatization of testosterone to estradiol[148].

The question remains: “Does testosterone serve as a marker, an association for increased cardiovascular mortality, or does it have a pathogenic role?” Even though Khaw and the other investigators of the EPIC-Norfolk study excluded men with serious disease and those who died within the first 2 years of the study (assuming they had subclinical illness) the authors were cautious in mentioning that they might have included men with subclinical disease[150]. However, given the results of these 3 large studies, the Rancho Bernardo study, the Shores study, and now the EPIC-Norfolk study, it is conceivable that testosterone has a pathogenic role in the development of cardiovascular disease, and is more than simply a marker of disease. The exact pathogenesis is still being debated.

This landmark study suggests that high endogenous testosterone concentrations appear to be beneficially associated with mortality due to all causes, cardiovascular disease and cancer. These findings require replication in other population studies, and safety outcomes in large-scale controlled trials.

4. TESTOSTERONE REPLACEMENT AND CARDIOVASCULAR DISEASE

Haddad and others[159] performed a systematic review and meta-analysis of 30 randomized, placebo-controlled trials to assess the effect of testosterone use on cardiovascular events and risk factors in men with different degrees of androgen deficiency. The included 1642 men of whom 808 were treated with testosterone. The trials had limited reporting of methodological features that prevent biased results (only 6 trials reported allocation concealment), enrolled few patients and were of brief duration (only 4 trials followed patients for > 1 year). Testosterone
use in men led to inconsequential changes in blood pressure and glycemia, and in lipid fractions. The OR between testosterone use and any cardiovascular event pooled across trials that reported these events (n=6) was 1.82 (95% CI, 0.78-4.23). Several trials failed to report data on measured outcomes.

Low-dose physiological testosterone therapy can improve cardiovascular functional capacity and symptoms in men with moderately severe CHF. In a randomized, double-blind placebo controlled study with Androderm 5 mg daily, Malkin et al demonstrated significant improvements using the parameter of the incremental shuttle walk test (ISWT) [164] (Figure 9).

Though this meta-analysis demonstrated that testosterone supplementation was relatively safe in terms of cardiovascular health, the problem of the study in evaluating safety of androgen replacement is that none of the available randomized controlled trials were designed to assess this outcome.

Therefore, no current evidence indicates that testosterone replacement reduces CVD. Testosterone replacement at present should be reserved for those who are symptomatic of testosterone deficiency. However, chronic illness is associated with low testosterone, and therefore, testosterone levels should be screened in those with diabetes and chronic CVD, including heart failure.

Another significant issue is whether testosterone should be conceived as a treatment versus prevention of common maladies of aging in older men. Studies of the sort as recommended by the Institute of Medicine[156] that the NIH support small and medium-sized randomized trials with one or more conditions or symptoms potentially attributable to hypogonadism, in order to determine whether or not testosterone treatment would improve or ameliorate these conditions. As mentioned earlier in this review, therapeutic targets included sarcopenia and muscle weakness, osteoporosis, sexual and erectile problems, cognitive impairment and depression.

Harman[193] astutely notes that “treatment and prevention are different strategies and frequently require different approaches. It is the failure to differentiate between prevention and treatment with regard to atherosclerosis that has led to the widespread misinterpretation of the Women’s Health Initiative regarding hormone therapy and increased cardiovascular risk, given that one cannot ‘prevent’ currently incident disease.” He goes on to note that most middle-age and older men are currently embarking on a regimen of testosterone treatment in order to slow progression or avoid onset of perceived age-related debilities such as diminished sexual capacity, loss of muscle mass and strength and bone loss.

In order to implement the large data we are collecting regarding testosterone and cardiovascular disease, we need to answer questions regarding the critical level for starting treatment, optimal dose, target testosterone level to be reached, duration of treatment, and long term safety. We argue what is needed is a Men’s Health Initiative Study, to critically evaluate the effects of testosterone treatment in long-term, double-blind, randomized, placebo-controlled trials of androgen replacement. “With all these data, androgens should no longer be considered as mediators of only sexual function or skeletal health, nor should they be discarded by defaming them as a fountain of youth.” [194]

VI. TREATING ED IN THE CARDIAC PATIENT

1. IS THE PATIENT OR THE DRUG HARMFUL?

ED is frequent in patients with diagnosed CAD and PDE-5 inhibitors are widely used in such patients[195]. A strong body of clinical data shows all 3 agents (sildenafil, tadalafil and vardenafil) do not increase the risk of nonfatal myocardial infarction, stroke, or cardiovascular deaths. These drugs do not exacerbate ischemia or worsen exercise tolerance in patients with known CAD who achieve levels of exercise comparable or greater than that achieved during sexual intercourse. Even in patients with severe CAD, sildenafil does not adversely affect coronary artery diameter, coronary blood flow, or coronary vascular resistance, while it even increases coronary flow reserve[196,197]. It has also been shown that PDE-5 inhibitors might reduce cardiovascular morbidity and mortality in diabetic patients with silent CAD and ED. These data support the American College of Cardiology/American Heart Association Consensus and the Princeton Consensus Conference statements that PDE-5 inhibitors are safe for patients with stable CAD who are not taking nitrates[133]. Nitrates in combination with PDE-5 inhibitors may cause a profound and unpredictable decline in blood pressure and are contraindicated. The 24-hour period between nitrate use and short-acting PDE-5 inhibitor administration (up to 48 hours for the long-acting tadalafil) appears prudent until additional data, including information on outliers and patients with CAD are available. After cessation of oral nitrate, and provided there has been no clinical deterioration, PDE-5 inhibitors can be used safely[198].

Regarding the effect of concomitant medication, while previous studies indicated the negative influence of cardiovascular drugs such as P-blockers and thiazide diuretics on erectile function, recently, baseline data of ONTARGET/TRANSCEND showed that only calcium-channel antagonists had a significant adverse effect on erectile function[199]. Treatment with β-blockers, diuretics, angiotensin-converting enzyme (ACE) inhibitors, angiotensin I (AT1) antagonists was not associated with a decreased erectile function, whereas statins had a beneficial effect. Follow-up data will provide more solid information on the effect of concomitant medication on sexual function.

Recognizing the need for advice on management of erectile dysfunction, two consensus panels (in the UK and the USA) have produced similar guidelines dividing cardiovascular risk into three practical categories, with recommendations for management[37,133]. The Princeton consensus guidelines have been updated. It is recommended that all men with erectile dysfunction should undergo a full medical assessment. Baseline physical activity needs to be established and cardiovascular risk graded as low, intermediate, or high (Table 5). Most patients with low or intermediate cardiac risk can have their erectile dysfunction managed in the outpatient or primary care setting.

There is no evidence that treating erectile dysfunction in patients with cardiovascular disease increases cardiac risk; however, this is with the provisos that the patient is correctly assessed and that the couple or individual (self-stimulation may be the only form of sexual activity) is appropriately counseled. Oral drug treatment is the most widely used, because of its acceptability and effectiveness, but all treatments have a place in management. The philosophy is to be always positive during what, for many men and their partners, is an uncertain time.

2. LIFESTYLE CHANGES

The commonest modifiable lifestyle factors associated with ED are obesity, cigarette smoking, hyperlipidaemia, and a sedentary lifestyle. In the Second Princeton Consensus on Sexual Dysfunction and
Cardiac Risk the role of lifestyle factors was emphasized regarding associated risk and evidence of benefit from intervention[133].

Due to their especially strong association with ED and CVD as well as their high prevalence in the population, physical inactivity and obesity present as ideal treatment targets for improving erectile function as well as the underlying vascular disease. For instance, overweight/obese men have up to double the risk of ED as compared to normal weight men[200] while sedentary men have twice the risk of ED as compared to active men[201]. Consistent with multiple disease outcomes, the emerging evidence suggests that abdominal obesity is the one phenotype most strongly associated with risk of ED[202]. When both abdominal obesity and physical inactivity are present men have a four-fold greater chance of developing ED in comparison to lean and active men[200]. Furthermore, even among men with ED, those who are overweight have significantly poorer erectile function than those who are not[203]. The strength of the causal relationship between obesity, inactivity and ED is further supported by the fact that changes in physical activity and obesity explain over 50% of the variance for changes in ED[202].

Thus, given that four out of five men with ED are obese or overweight and nearly half of these are also sedentary it is surprising that only limited prospective research has been conducted on the role of lifestyle changes on erectile function[202,204]. That said, the situation is complicated because while obesity and physical inactivity, are directly associated with both endothelial and erectile dysfunction they also contribute to insulin resistance, dyslipidemia, hypertension, and inflammation which are also distinctive risk factors for both endothelial and erectile dysfunction. Almost all of the risk factors (diabetes, dyslipidemia, smoking, obesity, hypertension, inactivity, and inflammation) have been suggested to have a final common pathway via disruption of normal endothelial function, in part, by the reduction of NO bioavailability through increased oxidative stress. Further complicating the issue, the use of some pharmacotherapy to control the underlying risk factors has been shown to result in an exacerbation of ED[19,205]. For example, as indicated in other sections the use of antihypertensive medication, such as beta-blockers and diuretics, as well as statins and fibrates, to control dyslipidemia have all been associated with hindered erectile function.

3. PHYSICAL INACTIVITY

Although the available clinical evidence is not yet definitive, overall the data strongly suggests that increased physical activity should be used as a preventative strategy against the development of ED[202] as well as a treatment strategy to improve erectile responses in those already suffering from ED. Coupled with the fact that increased physical activity can also improve other risk factors (obesity, insulin resistance, hypertension, dyslipidaemia, and inflammation) associated with endothelial and erectile dysfunction, cardiovascular disease, as well as poor response to PDE-5 inhibitors, it becomes an obvious strategy for improving both erectile function and systemic vascular health.

Some of the prospective evidence in this regard suggests that approximately one to two years of increased physical activity can improve erectile function[202,206]. Indeed, White et al[206] performed a 9 month aerobic exercise intervention trial in healthy middle-aged men, although with no diagnosed erectile dysfunction. Subsequently, as assessed by a non-validated self-report questionnaire, the exercising men reported less difficulty in maintaining erection from baseline measures as compared to the control group[202]. In the only randomized controlled trial to date, Esposito et al performed a 2 year lifestyle intervention including physical activity and caloric restriction in 110 healthy obese men with ED. The 55 men in the intervention arm attended monthly sessions aimed at improving exercise and diet in order to achieve a 10% weight reduction, while those in the control group received general information regarding exercise and diet. After the 2 years, men in the intervention group significantly increased their physical activity, reduced their caloric intake, improved the quality of their diet and accordingly, improved their erectile function from baseline, as compared to the control group. Indeed, the intervention lead to complete return of erectile function in over 30% of men.

In other experimental and clinical[207,208] studies, single exercise sessions have been shown to acutely enhance endothelial function for at least 24 hours by 1.5 to 2 fold, but are abolished by 48 hours[208]. In addition, aerobic exercise interventions of variable length (1-12 weeks) have found marked improvements in endothelial function, in particular increased bioavailability of NO as well as delayed progression and even regression of atherosclerosis[209]. More specifically, enhanced protein expression and increased phosphorylation of endothelial NO synthase (eNOS), the enzyme responsible for the synthesis of NO from its precursor, L-arginine, are likely responsible for the augmented NO availability post acute exercise. Considering that NO is the principal mediator of the penile erection, greater availability of endothelial NO should lead to enhanced physiological erectile function after acute exercise. Taken from another perspective, acute exercise has also been shown to counteract the postprandial endothelial dysfunction induced by high-fat and high-carbohydrate feeding, and improve brachial artery flow-mediated vasodilation in healthy adults[210].
4. OBESITY
Separate from physical inactivity, numerous studies have found obesity per se to be a clear risk factor for ED and reduction of obesity has been linked with improvements in erectile function[202]. Importantly, the health risk associated with obesity appears to be highly dependent on the regional deposition of adipose tissue[211]. Indeed, it is now well established that abdominal obesity is a strong predictor of various health outcomes irrespective of total obesity. The relationship between abdominal obesity and ED was first documented in 1956, and more recent studies demonstrate that abdominal obesity, as assessed by anthropometric measures may be a better predictor of ED risk than total obesity, as assessed by body mass index (BMI)[202]. The association between anthropometric measures of abdominal obesity (e.g. waist circumference) and ED may be explained by excess accumulation of adipose tissue in two distinct depots within the abdomen, namely abdominal visceral (VAT) and subcutaneous adipose tissue (SAT). Of the two abdominal fat depots, VAT has emerged as a strong and independent predictor of dyslipidemia and insulin resistance, cardiovascular disease, type 2 diabetes, inflammation, metabolic syndrome, and not surprisingly, endothelial function[212-214]. Various studies have established, that reductions in VAT are associated with consequent improvements in metabolic status, however, while it is a plausible link, no studies to date have assessed the effect of exercise-induced reductions of VAT per se on changes in erectile function[215].

5. CHANGES IN PHYSICAL ACTIVITY VERSUS OBESITY
Increased cardio-respiratory fitness is associated with reduced morbidity and mortality independent of total and abdominal obesity[216]. Indeed, obese and fit individuals are reported to have lower health risk than lean but unfit individuals. This is consistent with White et al observing that the improvements in self-reported erectile function following nine months of aerobic exercise were strongly correlated with individual improvements in cardio-respiratory fitness[206]. Furthermore, Esposito et al using a multivariate analyses, showed following two years of lifestyle intervention in obese men with ED, that increased physical activity was associated with an improvement in erectile function independent of changes in the obesity indices, and additional confounders[202]. These results are mechanistically corroborated by numerous exercise trials showing correlations between improvements in cardio-respiratory fitness and enhanced endothelial function. Indeed, it has been suggested that improved endothelial function, that is, greater endothelium-dependent vasodilatory function would lead to greater oxygen delivery to working muscle and thus augmented cardio-respiratory fitness. However, to date, no study has assessed the independent association between improvements in cardio-respiratory fitness and erectile function. Taken together, the above evidence suggests that both visceral adiposity and cardio-respiratory fitness mediate independent effects on the health risk associated with obesity, and that changes in these variables will likely causally impact erectile function.

6. SMOKING
In the Health Professionals’ Study, smoking increased the risk of developing ED by 50%[200]. In the Massachusetts Male Aging Study men who smoked at baseline increased their risk of developing moderate or total ED to 24%, compared with non-smokers at 14% \(P = 0.01\)[3]. Smoking has been shown to significantly adversely interfere with the cavernous veno-occlusive mechanism and to reduce the erectile response to intracavernous injections. When considering overall vascular health, advice and support to enable individuals to stop smoking are an essential lifestyle intervention.

7. THE METABOLIC SYNDROME
The metabolic syndrome, as discussed previously, consists of a cluster of risk factors that increase the risk of cardiovascular disease and type 2 diabetes. The Mediterranean-style diet (rich in whole grain, fruits, vegetables, legumes, walnut and olive oil) was evaluated in 35 men, with 30 active as control subjects[217]. All had the metabolic syndrome and ED. The intervention group was given detailed dietary advice, targets were set, and monthly small-group sessions were held to offer support. Men in the control group were given general oral and written information about healthy foods but no individualized support. After 2 years, markers of endothelial function and inflammation significantly improved in the intervention group but not in the control group. In the intervention group, 13 men achieved an IIEF of 22 or higher, compared with only two in the control group. The intervention group had a significant decrease in glucose, insulin, low-density lipoprotein cholesterol, triglycerides and blood pressure, with a significant increased in high-density lipoprotein cholesterol. Fourteen men in the intervention group had glucose intolerance and six had diabetes at baseline, but by 2 years the numbers had reduced to eight and three respectively.

We see here the evidence that multiple risk factor reduction benefits a multiple risk factor state in terms of both ED and CAD risk. A potentially important link is also emerging between inflammatory markers and their modification in the ED/CAD context and its therapy.

8. ALCOHOL
Excessive alcohol intake per se increases cardiovascular risk but there is little evidence of ED risk other than the acute effect of binge drinking. In addition, men with a very high alcohol intake are unlikely to
9. DEPRESSION

Depressive disorders range from mild symptoms to major depression with core symptoms of sadness or loss of interest/pleasure in usual activities for a period of at least two weeks accompanied by at least five of the following: sleep difficulties, fatigue, low self esteem, guilt, psychomotor agitation/retardation, loss of appetite. Not surprisingly, depressive symptoms may cause loss of libido and reduced sexual function, but conversely, ED may also lead to depression. Cross sectional studies have demonstrated a relationship between ED and depression but it remains unclear whether depression causes ED and, if so, what the underlying mechanism may be. The evidence that depression promotes coronary artery disease events in clinically healthy individuals as well as patients with known coronary heart disease is more established[218]. By analogy, it is conceivable that depression may cause vascular disease in the penile arteries therefore providing another link to ED.

Analysis of cross section results from the MMAS a decade ago established a relationship between erectile dysfunction and depression independent of aging, level of education, heart disease, diabetes, physical activity and other potential confounders[219]. Symptoms of depression (measured using the Centre for Epidemiologic Depression Scale (CES-D) and defined as a score ≥16)) were present in 12% of men across all ages. The estimated OR for ED was 1.82 in men who had depressive symptoms as compared with those who did not.

In the MMAS men were followed up for an average of 8.8 years, enabling a prospective analysis of a possible causative relationship between depression and ED[220]. Excluding men with ED, diabetes or heart disease at baseline as well as those who had undergone radical prostatectomy, 778 men were studied. Symptoms of depression were present in 9% at baseline. At follow up 168 of the men were classified as having moderate or complete ED (self-administered questionnaire with specific items as well as a single-item global self assessment). However, the presence of depressive symptoms at baseline was not a significant predictor of incident ED (p=0.12), with a greater percentage of men without depressive symptoms developing ED than those with depressive symptoms at baseline (21.3% vs 13.2%).

This result is at odds with the conclusion of a study of 1,683 men aged 50, 60 or 70 years from a Finnish cohort, 11.4% of whom demonstrated depressive symptoms (a score of ≥16) on the five-item version of the Mental Health Index) at baseline in five years follow up study[221]. In men free of ED at baseline (determined by two self-report items, adapted from the questionnaire used in the MMAS) the incidence of ED at five years was 59/1000 person-years (95% CI 39-90) in men with depressive mood and 37/1000 person years (95% CI 32-43) in men without depressive symptoms. After controlling for possible confounding variables (age, education, marital status, body mass index, smoking, diabetes, hypertension, heart disease, cerebrovascular disease and medication use), the incidence of ED was 4.5 times higher in men with treated depressive symptoms, but just 1.2 times higher in those with untreated depressive symptoms at follow up than those free of depressive symptoms and medication use for psychological disorders at baseline. In men free of depressive symptoms but who used antipsychotic medication, the risk of ED was doubled. The adjusted incidence density ratio of depressive mood was 1.9 (95% CI 1.1-3.3) in men with ED compared to those without it at baseline. The authors describe a bidirectional relationship between depression and ED, stating that ED may independently cause or increase depression, and moderate or severe depressive mood or antidepressant medication may cause ED. A suggested mechanism is decreased blood flow to the penis and inhibition of penile smooth muscle relaxation resulting from depression inhibiting the activity of parasympathetic nerves. The authors suggest low power in the MMAS as an explanation for the discrepancy between the MMAS results and their study.

The results of the Finnish study highlight the potential for antidepressant medication to cause ED. Drugs such as tricyclic antidepressants and selective serotonin reuptake inhibitors which are commonly used to treat depression may be associated with male sexual dysfunction including new onset erectile dysfunction and should be taken into consideration when treating depression[222].

Further evidence is needed to support a bidirectional relationship but given the well supported association between ED and depression, it is appropriate that patients presenting with ED should be screened for depression and vice versa.

VII. DRUG THERAPY

1. PHOSPHODIESTERASE (PDE) TYPE 5 INHIBITORS

PDE-5 inhibitors have transformed the management of erectile dysfunction[196]. The mechanism of action by blocking the degradation of cyclic guanosine 3’5’-monophosphate (cGMP) by PDE-5 promotes blood flow into the penis and the restoration of erectile function. They do not initiate an erection and sexual stimulation is needed to obtain an erection. They are not aphrodisiacs.

Hemodynamically, PDE-5 inhibitors have mild nitrate-like actions (sildenafil was originally intended to be a drug for the treatment of stable angina). As
PDE-5 is present in smooth muscle cells throughout the vasculature and the nitric oxide/cGMP pathway involves in the regulation of blood pressure, PDE-5 inhibitors have a modest hypotensive action. In healthy men, a single dose of sildenafil 100 mg transiently decreased blood pressure by an average of 10/7 mm Hg with a return to baseline at 6 hours after the drug was given[197]. There was no effect on heart rate. As nitric oxide is an important neurotransmitter throughout the vasculature and is involved in the regulation of vascular smooth muscle relaxation, a synergistic and clinically important interaction with oral or sublingual nitrates can occur, and a profound decrease in blood pressure can result. The mechanism involves a combination of increased formation of cGMP when nitrates activate guanylate cyclase, and decreased breakdown of cGMP as a result of the action of PDE-5 inhibitors. The concomitant administration of PDE-5 inhibitors and nitrates is thus contraindicated, and this recommendation also extends to other nitric oxide donors such as nicorandil. Clinical guidelines recommend that sublingual nitrate should be taken 12 hours after the PDE-5 inhibitors sildenafil or vardenafil; tadalafil, which has a longer half-life, ceases to react with nitrates only after 48 hours[133]. Oral nitrates are not prognostically important drugs, and they can therefore be discontinued and, if necessary, alternative agents substituted[198]. After cessation of oral nitrate, and provided there has been no clinical deterioration, PDE-5 inhibitors can be used safely. It is recommended that the time interval before the use of a PDE-5 inhibitor be five half-lives, which equates to 5 days in the case of most popular once-daily oral nitrate agents.

2. SILDENAFIL (VIAGRA)

Sildenafil was the first oral treatment for erectile dysfunction and is the most extensively evaluated[223]. Overall success rates of 80% or more in patients with cardiovascular disease have been recorded with no evidence of tolerance. Patients with diabetes, with or without risk factors, in whom the pathophysiology is more complex and extensive, have an average success rate of 60%. To date, randomized trials, open-label studies, and outpatient monitoring studies have not found the use of sildenafil to be associated with any excess risk of myocardial infarction, stroke, or mortality.

In patients with stable angina pectoris, there is no evidence of an ischaemic effect caused by coronary steal, and in one large, double-blind, placebo-controlled exercise study, sildenafil 100 mg increased exercise time and diminished ischaemia[224]. A study of the haemodynamic effects of sildenafil in men with severe CAD identified no adverse cardiovascular effects, and a potentially beneficial effect on coronary blood flow reserve[225]. Studies in patients with and without diabetes have demonstrated improved endothelial function acutely and after long-term oral administration, which may have implications beyond the treatment of erectile dysfunction. Sildenafil has also been shown to attenuate the activation of platelet IIb/IIIa receptor activity[196]. Hypertensive patients receiving monotherapy or being treated with several drugs have experienced no increased in adverse events, with the exception of those receiving doxazosin, a non-selective α-adrenoceptor antagonist. Occasional postural effects have occurred with sildenafil when it was taken within 4 hours of doxazosin 4mg; advice to avoid this time interval is now in place[226]. Sildenafil has also been proved to be effective in patients with heart failure who were deemed suitable for treatment of erectile dysfunction; the incidence of erectile dysfunction in patients with heart failure is 80%, making this finding of major clinical importance[227]. On average, the dose of sildenafil is 50 mg; 25 gm is advised initially for those older than 80 years because of delayed excretion. Onset of action is 30-60 minutes with a peak effect from 1-12 hours. A dose of 100 mg is invariably needed in patients with diabetes. An empty stomach and the avoidance of alcohol or cigarette smoking facilitate the effect of the drug. Sildenafil 100 mg has no adverse cardiac effects additional to those associated with the 50 mg dose and should be routinely prescribed if, after four attempts, the 50 mg dose is not effective.

Adverse effects are generally mild in nature (Table 11) with drop out rates similar to placebo in the randomized studies.

Table 11: Common adverse events of all three PDE-5 inhibitors (from EMEA statements on product characteristics).

The short half-life of sildenafil makes it the drug of choice in patients with more severe cardiovascular disease, allowing early use of supportive treatment if an adverse clinical event occurs.

3. TADALAFIL (CIALIS)

Tadalafil also has been extensively evaluated in patients with cardiovascular disease, and has a safety and efficacy profile similar to that of sildenafil[228]. Studies have shown no adverse effects on cardiac contraction, ventricular repolarization or ischaemic threshold. A similar hypotensive effect has been recorded with a dose of doxazosin 8 mg so caution is needed: as hypotension does not occur when the patient is in the supine position, and as tadalafil has a long half-life, it is suggested that tadalafil is taken in the morning and doxazosin in the evening. There is no interaction of tadalafil with the selective α-adrenoceptor antagonist, tamsulosin, which can therefore be prescribed as an alternative to doxazosin for benign prostate hypertrophy[229]. Tadalafil is effective from 30 minutes after administration, but its peak efficacy occurs at 2 hours. Efficacy is maintained for up to 36 hours and is not influenced by food. It is administered in 10 to 20 mg doses. The recommended starting dose is 10 mg and should be adjusted according to the patient’s response and side effects. Adverse events (Table 11) are generally mild in nature and the drop-out rate due to adverse events is similar to placebo.

Tadalafil improved erections by 67% and 81% in men taking 10 mg and 20 mg of tadalafil compared with 35% of men in the control placebo group[230]. Tadalafil also improved erections in difficult to treat subgroups. In diabetic patients 64% reported improved erections compared to 25% of patients in the control group.

Because of its long half-life, tadalafil may not be the drug of first choice for patients with a more complex cardiovascular disease. However, as 80% of patients with cardiovascular disease stratify as low risk it does represent an alternative for the majority.

Tadalafil is now approved as a daily therapy (2.5 and 5mg) which may improve spontaneity and effectiveness[231].

4. VARDENAFIL (LEVITRA)

Because vardenafil has a chemical structure very similar to that of sildenafil, it is not surprising that it has a similar clinical profile. One study has reported no impairment of exercise ability in patients with stable CAD receiving vardenafil 20 mg[232]. Daily therapy provides no advantage probably due to the short half-life[233].

Vardenafil is effective after 30 minutes from administration. Its effect is reduced by a heavy fatty meal. It is administered in 5,10 and 20 mg doses. The recommended starting dose is 10 mg and should be adjusted according to the patient’s response and side effects. Adverse events (Table 11) are generally mild in nature with a drop-out rate similar to placebo.

After 12 weeks of treatment in a dose-response study, improved erections were reported by 66%, 76% and 80% of men taking 5 mg, 10 mg and 20 mg of vardenafil respectively, compared with 30% of men taking placebo[234]. Vardenafil has also improved erections in difficult to treat subgroups. In diabetic patients 72% reported improved erections compared to 13% of patients taking placebo.

5. CARDIOVASCULAR SAFETY

Clinical trial results and post-marketing data of sildenafil, tadalafil and vardenafil have demonstrated no increase in myocardial infarction rates in patients that received these agents compared to expected rates in age-matched populations of men[235]. None of the PDE-5 inhibitors were found to adversely affect total exercise time or time to ischaemia during exercise testing in men with stable angina. In addition to established benefit in treating pulmonary hypertension, these are encouraging results in cardiac failure.

Organic nitrates (e.g. nitroglycerine, isosorbide mononitrate, isosorbide dinitrate) and other nitrate preparations used to treat angina, as well as amyl nitrite or amyl nitrate (‘poppers’ used for recreation) are absolute contraindications to the use of PDE-5 inhibitors. They result in cGMP accumulation and unpredictable falls in blood pressure and symptoms of hypotension. The duration of interaction between organic nitrates and PDE-5 inhibitors is dependent upon the PDE-5 inhibitor and nitrate under study.

If a PDE-5 inhibitor is taken and the patient develops chest pain, nitroglycerine must be withheld for at least 12 hours if sildenafil (and likely vardenafil) was used (half-life 4 hours) and for at least 48 hours if tadalafil was used (half-life 17.5 hours). If a patient develops angina while taking a PDE-5 inhibitor he should be told to discontinue sexual activity and stand up, as the venous pooling will imitate a nitrate[133]. If pain continues under hospital supervision alternate agents should be prescribed, though intravenous nitrates can be used under careful medical observation.

Co-administration of PDE-5 inhibitors with antihypertensive agents (angiotensin converting enzyme inhibitors, angiotensin receptor blockers, calcium blockers, betablockers, diuretics) may result in small additive drops in blood pressure, which are usually minor. In general, the adverse event profile of the PDE-5 inhibitor[226] is not worsened by a background of antihypertensive medicines, even when the patient is on multiple antihypertensive agents.

6. INJECTION THERAPY

Direct intracavernosal injection of vasodilating agents
began in the 1980s. Prostaglandin E1 is a natural substance that relaxes smooth muscle cells and dilates the arterioles, increasing blood flow into the penis. Alprostadil is a commercially available form of prostaglandin E1 that is effective in 5 to 15 minutes, with an erection that usually lasts 30 minutes but occasionally may persist for several hours[236]. The starting dose is 1.25 µg and can be increased to 40 µg, depending on effect. It is important that patients be taught the correct technique for injection; men with poor dexterity (e.g. arthritic hands or tremor) will need their partner’s help with the injection. In fact, partners may often perform the injection as part of the sexual activity. On removal of the needle, firm pressure is applied and the drug should be gently massaged into the penis for approximately 30 seconds. Men on anticoagulants, however, should compress the injection site for 5 to 10 minutes. The resulting erection occurs without stimulation, although stimulation may enhance its effects. The erections are occasionally painful, but usually feel natural. It is recommended that this treatment not be used more frequently than every four days. Alprostadil is effective in up to 80% of the cases and is associated with a return to spontaneous erections in 35%. It is safe and effective in diabetic patients who are used to self-injection of insulin. Although its efficacy rates are impressive, the discontinuation rate for alprostadil is high, with local pain and loss of spontaneity being the most commonly cited reasons.  

7. TRANSCUTRAL THERAL THERAPY  
Intraurethral therapy of alprostadil presents an alternative to injections[237]. Medicated Urethral System for Erection (MUSE) is a single-use transurethral system that involves the insertion of a 1.4 mm pellet into the urethra using a hand-held applicator just after micturition and about 15 minutes prior to sexual activity. As with injection therapy, the patient must be taught the correct technique of insertion. Patients should receive an initial dose of 250 µg with dosage titration between 125 and 1000 µg under medical supervision until the patient achieves a satisfactory response. These numbers are much higher than with injection therapy due to drug loss in the general circulation. A maximum of two doses are allowed per 24 hour period. Once the correct dose has been identified, success rates of up to 60% have been recorded, although in a comparative study with injections this fell to 43% (injections 70%).

VIII. NON-DRUG THERAPY  
1. PSYCHOSEXUAL THERAPY  
If psychogenic ED is present, appropriate counselling should be arranged. Even organic cases of ED may have a psychological component secondary to the dysfunction itself. Cooperative teamwork between the physician and the therapist is valuable when the organic and psychological causes of ED overlap.

2. ROLE OF COUNSELLING IN THE TREATMENT OF CAD PATIENTS WITH ED  
Patients may become noncompliant with their medical regimen for CAD or hypertension, fearing that such medications cause or worsen sexual function. On the other hand, they may defer sexual activity fearing either hypothetical risks of PDE-5 inhibitors or that their cardiac condition does not permit it. Many patients with CAD are uncomfortable discussing sexual function despite their informational needs and desire to discuss their sexual health. To dispel fear and anxiety, couples should receive information about the pathophysiology of cardiovascular disease (including its treatment) relative to sexual function, the physiologic requirements of sexual activity and the psychologic sequelae of CAD. It should be made clear that all of the currently recommended therapeutic methods (revascularization procedures, medications, aggressive risk factors management) aimed at reducing cardiovascular risk in general may also be effective in minimizing cardiac risks associated with sexual activity in particular.

Most patients at low risk may be permitted to engage in or resume sexual activity, and/or receive treatment for ED, provided that this does not include PDE-5 inhibitor use in the presence of concomitant nitrate regimens. Clinicians should reassure low risk cardiac patients that the stress on the heart during intercourse is no greater than that during normal working activities or moderate exercise and the existence of a stabilized cardiac condition does not increase the risk of a cardiac event during intercourse. Sexual activity should be resumed gradually and when the patient is rested and relaxed. Maintaining a moderate room temperature, as well as avoiding intercourse after a heavy meal or heavy drinking, can contribute to a relaxing and safe sexual encounter. If the patient is taking a PDE-5 inhibitor for ED, then he should not take a nitrate if angina occurs during sexual intercourse but should be advised to stop the activity. No further sexual activity should be undertaken until the patient has had an adequate medical evaluation. Patients should also be advised to report any angina, dyspnea, prolonged palpitations or dizziness, or intense and sustained fatigue experienced during sexual activity. Such symptoms may indicate a need to reappraise the safety of sexual activity. The need for lifestyle changes and intense risk factors management should be made clear. Further, physicians should remember that even organic cases of ED may have a psychological component secondary to the dysfunction itself. It is preferable that sexual counselling is provided to both the patient and their partner when this is feasible, since
the disease has great impact on relationship issues. Finally, the bottom-line of a successful counselling is to individualize the advice.

Patients and their partners should be provided with the opportunity to:

- dissolve misconceptions on the relationship between CAD (and its medication) and ED
- further their understanding of the risks associated with sexual activity and to adopt safe practices
- understand proper use of PDE-5 inhibitors and their contraindications
- be sensitized regarding warning symptoms of a cardiac condition
- to understand the importance of adhering to lifestyle changes and risk factors treatment

3. VACUUM CONSTRUCTION DEVICES

The vacuum constriction device is a long-established means of treating ED[238]. It is a non-invasive method that produces an erection by creating a pressure vacuum of up to 250 mm Hg, causing blood flow into the penis. The erection is then maintained with the placement of a rubber construction ring at the base of the penis. The constriction ring must not be left in place longer than 30 minutes, since ischaemic damage could occur.

It should be recognized that a significant hematoma (minor in 10% of cases) may occur in men on anticoagulants; so, this is a relative contraindication. Specific training and advice before commencing the use of a vacuum device are needed. Vacuum devices are also not recommended for men with penile curvature.

IX. POTENTIAL CARDIAC APPLICATION OF PDE-5 THERAPY BEYOND ERECTILE DYSFUNCTION

1. PULMONARY HYPERTENSION

Sildenafil has been shown to be beneficial to patients with pulmonary arterial hypertension, either idiopathic or secondary[239].

2. IDIOPATHIC PULMONARY HYPERTENSION

The treatment of idiopathic pulmonary arterial hypertension is the only non-erectile dysfunction PDE-5 inhibitors indication currently approved. Sildenafil has been approved at a dose of 20 mg three times daily for improving exercise tolerance in patients with pulmonary hypertension[240]. It significantly enhances exercise capacity by improving pulmonary hemodynamics and reducing right ventricular afterload[240,241]. It also reduces right ventricular mass, as determined by magnetic resonance imaging. Sildenafil might have the very desirable combination of primary inotropic, antihypertrophic, and afterload-reducing effects on the right ventricle without significantly affecting systemic hemodynamics. Thus, this agent appears very attractive for the treatment of pulmonary arterial hypertension involving the right ventricle[242].

The currently available PDE-5 inhibitors are not equally efficacious in the treatment of pulmonary hypertension[243]. Reduction in mean pulmonary artery pressure, in the pulmonary-to-systemic vascular resistance ratio and in right ventricle afterload, as well as an increase in cardiac index, has been reported with all three PDE-5 inhibitors. However, only sildenafil causes a significant improvement in arterial oxygenation. The etiology of these agent-specific characteristics may be related to the different selectivities of the three PDE-5 inhibitors with respect to other PDE isoforms or the difference in their binding capacity to PDE-5 during hypoxia[243].

3. SECONDARY PULMONARY HYPERTENSION

Pulmonary arterial hypertension is a life-threatening complication of several connective tissue diseases including scleroderma, systemic lupus erythematosus, mixed connective tissue disease, rheumatoid arthritis and dermatomyositis/polymyositis. Clinical studies suggest that sildenafil can be used as a pulmonary vasodilator in systemic sclerosis patients with secondary pulmonary hypertension[244]. Sildenafil also reduces pulmonary artery pressure and increases quality of life in patients with systemic lupus erythematosus[245].

4. HIGH-ALTITUDE ILLNESS

The term «high-altitude illness» is used to describe the cerebral and pulmonary syndromes that can develop in unacclimatized persons shortly after ascent to high altitude. Acute mountain sickness and high-altitude cerebral edema refer to the cerebral abnormalities, and high-altitude pulmonary edema to the pulmonary abnormalities. Because millions of visitors travel to high-altitude locations each year, acute mountain sickness is a public health problem and has economic consequences, especially for the ski industry. High-altitude pulmonary edema and high-altitude cerebral edema, though uncommon, are potentially fatal[246]. Exposure to high altitude causes alveolar hypoxia, induces pulmonary hypertension, and may even lead to pulmonary edema. The alveolar edema and ventilation/perfusion mismatch initiate a catastrophic downward spiral of worsening alveolar hypoxia[247]. PDE-5 inhibitors show promise in high altitude medicine, as, by virtue of their vasodilating effect on the pulmonary circulation, they suppress the altitude-induced pulmonary hypertension and they ameliorate pulmonary hemodynamics and gas exchange, thus limiting the altitude-induced hypoxemia and favoring cardiovascular adaptation to exercise[248].

5. SYSTEMIC HYPERTENSION

Because PDE-5 is present in artery and vein smooth muscle cells throughout the body, PDE-5 inhibitors have mild systemic vasodilatory effects and thus the potential to impact the vascular system. The vasodilating properties of PDE inhibitors in the systemic circulation account for the BP reduction observed in patients treated for ED[249]. Thus, these drugs would be theoretically suitable for treating hypertension in patients without ED. Additional benefits may be related to improved arterial stiffness and endothelial dysfunction, two early vascular abnormalities characterizing essential hypertension[250].

The potential of PDE-5 inhibitors as antihypertensive agents has not been thoroughly explored. Active midterm treatment with sildenafil reduced ambulatory and clinic blood pressure to a similar extent as that observed with other classes of antihypertensive drugs [251]. An incremental antihypertensive effect of a single dose of tadalafil has been demonstrated in uncontrolled hypertensive subjects on multiple agents[252]. However, at this stage, the use of PDE-5 inhibitors as antihypertensive agents cannot be advocated. More investigation is needed on PDE-5 inhibitors as antihypertensive drugs, especially with slow-release formulations or compounds with long half-life. Studies on safety during long-term administration, interactions with antihypertensive and non-antihypertensive drugs, and effect on target organ damage are needed.

Concomitant use of PDE-5 inhibitors with antihypertensive drugs results in either no or small additive reductions in blood pressure. Multiple trials support the safety of use of PDE-5 inhibitors in hypertensive men with ED being treated with monotherapy or a multidrug antihypertensive regimen. Concomitant use of PDE-5 inhibitors with α-blockers requires some caution, because some patients may develop orthostatic hypotension.

6. CORONARY ARTERY DISEASE

PDE-5 inhibitors have potential as cardiovascular drugs in patients with vasospastic angina or diffuse coronary microvessel disease and in patients undergoing coronary artery bypass grafting because of their favorable effects on vascular function and their ischemic preconditioning-like effects[253]. Furthermore, although their potency is modest compared with other agents that specifically target platelet adhesion/aggregation, their adjunctive use as antiplatelet agents could be also considered.

In a recent prospective study Gazzaruso et al., showed that in type 2 diabetic men with silent coronary artery disease, treatment with statins and 5-PDE inhibitors might reduce the occurrence of major adverse cardiac events.

7. HEART FAILURE

Treatment of heart failure is a challenging task. An impaired nitric oxide pathway contributes to several abnormal cardiac and vascular phenotypes typical of the failing cardiovascular system. Inhibition of phosphodiesterase-5 is a new therapeutic strategy for overexpressing nitric oxide signaling by increasing the availability of cyclic guanosine monophosphate[254].

Sildenafil at the dose of 50 mg twice per day for 6 months heightened ventilatory efficiency and exercise performance, tempered the peripheral stimulus to hyperventilation, and improved the NO-mediated vasodilation in patients with chronic systolic heart failure[255]. Furthermore, long-term treatment (12 weeks) with sildenafil improved peak VO2, 6-minute walk distance and right ventricular ejection fraction, in patients with systolic heart failure complicated by secondary pulmonary hypertension. Since many of the observed benefits of PDE-5 inhibition with regard to left ventricular hypertrophy, ventricular-vascular stiffening, renal dysfunction, and pulmonary hypertension may be particularly relevant to the pathophysiology heart failure in patients with preserved ejection fraction, there is compelling rationale for extending the preliminary physiologic benefits of sildenafil seen in <systolic> heart failure to the population with <diastolic> heart failure. The RELAX trial, which proposes to address this question, is currently in progress.
Landmark experiments by Takimoto et al performed in mice exposed to sustained pressure overload, have documented that chronic PDE-5 inhibition can prevent and reverse cardiac and myocyte hypertrophy and interstitial fibrosis[256]. Experimental data also suggest direct myocardial effects of PDE-5 inhibition that may counteract β-adrenergic, hypertrophic and pro-apoptotic signaling, three critical pathways in the development of left ventricle dysfunction[257]. Inotropic effects of sildenafil were shown in human and animal hypertrophied right ventricle models; however, whether this is present in failing right ventricles remains to be determined.

Inhibition of PDE-5 has been associated with improvements in endothelial function in patients with heart failure due to systolic dysfunction that are highly correlated with improvements in skeletal muscle perfusion, reduction in exercise-induced hyperventilation, and increased aerobic efficiency[258]. Associated reductions in large artery stiffness observed during sildenafil treatment may further contribute to improved baroreceptor function and enhanced heart rate recovery in patients with heart failure. Improvements in vascular function and pulmonary vascular resistance may account for the overall improvements in exercise capacity and health-related quality of life that have been observed during chronic administration of sildenafil to heart failure patients.

In summary, multiple lines of pre-clinical evidence support a therapeutic role for PDE-5 inhibitors in the management of heart failure patients. However, human trials to date are limited to small physiologic studies of patients with heart failure and reduced ejection fraction (most with associated pulmonary hypertension) followed for relatively short periods of time. Longer-term randomized trials are necessary to define the safety, tolerability, and efficacy of PDE-5 inhibitors for the management of heart failure across the spectrum of ejection fraction.

8. RAYNAUD’S PHENOMENON

Raynaud’s disease (RD) is a common disorder affecting 3% to 5% of the healthy population, and occurs in more than 90% of patients with connective tissue diseases. The therapeutic options remain limited, particularly in patients with secondary RD due to connective tissue disease. Theoretical considerations lead to the expectation that phosphodiesterase type 5 inhibitors may improve clinical symptoms and digital blood flow in patients with RD.

Digital ischemia results from vasoconstriction of the digital arteries, precapillary arterioles, and cutaneous arteriovenous shunts. Despite various hypotheses, the mechanism of local vasoconstriction is not well understood. Nevertheless, there is increasing evidence that the NO/cGMP system plays a major role. PDE-5 inhibitors, through their vasoactive and platelet-inhibitory effects, may lead to improved microcirculation, decreased frequency and shorter duration of attacks, and ulcer healing in patients with vasodilator-resistant Raynaud’s phenomenon[259,260].

Based on current data from small clinical trials, open-label pilot studies and case series and reports, phosphodiesterase 5 inhibitors may help some patients with very serious Raynaud’s. A large, well-conducted multicenter, double-blind study is needed to determine the benefit and risk of these agents in Raynaud’s phenomenon[261].

9. PERIPHERAL ARTERY DISEASE

Therapeutic use of PDE-5 inhibitors may extend to the chronic tissue ischemic states such as peripheral artery disease. In a recent study on limb ischemia, sildenafil therapy resulted in increased angiogenic activity through a PKG-dependent pathway that is independent of nitric oxide production or NOS activity and a finding which identify the angiogenic therapeutic potential of sildenafil for critical limb ischemia[262].

10. CONGENITAL HEART DISEASE

Endothelium-dependent pulmonary artery relaxation is impaired in young patients with increased pulmonary flow secondary to congenital heart disease. This impairment may be an important early event in the pathogenesis of pulmonary vascular disease. Sildenafil increases pulmonary blood flow and improves cyanosis in patients with Eisenmenger syndrome. Efficacy of sildenafil as treatment for idiopathic pulmonary arterial hypertension may be extended to patients with Eisenmenger syndrome[263]. Preliminary evaluation of tadalafil has shown efficacy and safety in selected patients with Eisenmenger syndrome[264]. Finally, sildenafil was reported to improve pulmonary arterial hemodynamics and right ventricular function and relieve symptoms associated with severe pulmonary arterial hypertension in patients with large atrial septal defects[265].

11. DIABETES

PDE-5 inhibitors have shown to display beneficial cardiovascular effects, suggesting that they may have other systemic benefits involving the endothelium. There is currently little evidence available regarding the effects of PDE-5 inhibitors—beyond treatment of ED—in patients with type 2 diabetes. In a double-blind, randomized, controlled trial in 40 male patients, with type 2 diabetes the administration of 50mg of sildenafil citrate for 30 consecutive days diminished microalbuminuria and the percentage of Hb A1c, suggesting a protective effect of this drug against target organ damage of diabetes[266].

X. CARDIOVASCULAR ASPECTS OF FEMALE SEXUAL DYSFUNCTION

Female sexual dysfunction (FSD) is defined as disorders of sexual desire, arousal, orgasm and/or sexual pain which result in significant personal distress and may have a negative effect on a woman's health and her quality of life[267]. It is an age-related, progressive and highly prevalent disease, affecting 22-76% of women. An analysis of data from the National Health and Social Life Survey found that sexual dysfunction is more prevalent in women than in men (43% vs. 31%)[268]. Shifren et al[269] found an age-adjusted prevalence of any sexual dysfunction and sexually related distress of 43.1% and 22.2%, respectively in a large (n=31,581) female population representative of U.S. women. The two conditions occurred together in 12% of cases and were more common in middle-aged women.

Sexual symptoms may signal serious underlying disease. Although the same diseases, risk factors and medications that are associated with male erectile dysfunction, such as heart disease, hypertension, diabetes, smoking and hypercholesterolemia, antidepressants and anti-hypertensives are also associated with FSD, specific underlying causes are not well described and the association with cardiovascular disease has not been fully explored[270].

The heterogeneity of the patient population enrolled into the studies, the change over time in either FSD definition or classification, the confounding factor of the menopause, the profound effect of psychological and psychometric variables, the different methods used to diagnose both FSD and underlying vascular disorders and the lack of direct, “user friendly” indices of FSD (compared for example with penile erection in men) accounts for many uncertainties and the wide gap of information in this field[271]. Thus, a comparison with male erectile dysfunction is difficult and requires further research (Table 12).

1. PATHOPHYSIOLOGY OF FSD

The sexual response in women schematically includes excitement/arousal, plateau, orgasm and resolution. Physiologic changes that take place during sexual activity start with increased flow to the genitalia with engorgement. Vaginal lubrication occurs and precedes vagina lengthening and dilation due to smooth muscle relaxation. The increased blood flow to clitoris increases intracavernous pressure, tumescence, protrusion of the glans clitoris and eversion and congestion of the labia minora[272]. Common vascular risk factors may alter the NO-mediated vasodilation process that ultimately leads to vaginal engorgement and clitoral erection (the "vascular phases" of female sexual activity). Thus, similarly to male sexual dysfunction, a preserved endothelium integrity and a patent hypogastric-pudendal artery supply are needed for a correct sexual response. Animal models have shown that atherosclerosis of the aorto-iliac arteries causes clitoral fibrosis and significantly inhibits the vasculogenic response to stimulation[273].

Despite the high prevalence of FSD, little attention has been paid to this disorder. The fault is equally distributed between physicians and patients. From one side, a recent survey of members of the American Urogynecologic Society has shown that only a minority screen for FSD, mainly due to lack of time and uncertainty about the treatment[274]. From the other side, a very small proportion of women seek medical attention for FSD. In a UK-based survey[275], despite 54% of women reported at least one sexual problem lasting at least one month during the last year which caused 65% of them to avoid sex, only 21% had sought help (>70% the general practitioner). The most frequent reasons for that were embarrassment and feeling that there was no remedy for this problem. Thus, women are reluctant to talk about sexual problems with their GP, and time constraints of the every day clinical practice lead to doctors failing to address sexual dysfunction.

2. SPECIFIC RISK FACTORS FOR FSD: ROLE OF DIABETES, CARDIOVASCULAR DISEASE AND HYPERTENSION

a) Diabetes

Among the common risk factors, diabetes plays a pivotal role in sexual dysfunction either in men and in women. Prevalence varies between 27% and 49% with values as high as 80% reported in type 2 diabetics over 50 years (10-12). The pathophysiology of the association between diabetes and ED/FSD is multifactorial including endothelial and smooth muscle dysfunction and autonomic neuropathy. Diabetic women are prone to develop a "global sexual dysfunction" leading to decrease sexual desire, dyspareunia, decrease sexual arousal and inadequate lubrication. Overall, results of the association between diabetes and FSD in women are far less consistent than in ED mainly due to the difficulty in quantifying the sexual response in women. Studies exploring the effect of diabetes on the vascular component of sexual function found that both vaginal lubrication and clitoral erection are frequently affected as compared to non diabetic women[276]. Interestingly, a poor correlation between FSD and either duration of diabetes or diabetic complications has been reported in previous studies reinforcing the concept of the role of "extra-vascular" causes, included depression, in determining FSD[277,278].

b) Cardiovascular disease

Evidence is accumulating in favor of a strong association between various CV disease and male sexual dysfunction. Coronary artery disease (CAD) is often associated with hypertension, obesity and metabolic syndrome, sharing endothelial dysfunction as the pathophysiologic background. These conditions have been found to produce FSD as well. Interestingly, many cardiovascular diseases lead to decrease physical activity which in turn has been found to be one of the primary determinants of FSD[279].

c) Hypertension

The prevalence of FSD in hypertensives averages up to 40% and it is usually higher than in normotensives (42.1% vs. 19%, p<0.001)[280,281]. Variables that have been reported to significantly affect FSD rate are duration of the hypertension, age and anti-hypertensive medications[280]. As previously shown in hypertensive males with ED, no significant difference was found between treated vs. untreated patients in the female sexual function index scores (26.5±5.4 vs. 24.8±6.2, p=0.11)[280] confirming the role of the hypertensive process per se in the determination of FSD.

d) Menopause as a confounding factor

Menopause is characterized by a series of neuroendocrine changes that ultimately lead to reduced estrogen production[282]. The decline in ovarian hormones accounts for an increased rate of both sexual disturbances and cardiovascular disease. Prevalence of FSD in post-menopausal women varies between 68% and 87%, mainly due to a decrease in sexual desire and onset of dyspareunia. Many factors, such as age, hypertension, hypercholesterolemia and diabetes, metabolic syndrome, come into play to explain the increased CV risk in postmenopausal women. All these factors negatively affect endothelial function and accelerate the systemic atherosclerosis process, included CAD. In this situation, the association between FSD and CAD should be sought as a frequent occurrence rather than a peculiarity and correction for many covariates should be taken into consideration.
3. SELF-REPORTED QUESTIONNAIRE FOR FSD DIAGNOSIS

Self-reported questionnaire to assess FSD are well standardized and inexpensive diagnostic tools, easy to administer and score and normative values are available in both clinical and nonclinical populations. As with ED questionnaires (e.g., the IIEF), differences in educational, ethnic or cultural background may hamper the results of these tests. Among the several assessment tools available to investigate sexual dysfunction, the Female Sexual Function Index (FSFI) is probably the most popular and widely accepted and is becoming the gold standard for the evaluation of FSD[283]. It is a brief (19 items) questionnaire that assesses sexual functioning in women over the past 4 weeks in six separate dimensions (desire, arousal, lubrication, orgasm, satisfaction and pain). The test has been validated and the measure was shown to have a high degree of internal consistency and reliability. Other tests include the Self Function Questionnaire (SFQ), the Brief Sexual Function Index for Women (BSFI-W) and the Female Sexual Distress Scale (FSDS).

4. FEMALE SEXUAL DYSFUNCTION-CAD LINK: CLINICAL EVIDENCE

The clinical evidence of a link between FSD and CAD is far less robust than between ED and CAD. The few studies that have dealt with this link addressed the general relationship between obstructive vascular disease and complaints of sexual disorders. Kaya et al[284] assessed sexual function in 20, sexually active, young women (mean age 38±3.8 years) with angiographically proved CAD compared to 15 age-matched healthy controls. The FSFI test was used. Patients with CAD had higher rate of sexual dysfunction (60% vs. 33%, p<.05) and significantly lower total FSFI score (18±3 vs 26±5, p=0.001) as compared to normals. The most affected domains were orgasm and lubrication. No comparison was made between the extent and severity of CAD and the FSFI score. Tessier et al[285] evaluated the prevalence of sexual dysfunction in a population of women who underwent elective abdominal aortic surgery either for dilative or occlusive disease using the FSFI and SF-36 questionnaires. Mean age was 67.8 years with 93% being post-menopausal women on hormone replacement treatment. They found that FSD was more frequent in women with occlusive rather than dilative aortic disease, supporting the role of obstructive vascular disease in the genesis of FSD.

In 2005 Salonia A. et al[286] first presented a preliminary report on 39 consecutive women with angiographically proved CAD who were assessed for sexual dysfunction by FSFI and SDS test. FSD was detected in 12/39 women (30%). Interestingly, 10/12 (83%) of those with both FSD and CAD developed sexual symptoms prior to CAD onset with a median time interval of 62 months (12-108 months). CAD women had a significantly lower total-FSFI and FSFI-arousal scores as compared to a normal control group (n=102). Finally, The Women’s Health Initiative Observational Study (WHI-OS) explored the association between sexual satisfaction and cardiovascular conditions at baseline, in 46,525 sexually active, postmenopausal women aged 50 to 79 years[287]. Women were classified as sexually satisfied or dissatisfied. In logistic regression modeling dissatisfaction was significantly associated only with peripheral arterial disease (adjusted odd ratios 1.44, 95% CIs, 1.15-1.82), whereas no correlation was found with myocardial infarction, stroke, coronary revascularization either with coronary artery bypass or percutaneous coronary angioplasty, congestive heart failure and angina pectoris. Women were followed up for an average of 7.8±1.4 years. No increased prevalence or incidence of cardiovascular disease among the sexually satisfied vs. dissatisfied was detected. Authors concluded that the lack of predictive value of sexual dissatisfaction in this specific subset of women may be the result of physiological differences in sexual functioning between sexes. In a commentary to this article by R. Lane and J. Thayer[288] authors pointed out that sexual satisfaction in women is determined by multiple factors, of which vaginal lubrication (not assessed in that study) is only one. Sexual satisfaction/dissatisfaction is driven by different determinants in women and in men and are assessed by direct/indirect indexes. They concluded that it is of paramount importance to establish equivalent psychological markers across the sexes and to fully consider the role of emotions, both negative and positive, as important factors influencing the CV outcome.

An additional issue that merits some comments is the resumption of sexual activity after an acute coronary event (usually acute myocardial infarction). A somewhat “physiologic” change in the patient’s sexual activity up to 6 months after hospital discharge is a frequent occurrence (40-50%) and may vary from a reduction in the frequency/intensity of sexual intercourse to a true sexual dysfunction[47]. Reasons include anxiety, depression, loss of libido, fear of worsening the cardiac condition in both the patient and the partner and side-effects of cardiovascular medications. Those patients who had a degree of pre-existing sexual dysfunction were more likely to develop severe and long-standing sexual dysfunction.

5. RECOMMENDATION FOR SCREENING IN FSD

While evidence is accumulating supporting the concept that every patients with ED should be considered as a cardiac patient until otherwise proved, results are much less than conclusive for women with sexual dysfunction. Nevertheless, the Princeton Consensus Conference recommendations or any others available CV risk assessment tool[47] should
be applied to any woman with suspected or proved sexual disorder in order to stratify her own 10-year CV risk. Additional diagnostic tests should be performed when indicated. In those with proved sexual function disorder and heart disease, especially CAD, priority should be given to cardiologic diagnostic and therapeutic strategies before starting a specific approach to sexual disturbances.

6. TREATMENT OF FSD

Cardiovascular aspect of the treatment of FSD relates primarily to the use of medications that can influence sexual function. Similarly to men with ED, the avoidance of specific drug categories, such as beta-blockers and diuretics, may help to reduce sexual side-effects[280].

The development of phosphodiesterase-type-5 (PDE-5) inhibitors, such as sildenafil, tadalafl and vardenafil, has certainly revolutionized the treatment of sexual dysfunction in men. While improving erection, they exert beneficial effects on the heart and coronary, peripheral and pulmonary circulations. Basically, the inhibition of cGMP breakdown by phosphodiesterase type-5, PDE-5 inhibitors enhance muscle relaxation allowing for subsequent vasodilation and cavernosal engorgement. Moreover, the presence of NO synthase and PDE-5 in both animal and the human clitoral and vaginal tissues have been reported in previous studies. Despite this background, clinical studies with sildenafil, the only tested PDE-5 inhibitors in FSD, gave mixed results, suggesting a more complex mechanism of sexual dysfunction in women[289,290].

7. CONCLUSION

Female sexual dysfunction is a complex, multi-faceted, widely under diagnosed disorder affecting a substantial number of women

It is affected by common risk factors and clinical co-morbidities

Unlike ED, the association with CAD, the role as warning sign of sub-clinical vascular disease and as a predictor of future CV events has not been demonstrated

8. RECOMMENDATIONS

FSD should be evaluated in all female cardiac patients

XI. CONCLUSION

Cardiac patients may have anxieties about sexual activity because of their false belief of substantially increased risk. ED is common in cardiac patients because of the shared risk factors that adversely impact endothelial function. Signs of ED often present before overt cardiac symptoms develop; therefore a cardiac workup may be warranted for these patients, even without relevant cardiovascular histories. There is now increasing awareness of therapy for ED, but many patients remain reluctant to come forward for advice. The question of sexual activity and ED therapy should be raised by healthcare professionals as a routine part of the management of cardiac patients. Treatment is available. With reassurance, support, and careful explanation, sexual relationships can be
enjoyed by cardiac patients who receive appropriate advice.

With the recognition that ED is an early warning sign for silent coronary and vascular disease, screening for men presenting with ED and no cardiac symptoms is widely advocated. According to the second Princeton Consensus Guidelines, all men with ED and no cardiac symptoms should be considered as cardiac (or vascular) patients until proven otherwise. Such patients should undergo a full medical assessment with stratification of cardiovascular risk as high, medium or low. Those patients at low risk should receive lifestyle advice regarding physical activity and weight control and undergo regular monitoring by their general practitioner. Patients at increased risk for cardiovascular events should ideally undergo stress testing and referral for risk reduction therapy.

Although an exercise ECG is advocated to identify patients at increased cardiovascular risk, this method will identify only those people with obstructive flow-limiting CAD. Wherever possible, intermediate and high-risk patients should be considered for elective computed tomography coronary angiography to identify the presence of non-flow limiting lipid plaques that are potentially vulnerable to rupture. By implementing these measures, it should be possible to initiate early aggressive cardiovascular risk reduction in ‘at-risk’ patients, thereby taking advantage of the 2-5 year window of opportunity between the development of symptomatic ED and CAD. However, for the full potential of this approach to be realized, comprehensive education programmes are required to encourage men with ED to present to their general practitioner as soon as possible. In addition, a multidisciplinary approach is required, involving teamwork between the family doctor, nurse, pharmacist, urologist, diabetologist and cardiologist.

INTRODUCTION

I. COMPLEXITIES AND RELEVANCE OF SEXUAL FUNCTION WHEN LIVING WITH CHRONIC DISEASE

Advances in surgical and medical treatment have greatly improved survival for patients with chronic illness, including many types of cancer. Surveys of patients who had received treatment for a variety of cancers in recent years suggest some 50% of the respondents developed sexual difficulties, half of whom would definitely seek treatment were it available. [1] As well, sexual dysfunction can reflect serious medical complications. For example severe ED in men with renal failure is known to be typically associated with coronary artery calcification which in turn is reflective of coronary artery disease. [2] The treatment of sexual dysfunction resulting from a medical condition, or commonly, from its treatment, has become an important component of medical care. Improved understanding of sexual physiology allows more effective therapy of dysfunction and even the opportunity of preventing some disease-related or iatrogenic dysfunction. Many factors contribute to sexual dysfunction related to chronic illness as shown in Table I.

In this chapter, we will identify the prevalence and underlying pathophysiology of sexual dysfunction associated with chronic illness and its treatment. We will address psychosocial factors contributing to sexual problems. Particularly in women, mood and relationship issues may be more crucial determinants than medical or surgical interruption of the sexual response. Currently accepted treatments, as well as emerging treatments, will be summarized. Potential prevention of dysfunction will be included.

II. ASSESSMENT

Because the sexual problems related to chronic illness are multifactorial, assessment and treatment should be from a multidisciplinary perspective. The most important assessment tool remains the structured interview. For patients in committed relationships, it is optimal to include both partners, seeing them together and individually. In the conjoint interview, the history of the sexual difficulties and each partner’s reaction to them can be evaluated. In individual sessions, the interviewer can ask about sensitive topics including past and present psychosocial difficulties, sexual trauma, sexual function with self-stimulation, with other partners, or emotions difficult to reveal in the partner’s presence. Table 2 outlines items requiring assessment when chronic illness is present in one or both partners.

A. NEUROLOGICAL DISORDERS

“Be near me when the light is low, when the blood creeps, and the nerves prick and tingle.”

Tennyson

I. NEUROPHYSIOLOGY AND NEUROANATOMY OF SEXUALITY IN HEALTH AND DISEASE

During the second quarter of the 20th century Wilder Penfield, in his cortical mapping experiments upon the brains of awake neurosurgical patients, found that genital tingling could be elicited by stimulating a small area of the right or the left parietal cortex in the interhemispheric fissure [22]. Stimulation was by surface electrodes. Later, neurosurgeon Robert Heath (1964) published a remarkable series of experiments whereby depth electrodes were

implanted into the deep mesiolimbic structures and other dopamine-rich 'pleasure centres' of the brain including the septal nuclei in the vicinity of the nucleus accumbens [23] (Figure 1). The ambulant patients were able to elicit orgasms at will by stimulating the implanted septal electrode connected to an external self-controlled button device. Fortunately by the turn of the millenium it became possible to map the topographic areas of sexual activation non-invasively by functional imaging with positron emission tomography (PET) and magnetic resonance (fMRI) as reviewed elsewhere [5] and addressed in greater detail in chapters 13 and 22 of the present book.

The septal nuclei are located adjacent to the cingulate gyrus on the medial surface of the frontal lobe and have massive projections to other limbic/paralimbic centres including the hippocampus, hippocampal fornix, amygdala, and hypothalamus (Figure 1). In some of those areas androgen receptors are present, and there is complex interaction between these receptors and hypothalamopituitary peptides including oxytocin, prolactin, and beta-endorphin to possibly contribute to arousal and to the 'satiation' that follows orgasm.

Neuronal damage to the frontal and temporal lobes of the brain, including the more deeply-located limbic structures, is the main vehicle of organic sexual dysfunctions brought about by brain trauma and stroke. Limbic and paralimbic areas of the brain involved in stroke include the insular cortex (middle cerebral artery stroke), the mesofrontal cortex/cingulate gyrus (anterior cerebral artery), the hypothalamus (contributions from both the anterior and posterior cerebral arteries), and the mesiotemporal structures (anterior choroidal artery). Epilepsy commonly arises in the hippocampal/
amygadaloid circuitry of the temporal lobe to potentially affect sexuality which can be further compromised by side effects from medications used to treat the seizures. Sexual dysfunctions in Parkinson’s disease are linked both to central dopamine depletion and peripheral autonomic neuropathy. Spinal autonomic pathways and ascending sensory pathways from the genitalia are selectively implicated in multiple sclerosis as well as spinal cord injury. Compromising the peripheral link are interruptions to the lower motor neuron connections between spinal cord and genitalia, by way of somatic/autonomic peripheral neuropathies, cauda equina injury, and iatrogenic pelvic nerve plexus injury brought about by surgical disruption or irradiation of the genital autonomic nerve supply (chapters 9 and 13) [5]. Ubiquitous in many of these neurological disorders are co-morbid disturbances of mood including depression (section C of present chapter and chapter 3) to potentially generate sexual anhedonia by way of frontolimbic inhibition [24].

II. EPIDEMIOLOGY OF SEXUAL DYSFUNCTION IN NEUROLOGICAL DISEASE

Uncertainties cloud the true prevalence of sexual dysfunctions in neurological disorders (Table 3) particularly in women in whom prevalence rates carry uncertainty even in health. Sexual difficulties following traumatic injury to the brain or to the spinal cord present a special case. Firstly, sexual losses can be total following spinal cord trauma depending on the completeness of paraplegia or quadriplegia and its segmental level along the spinal neuraxis. Second, in brain and spinal cord trauma, co-existing multiple injuries - including orthopedic injuries - exert their own, confounding effects upon sexuality by way of pain and disturbed sleep. Therefore, without inclusion of a control population of non-cerebral injuries, published figures on prevalence are a blend of brain (or cord) injury together with the sexual effects of ‘other’ bodily injuries [38,39]. By similar token, published rates of sexual dysfunction after stroke are clouded by comorbid vascular disease affecting the genital engorgement capacity in both men and women.

III. TREATMENT

Co-morbid depression to require treatment is a recurrent theme across the spectrum of chronic neurological illness. Pharmacological interventions for mood disorder can impact both positively and negatively upon sexual well-being. We recommend to screen and treat comorbid depression in patients with all neurological illness [5]: Grade C outlined in Table 4 are levels of evidence on selected treatment options for sexual difficulties in neurological disorders.

IV. INDIVIDUAL DISEASES

1. HEAD INJURY

a) Brain trauma

Sexual sequelae are not always linked to duration of coma, to the degree of global brain tissue loss, or the focality of brain injury. An exception is severe trauma to the prefrontal regions to produce a spectrum of change that ranges from disinhibited hypersexuality at one extreme to apathy and hyposexuality at the other.

Our specific recommendations for the management of hypersexuality include: CBT, SSRIs, clobazam, antiandrogens, GNRH agonists, and atypical antipsychotics: [5] Grade C.

Hypoactive sexual desire disorder is linked to disturbances of mood at all grades of head...
b) Pituitary trauma

Head injuries may give rise to sexual disorders not only as a result of injury to the brain tissues but also from co-occurring damage to the pituitary gland located on the undersurface of the brain. Injury of this type occurs mostly with, but is not limited to, severe levels of head trauma. Herrmann et al [65] found that pituitary deficits mostly occur when trauma-induced coma has exceeded 10 days. A ‘red flag’ for pituitary injury is the detection of basal skull fracture involving the sphenoid bone that harbours the pituitary gland; or by the finding on acute-phase CT or MRI of diffuse cerebral edema with resultant compression of the third ventricle as an indirect marker of disruption to the neighbouring hypothalamus and the connecting portal veins within the pituitary stalk.

### Table 3: Epidemiology of sexual dysfunctions in neurological disorders [5, 7, 25, 26, 27, 28, 29, 30, 31, 32, 33, 34, 35, 36, 37]

<tbody>
<tr>
<td>Head Injury</td>
<td>36-54% for severer levels of TBI compared to 15% of healthy controls [25] Mostly erectile/ejaculatory dysfunction in men, reduced lubrication/dyspareunia in women.</td>
<td>Depression more important than severity of TBI in both sexes [34] Medications (especially mood-altering) account for up to one-quarter of cases of ejaculatory failure[26]</td>
</tr>
<tr>
<td>Spinal Cord Injury</td>
<td>Orgasm is achieved by less than half of subjects of either gender. About 50% of men are able to ejaculate when incomplete cord lesions are included. As few as 4% of men with complete, high lesions achieve ejaculation even though reflex erections remain intact[35].</td>
<td>Chronic pain in relation to cord injury occurs in as many as one-third of cases at least in men to potentially interact with depression and the autonomic aspects of sexual dysfunction[35]</td>
</tr>
<tr>
<td>Multiple Sclerosis</td>
<td>Of men who are still ambulant, 60% have ED and 40-50% ejaculatory/organic dysfunction with reduced desire[27]. In ambulant, newly diagnosed women (mean time since first symptoms of MS, 2.7 years), sexual dysfunctions according to FSFI scores were present in 34.9% of sample compared to 21.3% healthy controls[7].</td>
<td>Eventually well over half of either sex are affected, predominantly by ED in 75% of men and by loss of genital sensation in up to 62% of women[5]</td>
</tr>
<tr>
<td>Stroke</td>
<td>An internally controlled study of 75 men and 25 women showed a dissatisfaction rate of 58.6% of men compared to 21.3% before the stroke and in 44% of the women compared to 20% prior to the stroke[28].</td>
<td>With depression as one of the exclusion criteria, post-stroke libido in patients 40-80 years, was still decreased or absent compared to pre-stroke in 61.9% of men (n=63) and 52.5% of women (n=40) having mild or no neurological disability after 6 months[29]. ED has a better prognosis under age 65[33]</td>
</tr>
<tr>
<td>Parkinsonism</td>
<td>Both men[30] and women[30,31] with PD report sexual dissatisfaction more commonly than controls – the major determinants being age, severity of disease, and depression.</td>
<td>Caregiver partners (especially women partners) show an important degree of sexual dysfunction in several studies[32]</td>
</tr>
<tr>
<td>Epilepsy</td>
<td>Hyposexuality follows but does not predate the onset of epilepsy[5] and is more common in TLE. Men with localization-related epilepsy taking no AED’s have abnormally low sexual function[36]. Women with epilepsy have higher rates of disinterest and orgasmic dysfunction compared to controls[37].</td>
<td>Epilepsy has biological as well as psychological effects upon sexual well-being.</td>

</table>
Recently published rates of pituitary hypogonadism following head injury have shown a wide range of 1% to 22.7% [60, 61, 62, 64, 65] that varied according to laboratory methods, liberal interpretation of gonadotropin values, and the acceptance of low testosterone levels not always in accordance with those defined by the US Endocrine Society [68]. Two of the seven studies were uncontrolled, and none took account of sexual symptoms, so that diagnosis was solely on biochemical grounds.

Severe levels of pituitary growth hormone (GH) deficiency were at an incidence ranging from 2% to 25% [60, 61, 62, 64, 65, 69].

Trauma-induced hyperprolactinemia when severe produces hypoactive sexual interest and is associated with both elevated thyrotropin (TSH) and hypogonadism [70]. The commonest causes of hyperprolactinemia in men and women in the head-injured population, however, are antidepressants [71] and antipsychotics [72].

A consensus recommendation supports hormonal screening for pituitary injury at 3 months and at 12 months following severer brain trauma [73]. Acute-phase screening is only necessary if there is early diabetes insipidus to suggest an important degree of acute hypopituitarism. Regardless of whether there is trauma to the brain, temporary hypopituitarism can occur in any critical illness that requires intensive care especially in the presence of hypotension and hypoxemia.

KEY: AED = anti-epileptic drug. PGE1 = intracavernosal prostaglandin E-1. CBT = cognitive behavioural therapy. SSRI = selective serotonin reuptake inhibitor. GnRH = gonadotrophin releasing hormone. HHSD= Hypoactive Sexual Desire Disorder

Our recommendation is to identify and treat deficiencies of gonadotrophins [68] and GH as defined by the U.S. Endocrine Society. Grade C

2. SPINAL CORD/CAUDA EQUINA INJURY

Of the various neurological disorders under discussion, the highest rates of sexual dysfunction come from severe cauda equina lesions and spinal cord injuries - yet 86% of cord-injured patients retain their libido according to one cross-sectional study [74]. This is particularly disturbing as the prevalence of spinal cord injury is skewed towards younger people.

Reflex erections of the penis and reflex clitoral swelling and vaginal lubrication are lost in very low cord lesions involving S2, 3, 4 while psychogenic erections and psychogenic lubrication remain possible [75]. The hypothesis is that psychogenic erection and female genital congestion/lubrication are dependent upon the T12-L2 sympathetic outflow from the spinal cord above the medullary cone (Figure 2). Injuries to the medullary cone itself, or to the cauda equina, will interrupt the innervation of the genitalia and the pelvic floor by way of the autonomic and somatic nerve fibres leaving the lower end of spinal cord to then 'hitch-hike' in the S2, 3 and 4 nerve roots (Figure 2). In men and women with complete lower motor neuron dysfunction from these injuries, orgasms are generally lost [53, 76].
A complete loss of genital sensation together with loss of voluntary control of bladder and bowel, may compound severe traumatic lesions of the cauda equina brought about by spinal fracture below L1 or stenosis of the central canal below L1 occuring usually with massive central disc herniation. Depending on the segmental level of cord injury, more than one-third of men overall are able to self-ejaculate even with complete lesions [77]. The climactic experience of ejaculation seems related to blood pressure surge and other vascular parameters of autonomic dysreflexia (AD), the climax being pleasurable in mild to moderate AD but unpleasant or even painful with severe AD [52]. When penile vibrostimulation is added to regular sexual stimulation, some three-quarters of men with higher lesions can ejaculate.

Our specific recommendation is for the addition of alpha-adrenergic agonist midodrine as an adjunct to facilitate ejaculation in injuries at T10 and above: [51, 52], Grade C

Remarkably, women with complete lesions of the cord can still experience orgasm from cervical vibro-stimulation mediated, perhaps, through intact neural supply to the cervix travelling separately in the vagus nerve outside of the spinal neuraxis [53, 78].

It is suggested that neuroplasticity occurs over time post-injury in the ascending sensory pathways of the spinal cord [35] with the result that body areas such as the torso and shoulders can become highly arousing when stimulated under sexual circumstances - even in Asia A injuries (ie no sensation in the anal or genital areas and no motor function below the lesion level).

Our recommendation for SCI associated ED is for sildenafil to enhance reflex and psychogenic erections [47, 48], PGE1 to enhance reflex and psychogenic erections [5], for tadalafil to increase erectile and ejaculatory capacities at all spinal levels [49], and for vardenafil to increase orgasmic awareness and likelihood of ejaculation [50]: Grade A. Sildenafil may increase vaginal lubrication [53]: Grade C. Recommended also is baclofen, tizanidine, botox, and sclerosing agents to lessen spasticity interfering with sexual engagement: Grade C.

3. MULTIPLE SCLEROSIS

Lesions in the spinal cord more so than brain, have been implicated as the main cause of sexual dysfunctions in multiple sclerosis [79]. Dysfunctions increase with time since diagnosis and with disease burden (Table 3). Co-morbid incontinence, fatigue, and spasticity, contribute to sexual difficulties in both genders.

In a sample of 63 newly diagnosed women, Tzortzis [7] found that the most significant differences compared to controls were in the parameters of desire, satisfaction, and lubrication. Reduced sensation of the genital area was the only presenting symptom in 4 out of the 63 women with early MS all of whom were pre-menopausal; depression and other psychiatric or psychological disorders formed part of the exclusion criteria in both the study sample and the control sample [7].

We recommend using sildenafil for ED [44]: Grade A, or PGE1 [45]: Grade B.

Sildenafil may assist vaginal lubrication [46]: Grade C.

Recommended also is baclofen, tizanidine, botox, and sclerosing agents for spasticity: Grade C.

4. STROKE

Major stroke has special propensity to influence bodily positioning and movements during sex, compounded by spasticity, hemisensory neglect, and aesthetic considerations including loss of sphincter control. Lowering of cavernosal pressure by antihypertensive agents commonly received by stroke patients, adds further challenge.

In a study of 50 stroke patients (38 men, 12 women), 28% had ceased having sexual intercourse at 2 months and partner dissatisfaction was also high.
At 6 months, sexual activity was resumed by half of those patients [80]. Men under the age of 65 usually regain their erections within months of injury [33].

Of interest is that ischemic lesions in the right cerebellum and the left basal ganglia can be associated with a significant ejaculation disorder [81]. In Korpelainen's series of 192 stroke patients [82], 10% reported increased libido. Hypersexuality appears to be more prominent in lacunar strokes that affect the frontolimbic connections or the thalamic/subthalamic nuclei [4]. In a study from China, fear of recurrent stroke from sexual activity was noted in more than half of the patients [83] even though the risk of stroke from sexual excitement is said to be very low [84].

Recommended is sildenafil for ED: [5] Grade C and to treat hypersexuality with CBT, SSRIs, antiandrogens, GnRH agonists, and atypical antipsychotics: [5] Grade C

5. PARKINSON’S DISEASE

Of great interest is that in 32,616 healthy male participants in a U.S. study reporting erectile dysfunction in 1986, there was a four-fold higher risk of developing Parkinson’s Disease (PD) over the next 16 years of followup - to suggest that erectile difficulties can precede the onset of the classic motor features of Parkinsonism by a substantial margin [85].

Central dopaminergic mechanisms have a role both in initiation of sexual desire and induction of penile erection [86, 87] and are especially vulnerable to the depletion of dopamine within the basal ganglia in Parkinsonism. Autonomic failure (which is present in up to 90% of patients with PD) [88] also has the potential of impairing function by way of (a) parasympathetic cholinergic denervation to impede genital congestion, and (b) sympathetic noradrenergic denervation to inhibit orgasm and ejaculation [88, 89]. Whereas sympathetic neuropathy is mostly peripheral (ganglionic or post-ganglionic) in PD it is exclusively central (pre-ganglionic) in the variant MSA, Multiple System Atrophy [90].

Much interest has accrued concerning hypersexual behaviour in PD arising out of treatment with levodopa and more particularly dopamine agonists. Of 300 patients with Parkinson’s disease taking dopamine agonists such as the D3 agonists ropinirole and pramipexole, 25 had sexual compulsions and 28 had co-morbid or separate compulsive gambling of whom 17 met criteria for pathological gambling; men were over-represented [59]. In a Mayo Clinic database, where there was hypersexual behaviour, this developed within 8 months of starting dopamine agonist therapy in the majority of cases [57]. When considering these reward-seeking behaviours, it is of note that positron emission tomography scans of healthy volunteers during orgasm and ejaculation show strong activation in the dopamine-rich mesiodiencephalic and ventral tegmental areas [91]. These areas are also activated during the orgasm-like ‘rush’ experienced by heroin addicts.

It is ironic that hypersexuality in Parkinsonism should be so predominantly iatrogenic. The combination of greatly enhanced sexual drive with disrupted genital function can be highly problematic in partner relationships in the home or in a nursing home environment. Sexual compulsions can completely resolve after stopping the agonist, despite continued levodopa therapy [57].

For ED, we recommend sildenafil [92] using caution re orthostatic hypotension: Grade A; or apomorphine [93]: Grade B.

Deep brain stimulation can improve sexuality in men only [56]: Grade C.

For hypersexuality, discontinue dopamine agonist and continue levodopa. If necessary, add quetiapine and not risperidone, olanzepine, haloperidol or other dopamine antagonist [5, 57, 58, 59].

6. EPILEPSY

Of neurological disorders, epilepsy is unique in its ability to provoke - during a seizure - involuntary sexual gestures. This occurs when the seizure is of focal onset in the mesolimbic temporal structures or (less commonly) the area of the interhemispheric parietal cortex subserving genital sensation [94]. An erotic aura can precede an attack. Genital automatisms during a partial seizure can take the form of self-fondling or scratching of the genitals, masturbatory movements, or pelvic thrusting [95]. Because amnesia usually accompanies such automatisms, their frequency is probably under-reported: automatic sexual gestures were recorded in 11% of more than 200 selected patients who underwent video-electroencephalography for medically refractory seizures [95]. Profound hyposexuality has been noted in women who have reflex orgasms with their seizures.

Older-style anti-epileptic drugs (AED’s) such as phenytoin, barbiturates, and carbamazepine (but not oxcarbazepine) are inducers of the hepatic P450 enzyme system. This in turn causes increase in levels of SHBG with subsequent hyposexuality either with [36] or without [96] a reduction in levels of free bio-available testosterone. The deleterious effect of these older AED’s upon sexuality is affirmed in men but not in women [96].

The P450 enzyme-inhibiting AED valproic acid, has some propensity to increase serum androgen levels and also estradiol levels in both sexes [97, 98, 99] but with the risk of an increased incidence of infertility due to polycystic ovary syndrome in women of childbearing age [99].
Theoretically, enzyme-neutral AED’s are less likely to cause sexual side effects. These include oxcarbazepine, gabapentin, pregabalin, levetiracetam, and lamotrigine.

There is limited evidence that lamotrigine has the lowest profile of sexual side effects [36, 40]. Carbamazepine in men, and gabapentin [100] and topiramate [101] in both sexes, may cause reversible anorgasmia due to uncertain mechanisms [102].

We recommend men with epilepsy having phenytoin or carbamazepine-induced hypogonadism to switch to a P450 enzyme-inhibiting or an enzyme-neutral anti-epileptic drug [36]: Grade C. For hypogonadal men unable to discontinue phenytoin or carbamazepine, treat with testosterone [41]: Grade B.

When valproic acid causes unwanted weight gain or symptoms of polycystic ovary syndrome, use an enzyme-neutral AED [99]: Grade C.

That lamotrigine lacks sexual side effects, remains unclear: Grade D.

Anterior temporal lobectomy may eliminate epileptic sexual automatisms [43]: Grade C.

B. END STAGE RENAL DISEASE (ESRD)

I. INTRODUCTION

Sexual dysfunctions are frequent in men and women with end-stage renal disease (ESRD) and their etiology is multi-factorial given the complex pathophysiology of chronic renal failure: co-morbid diabetes, hypertension, coronary artery disease and peripheral vascular disease are common. Sexual dysfunction increases as renal function deteriorates [103] such that the former is apparent well before renal replacement therapy is necessary, i.e. ESRD where usually <10% of kidney function remains [103]. Furthermore, dialysis and even transplantation may not improve sexual function [104,105]. Sexual dysfunction in men appears to have the same prevalence whether dialysis is peritoneal (PD) or hemodialysis (HD) [3] but may be more common with the latter in women [106,107].

1. HIGH BURDEN OF PHYSICAL SYMPTOMS

Patients’ sexual dysfunction must be understood in the context of multiple symptoms. As the estimated glomerular filtration rate (eGFR) reduces to below about 15 mL/min/1.73m² multiple symptoms commonly ensue including bone and joint pain from renal osteodystrophy, fatigue, anorexia, nausea, stomatitis, and an unpleasant taste in the mouth. Pruritus is common and malnutrition and generalized wasting can occur. Medical complications such as pericarditis, GI bleeding and cardiac complications may follow. Moreover, the underlying pathology of the ESRD may contribute to symptoms, for example the pain of diabetic neuropathy. Symptom burden may preclude motivation to seek treatment for sexual dysfunction: in one study of men with ESRD on PD of those who had ED only 50% were willing to enter a trial of Sildenafil [108] and only a minority actually completed the study. Even after transplantation, studying 161 men, only 78 of the 126 with ED were interested in treatment [109].

2. HIGH PREVALENCE OF COMORBID DEPRESSION

Depression is independently associated with sexual dysfunction in men [110] and women [19] and is frequently undiagnosed or undertreated [111]. Self image, known to be highly correlated with sexual function especially in women is vulnerable: physical changes including altered skin color and presence of AV fistula or PD catheter, muscle wasting and dependence on dialysis may all have negative impact. Frequently compounding depression is discord within the sexual relationship from the multiple stressors [103].

II. PREVALENCE AND PATHOPHYSIOLOGY OF SEXUAL DYSFUNCTIONS IN ESRD

Prevalence and pathophysiology of dysfunctions in men and women with uremia, receiving HD and PD are given in tables 5 and 6.

III. ASSESSMENT

In addition to the detailed assessment of dysfunction, (see previous pages) certain medical parameters need specific review including the adequacy of the dialysis regime to minimize the deleterious effect of uremia on nerve function and reduce the progression of vascular disease. Blood pressure and signs of autonomic neuropathy are reviewed and lipids, blood glucose, hemoglobin, testosterone and prolactin measured—all of these potentially impacting on sexual function. Levels of estradiol, LH and FSH may be indicated: amenorrhea, anovulation, a hypoestrogen state despite menstruation or premature menopause are all common. Mood, stress levels and fatigue are assessed along with pain and pruritis management—all of these modulating sexual desire and motivation, see tables 1 and 2.

IV. TREATMENT

Treatment modalities that have been shown to have benefit are shown in tables 1 and 2. Women have received minimal study.
Table 5: Pathophysiological Mechanisms Involved In Dysfunction Associated With End Stage Renal Disease In Men And Therapy Options.

1. ERYTHROPOIETIN

Recombinant human erythropoietin (EPO) has been shown to benefit sexual desire and erectile function in some but not all men [114, 115, 116]. Women’s sexual function improves [141] but is minimally studied.

2. SILDENAFIL DURING DIALYSIS

The reported response to sildenafil for ED is from 33-80% [108, 123, 142, 143]. Clearance of the drug is decreased in renal failure, but for men receiving dialysis the pharmacokinetics resemble those of normal volunteers [144].

3. SLOW NOCTURNAL HEMODIALYSIS

There is some evidence of benefit for ED from nightly at home hemodialysis [145].

4. RENAL TRANSPLANTATION

a) Renal transplantation in men

Renal transplantation may or may not reverse ED with studies showing response rates of 32-81% [104, 105, 109, 120, 127, 146, 147]. Higher response rates may be associated with shorter duration of dialysis [105]. Transplantation may not improve testicular function. Possibly elevated FSH levels suggest testicular function will not return [148]. Prolactin levels do reduce after transplantation: sexual desire although minimally studied may increase [149].

b) Renal transplantation in women

Return of menses, fertility and successful pregnancy may occur with transplantation. Of 48 women, of whom 27 were post transplant, desire and arousal disorders were significantly lower than in the dialyzed women as was dyspareunia. However, when those willing to measure increase in genital congestion with VPP (7 out of 21 dialyzed women and 20 out of 27 transplanted women), no differences were seen [107]. Although minimally studied desire may improve [149].

5. SILDENAFIL FOR ERECTILE DYSFUNCTION POST TRANSPLANT

Sildenafil post transplant has been seen to be effective and safe [127, 147]. A useful increase in GFR has been seen in kidney transplant recipients after the use of sildenafil [150].

V. FUTURE RESEARCH

Further investigation of sexual benefit to women from EPO is needed along with study of benefit to both genders from slow nightly dialysis.
VI. RECOMMENDATIONS

Recombinant EPO therapy is guided by hemoglobin level. However, its use improves ED and low desire in men and women [132]: Grade C.

Sildenafil is of benefit for ED during hemodialysis and peritoneal dialysis [123]: Grade B. Transplantation may improve ED 105]: Grade C.

Sildenafil is effective for ED post-transplant [105, 127]: Grade B.

Transplantation may improve sexual desire in men and women [148]: Grade C.

C. PELVIC DISEASE NON MALIGNANT

I. HYSTERECTOMY FOR BENIGN CONDITIONS

When hysterectomy is performed for benign conditions the concerns for post operative quality of life and sexual functioning are paramount. Some women will report increased sexual satisfaction and pleasure following hysterectomy due to improved dyspareunia, dysmenorrhea or menorrhagia. [151, 152]. Studies examining sexual function and hysterectomy are often heterogeneous, complex and inconsistent, fraught with methodological errors, confounders and a lack of standardized instruments. Retrospective design and limited sample size often hinder global interpretation of medical data. However, the method of hysterectomy (abdominal, laproscopically assisted or vaginal, subtotal or total) has been studied and no differences between groups have been documented. Sexual satisfaction improved in a majority after surgery irrespective of surgical approach [153,154]. Of note simple hysterectomy does not damage the autonomic nerves subserving genital vasocongestion that traverse the lateral portions of the uterosacral and cardinal ligaments [155].

II. LOWER URINARY TRACT SYMPTOMS IN WOMEN

1. INTRODUCTION

A number of syndromes give rise to lower urinary tract symptoms (LUTS) in women. The symptom spectrum consists of storage symptoms (frequency, urgency, nocturia and urinary incontinence), voiding symptoms (slow stream, splitting or spraying, intermittent stream, hesitancy, straining and terminal dribble), and post micturition symptoms (feeling of incomplete emptying and post micturition dribble) [156]. The urinary urgency with frequency and nocturia (with or without urge incontinence) is defined as overactive bladder (OAB) syndrome [156]. Urinary urgency, frequency, nocturia, pelvic pain and dyspareunia in the absence of bacterial infection or other definable pathology are characterized as symptoms of interstitial cystitis/ painful bladder syndrome (IC/PBS) [157, 158]. Emerging epidemiologic evidences have shown that LUTS is linked to female sexual dysfunction (FSD), but the pathophysiology of this relationship is poorly understood. Clinical therapies, particularly surgical therapy for certain types of LUTS (such as urinary incontinence) and the causes of LUTS (such as pelvic prolapse) can either positively or negatively affect sexual function.

2. PREVALENCE AND RELATIONSHIP OF LUTS AND FSD

a) Epidemiology studies for LUTS

The prevalence of LUTS in women was studied with the use of the International Prostate Symptom Scores (IPSS)/American Urological Association Symptom Scores (AUASS) designed for both genders. IPSS/AUASS of 8 or greater were used as the definition of LUTS (Table 7). There was no significant culture variation or difference between racial/ethnic groups in the prevalence of LUTS.

N/A: no information for control. *: OR (odds ratio) varies by the type of LUTS. FSFI: Female Sexual Function Index (data with significant difference are included).

b) Association of LUTS and FSD

Epidemiological studies suggest an association of LUTS with FSD, but well designed population study is lacking in part to the complexity of FSD and the wide spectrum of LUTS. It is suggested that all women with FSD should be screened for the presence of bladder dysfunction regardless of age [161]. Studies regarding the risk or the severity of FSD in patients with LUTS are summarized in Table 8.

3. PATHOPHYSIOLOGY

The pathophysiology of FSD associated with LUTS is poorly understood. Both the anatomical proximity of the bladder and urethra to the vaginal canal and the shared spinal reflexes that are under descending control from higher centers may be relevant [168]. However, LUTS in women may also have a much more complex psychological impact relevant to FSD. The possible mechanisms involving in the development of LUTS and FSD are summarized in Table 9.

4. TREATMENT CONSIDERATIONS

a) Pharmacotherapy

Pharmacotherapy including anticholinergic oxybutynin, tolterodine, trospium chloride, solifenacin and darifenacin [181] is the mainstay of therapy for LUTS and the treatment of choice for OAB. However, there are very few publications regarding this class of medications on female sexual function (table 10).

b) Pelvic floor muscle training

Pelvic floor muscle (PFM) training has been shown to be effective in the treatment of genuine stress incontinence by multiple randomized controlled trials [174]. The PFM training for LUTS with electrical stimulation, biofeedback and/or Kegal exercises also appears to improve female sexual function (table 11).

c) Sacral neuromodulation implant

Sacral neuromodulation (SNM) has become an established treatment option for LUTS. Some benefits of SNM on sexual function were also observed recently in a very small study [185], but the mechanism by which SNM improves sexual function is unknown.

d) Impact of Urogynaecological operations for LUTS on sexual function

Available data show conflicting effects of urogynaecological surgeries for LUTS on female sexual function with improvement, no change or worsening reported after surgeries [180]. Improvements in sexual function following vaginal surgery may follow improved continence during sexual activity whereas the etiology of worsening sexual function is more complicated involving organic and psychological factors [179].
Table 9: Pathophysiology associated with FSD and LUTS [162, 168, 169, 170, 171, 172, 173, 174, 175, 176, 177, 178, 179]

<table>
<thead>
<tr>
<th>Pathophysiology</th>
<th>Rationale</th>
<th>Comment</th>
</tr>
</thead>
<tbody>
<tr>
<td>Embryological and neurological relationship</td>
<td>(1) The urinary and reproductive systems are embryologically related and share common nerve pathways[168, 169].</td>
<td>LUTS are also common symptoms for patients with IC/PBS. Mechanical irritation of the urethra and/or bladder during intercourse may also cause dyspareunia in patients with IC/PBS and exacerbate their LUTS[171].</td>
</tr>
<tr>
<td></td>
<td>(2) Pelvic autonomic nerves innervating the vagina, urethra and bladder are critical for normal sexual function and urinary continence: the anterior and lateral vaginal walls are most densely innervated by neuronal nitric oxide synthase immunoreactive nerves involved in sexual function[170]. LOE: IV</td>
<td></td>
</tr>
<tr>
<td>Changes of pelvic floor muscle tension</td>
<td>Pelvic floor muscles are important in maintaining urinary continence and also play a critical role in female sexual function. Chronic increase of muscle tension may be associated with vaginismus and dyspareunia[172, 173]. LOE: IV</td>
<td>No evidence is available to link the degree of pelvic muscle tension to FSD. Pelvic floor muscle training improves urinary continence and sexual function in women with urinary stress incontinence[174, 175].</td>
</tr>
<tr>
<td>Decreased blood flow</td>
<td>Bladder wall resistance to bacteria seems to partially depend upon the amount of local parietal blood flow. Decreased local blood flow is suggested in patients with LUTS due to bacterial cystitis[162]. LOE: IV</td>
<td>Blood flow increase to the vagina and uterus leads to increased secretion which lubricates the vagina. The transudation of plasma from engorged vessels in the vaginal wall also contributes to the vaginal lubrication.</td>
</tr>
<tr>
<td>Hormonal change</td>
<td>(1) Estrogen plays a major role in regulating female sexual function and nitric oxide synthesis in the vagina and clitoris[172]</td>
<td>Estrogen is important in maintaining the integrity of vaginal and urethral mucosal epithelium and promotes vaginal lubrication. Estrogen cream is empirically used for atrophic urethritis associated LUTS but currently, there is no clear role for estrogen in improving LUTS[176].</td>
</tr>
<tr>
<td></td>
<td>(2) Lower levels of estrogen in the urogenital tract suggests a relationship to FSD and LUTS as they are more prevalent in menopausal women[162].</td>
<td></td>
</tr>
<tr>
<td></td>
<td>(3) Estrogen therapy improves vaginal lubrication in postmenopausal women[177, 178]. LOE: IV</td>
<td></td>
</tr>
<tr>
<td>Psychological distress</td>
<td>The distress from chronic urinary symptoms may lead to sexual difficulty. Psychological distress may predispose to both sexual dysfunction and to LUTS[179, 180]. LOE: IV</td>
<td>Fear of urinary leakage during penetration or at orgasm, dyspareunia due to urine dermatitis, lowered self esteem may all play a significant role.</td>
</tr>

1. SURGERY FOR UI

The variable effects on sexual function after suburethral slings are shown in Table 12.

2. SURGERY FOR PROLAPSE

Pelvic organ prolapse affects many women worldwide and is commonly associated with LUTS [192]. The effect of reconstruction surgery for prolapse on sexual function is controversial as shown in Table 13.

PISQ: Pelvic Organ Prolapse/urinary incontinence sexual function Questionnaire
5. PREVENTION
There is no publication to evaluate any prevention strategy for LUTS associated sexual dysfunction. Educating women about the anatomical relationship of urinary and sexual organs may encourage compliance with pelvic floor exercise. Studies are needed to address psychological aspects of LUTS and effects on sexuality.

6. CONCLUSION
Epidemiology studies suggest an association of LUTS with FSD. However, well designed population studies with validated questionnaires to look at this association are needed given the complexity of FSD and the wide spectrum of LUTS. The pathophysiology of LUTS associated FSD is poorly understood and research is greatly needed. Limited publications suggest that non-surgical treatment for LUTS appears to benefit sexual function. However, current urogynecologic pelvic surgeries for LUTS can improve, worsen or have no effect on female sexual function. All patients should be well informed regarding this conflicting information before their surgical procedures. Currently, there is no publication available to recommend any prevention strategy for LUTS associated FSD. Through better understanding of their pathophysiology, prevention of both conditions may be possible.

7. RECOMMENDATIONS WITH GRADES
There is no publication available to recommend any prevention strategy for LUTS associated female sexual dysfunction: Grade C.
Non-surgical treatment for female LUTS appears to benefit sexual function [182, 183, 174, 175, 184]: Grade C.
Current urogynecological pelvic surgeries for LUTS can improve, worsen or have no effect on female sexual function: Grade C.

III. LOWER URINARY TRACT SYMPTOMS IN MEN
1. INTRODUCTION
Male lower urinary tract symptoms (LUTS) and sexual dysfunction are conditions encountered on a daily basis in urology practice. There is an increasing focus on the study of the relationship between LUTS and sexual dysfunction, both conditions increasing with advancing age. Considerable epidemiologic and clinical research has shown that LUTS and sexual dysfunction are strongly linked and investigation continues into the etiology of both, with particular attention to common pathways. Current clinical research focuses on the overlap and interactions of therapies for these conditions.

2. PREVALENCE AND RELATIONSHIP OF LUTS AND SEXUAL DYSFUNCTION

a) Epidemiology studies for LUTS
Lower urinary tract symptoms in men are mainly the manifestation of benign prostatic hyperplasia (BPH), bladder outlet dysfunction and the underlying bladder storage dysfunction. Although BPH can lead to complaints of LUTS, not all patients with BPH develop the symptoms (table 14) [196]. Similarly not all patients presenting with LUTS have objective evidence of BPH.

b) Association of LUTS and sexual dysfunction
Epidemiologic data cannot establish causality between LUTS and sexual dysfunction, but they can and do demonstrate reproducible association between the two conditions. At the present time, most studies are focused on the association of LUTS and ED (table 15).
Ejaculatory dysfunction (EjD) was also related to LUTS severity (table 16).
LUTS is also a risk factor for low sexual drive (OR of 1.37) [159]. It is clear that the presence of LUTS and the severity of LUTS are closely linked to the presence and the severity of sexual dysfunction.

3. PATHOPHYSIOLOGY
Even though the underlying cause has not been established, a bi-directional relationship between LUTS and ED suggests a common underlying pathophysiology or etiology. Research has identified several possible pathways and their links through which LUTS and ED develop (table 20). Metabolic syndrome and atherosclerosis may induce
autonomic nervous system hyperactivity in the lower urinary tract, prostate and penis with the changes of adrenergic receptors sensitivity and density, increase Rho-kinase and ET1 activity, reduce NOS expression and eventually cause LUTS and ED. In addition to common risk factors, it is thought that the psychological impact of LUTS on quality of life may also alter a patient’s erectile function[206].

4. TREATMENT CONSIDERATIONS

Current treatment modalities for LUTS can have negative or positive effect on erectile function, while emerging evidence shows that medical treatment of ED has positive impact on LUTS.

a) Effect of medications used to treat LUTS on ED

Medications for LUTS include traditional therapy (α-adrenergic receptor antagonists and 5-α reductase inhibitors) and novel therapy (antimuscarinics and PDE5 inhibitors)[226]. Table 18 summarizes their effect on sexual function. Investigational therapy for LUTS (luteinizing hormone releasing antagonists, β3-adrenergic receptor agonists and Vitamin D3 agonist) will not be discussed.

b) Effect of Medications used to treat ED on LUTS: Phosphodiesterase-5 inhibitors

At the present time, the data from three large, multicenter, randomized, placebo controlled trials are available[242, 243, 244] (Table 19). These sets of preliminary evidence open many avenues for further investigation into the benefits of PDE-5 inhibitors on LUTS.

c) Effect of combined treatment with PDE-5 inhibitors and medications for LUTS

The greatest improvement of erectile function in recent pilot studies in patients with LUTS was found with the combination of α-adrenergic receptor antagonists and PDE-5 inhibitors (Table 20). Cardiovascular effect is a concern with using PDE-5 inhibitors in conjunction with α-adrenergic receptor antagonists[226, 245, 246]. In men who have been on long-term therapy with α-adrenergic receptor antagonists, the effect of PDE-5 inhibitors on blood pressure may be less significant[247, 248].

d) Effect of Surgery for BPH on Erectile Function

### Table 17: Common Pathophysiology for ED and LUTS.

<table>
<thead>
<tr>
<th>Pathophysiology</th>
<th>Evidence</th>
<th>Comment</th>
</tr>
</thead>
<tbody>
<tr>
<td>Metabolic syndrome/autonomic hyperactivity</td>
<td>(1) Metabolic syndrome may affect autonomic nervous system activity. Increased autonomic nervous system activity can induce BPH and ED in rats[207]. Spontaneous hypertensive rats revealed autonomic hyperactivity, prostatic hyperplasia with ED, increased voiding frequency and detrusor overactivity[208]. Clinical study showed significant association of sympathetic tone with the severity of LUTS that may co-exist with ED[209]. LOE: III. Noradrenaline and α&lt;sub&gt;1&lt;/sub&gt;-adrenergic receptors in the sympathetic nervous system mediate adrenergic contraction of smooth muscles in the prostate, bladder neck, urethra and the corpus cavernosum, therefore, constituting the common link.</td>
<td></td>
</tr>
<tr>
<td>Imbalance in α-adrenergic receptor regulation</td>
<td>(1) Various subtypes of α-1 adrenergic receptors have been studied and identified in the bladder, prostate, and penile tissue[196]. With age, glandular proliferation occurs and the density of α-adrenoceptors increases. α&lt;sub&gt;1a&lt;/sub&gt; receptors concentrated in prostate and bladder neck are involved in voiding problems and α&lt;sub&gt;1d&lt;/sub&gt; receptors found in hypertrophied detrusor muscles are involved in storage problems[210]. LOE: N/A (basic research).</td>
<td>Adrenergic receptors mediate smooth muscle tone. Aberrant smooth muscle contraction may be a common cause of both LUTS and ED.</td>
</tr>
<tr>
<td>Increased Rho-kinase activity</td>
<td>(1) Increased RhoA/Rho-kinase signaling is involved in the development of ED with aging in rats[211]. Inhibition of Rho-kinase in the rat model has been shown to decrease prostatic smooth muscle cell proliferation and to decrease adrenergic contractions[212]. Rho-kinase inhibitor, fasudil, can prevent atherosclerosis, endothelial injury, and ED in rats[213]. LOE: N/A (basic research).</td>
<td>Rho-kinase activation leads to increased smooth muscle contraction by modifying the sensitivity of contractile and regulatory proteins to intracellular calcium, which in turn contributes to impaired erectile function and changes in bladder outlet tone[214].</td>
</tr>
<tr>
<td>Endothelin-1 activation</td>
<td>(1) Endothelin-1 (ET-1) is a potent vasoconstrictor and acts by stimulating ET type a (ETα) and b (ETβ) receptors. ETα is the predominant receptor in the smooth muscle cells of the corpus cavernosum, prostate and bladder[215, 216]. ET-1 has been suggested to be an important regulator for ED associated with other ED risk factors, such as diabetes[217]. LOE: N/A (basic research).</td>
<td>Studies are needed to look at the direct link of ET-1 activity in the presence of LUTS associated ED.</td>
</tr>
<tr>
<td>Nitric Oxide (NO)/phosphod-esterase (PDE) theory</td>
<td>(1) NO/PDE pathway is well known in the regulation of the corpus cavernosum smooth muscle tone[218]. Nitrergic oxide synthase (NOS) gene expression is reduced with age in rat prostate tissue and may be a factor in the increased smooth muscle tone associated with LUTS[219]. PDE-5 signaling is involved in bladder smooth muscle tone and prostatic stromal proliferation in rat[220]. The most abundant PDE isoforms in the prostate are PDE 4 and 5[221]. LOE: N/A (basic research).</td>
<td>NO/PDE theory gives the most logical explanation to link LUTS to sexual dysfunction. Reduced NOS/NO is related to ED and may also cause structural changes in the prostate and increase contraction affecting outlet resistance and bladder compliance, leading to LUTS.</td>
</tr>
<tr>
<td>Atherosclerotic changes</td>
<td>(1) Similar smooth muscle atrophy and fibrosis of the detrusor and corpora with production of transforming growth factor (TGF-β1), and stromal fibrosis, glandular cystic atrophy with increases of smooth muscle contractility of the prostate are observed in animal models with pelvic ischemia and hypercholesterolemia[222, 223, 224].</td>
<td>Atherosclerosis causes chronic ischemia and hypoxia to pelvic organs, including the bladder, prostate and penis that may contribute to the pathogenesis of both LUTS and ED.</td>
</tr>
<tr>
<td></td>
<td>(2) (1) An analysis of 1,724 men with more than one major vascular risk factor had significant increased IPSS suggesting an impact of predisposing factors of atherosclerosis on the bladder and lower urinary tract[225]. LOE: III.</td>
<td></td>
</tr>

Δ: Change of scores
C: placebo group
T: treatment group
Surgical therapy remains the most effective modality in improving LUTS [251]. The risk of ED after transurethral resection of the prostate (TURP), holmium laser enucleating of the prostate (HoLEP) and open prostatectomy (oP) is approximately 10% [227, 252, 253]. However, there is a report of marginal improvement of erectile function after TURP or HoLEP [253]. The risk of EjD after TURP, HoLEP and OP is over 60% [254, 253]. The risk of ED after transurethral microwave thermotherapy or Transurethral needle ablation was less than the risk associated with TURP [227].

e) Effect of parenteral therapies for ED on LUTS

There is no evidence to show vacuum erectile device, intracavernosal injection and penile vascular surgery for ED have effect on LUTS. It is well known that intraurethral use of alprostadil can cause urethral pain in some patients. A side benefit of penile prosthesis implantation for ED has been improved urinary control for some patients with mild stress incontinence, but there has been no prospective study.

5. PREVENTION

No publication is available to evaluate any prevention strategy for LUTS associated sexual dysfunction. However, targeting the pathological conditions underlying LUTS and sexual dysfunction through dietary and lifestyle modifications or therapies may prevent or decrease both sexual dysfunction and LUTS. Specifically, decreasing the risk factors for metabolic syndrome and atherosclerosis may reduce the suspected autonomic nervous system hyperactivity in lower urinary tract, prostate and penis.

6. CONCLUSION

Compelling evidence has established an association of LUTS with male sexual dysfunction. Many theories on the pathophysiology of these two conditions have been proposed and their testing may lead to novel and integrated treatments. For now, available treatments are proving to be beneficial in ways not previously known or studied. As research continues, both conditions may prove preventable.

7. RECOMMENDATIONS

Alpha adrenergic receptor antagonists do not have a negative effect on erectile function. Tamsulosin does cause significant ejaculation dysfunction [235]: Grade B.

5-α-reductase inhibitors for LUTS are associated with adverse effects on sexual function in the first two years of treatment [236, 237, 238, 239, 240]: Grade A.

PDE5 inhibitors have significant and clinically relevant effect to improve LUTS [242, 243, 244]: Grade A.

Future studies are needed to target the pathogenesis pathways of LUTS associated ED to identify novel pharmacotherapy: Grade C.

D. CANCER IN MEN

I. PROSTATE

1. WATCHFUL WAITING

a) Introduction

The diagnosis of prostate cancer has increased dramatically following widespread introduction of prostate-specific antigen (PSA) testing [255]. However, prostate cancer treatment continues to be a controversial topic given the heterogeneous clinical presentation among the diverse patient population, the protracted natural history of the disease and the real risk of treatment related side effects [256]. The risk of over diagnosis and overtreatment poses a tremendous clinical and ethical dilemma [257]. Recent systematic review concluded that assessment of the comparative effectiveness and harms of localized prostate cancer treatments was difficult due to the limitations of the evidence [255]. Nevertheless, watchful waiting (WW) is still a viable treatment option for clinically localized disease with low grade and low volume of prostate cancer, particularly for older patients with a life expectancy of less than 10 years. One of the major considerations for WW is to preserve or maintain the patients’ quality of life (QoL) including their sexual function. However, very few randomized, controlled trials are available.

</tbody>
</table>

De Rose et al [249]

Kaplan et al [250]
to compare the QoL and sexual function for men who select WW, to age and cofactor matched men without prostate cancer, and to men with prostate cancer who received active treatment.

b) Sexual dysfunction in patients on WW

1. Sexual function in patients on WW versus in general population

No study has specifically compared sexual function in men with prostate cancer on WW to age and cofactor matched men without prostate cancer. However, limited publications suggest that men on WW for prostate cancer have increased risk for sexual dysfunction compared to men without prostate cancer (table 21).

2. Sexual dysfunction on WW versus other treatment groups

The recent comparison studies of WW to active treatment modalities on sexual function with relatively large numbers of patients are summarized in table 22. It appears that WW has less impact on sexual function compared with active treatment modalities.

c) Pathophysiology

There are no publications exploring the specific mechanism of sexual dysfunction in patients on WW for prostate cancer. Patients with prostate cancer on WW should have the same risk factors (such as cardiovascular diseases, metabolic syndromes) for developing sexual dysfunction when compared to age matched men in the general population. However, patients on WW may have psychological distress due to the uncertainty regarding the disease course and the possibility of regret for not receiving curative treatment [265]. This distress may be associated with increased sexual dysfunction. Patients on WW for prostate cancer also have worse LUTS (mostly obstructive symptoms) compared to patients after RP [261]. It is well known that LUTS is associated with male sexual dysfunction [266].

d) Treatment considerations

Treatment of sexual dysfunction for patients on WW for prostate cancer is the same as the treatment for patients without prostate cancer. This includes oral medications, vacuum erectile devices, transurethral use or intracavernosal injection of vasodilators, and surgical implantation of prosthesis for ED. However, particular attention should be given to counseling patients about the nature and history of prostate cancer to ease the psychological stress that may affect their sexual function. Also, identification and treatment of LUTS is needed in these patients.

e) Prevention

There is no publication discussing prevention strategy. Educating men about common risk factors for sexual dysfunction, counseling patients about the disease course of the prostate cancer and early treatment of any LUTS should be considered as the prevention modality at the present time.

f) Conclusion

Data are limited on sexual function in men on WW for prostate cancer as compared to men without prostate cancer. Most studies support that WW has less impact on sexual function compared to active treatment. Management of sexual dysfunction includes addressing the psychological distress associated with knowing the diagnoses as well as standard medical options. Included also is treatment of any associated LUTS.

g) Recommendations

Watchful waiting has less impact on sexual function compared to active treatment modalities [258, 259, 261, 263]: Grade C.

Treatment of sexual dysfunction for patients on watchful waiting should be the same as the treatment for patients without prostate cancer: Grade C.

2. RADICAL PROSTATECTOMY

a) Introduction

Different options are available for treating localized prostate cancer, with disease-free survival rates nearly equivalent, hence current major efforts to optimize treatment outcomes are aimed to reduce the morbidity of these procedures [267].

Today the majority of men usually achieve resumption of all physical activities, recovery of urinary control and normalization of bowel function within a few months of surgery. However, ED confronts all men as a long-term and sometimes permanent complication following this treatment even when maximal cavernous nerve sparing techniques are applied. Sexual function, an important aspect of quality of life [268], is reportedly more commonly influenced after prostate cancer therapy than other domains of health related quality of life [269, 270, 271].

b) Radical prostatectomy (RP): the gold standard for the treatment of localized prostate cancer

Radical perineal prostatectomy, first described by Young in 1905 for early (localized) prostate cancer was the standard of care until 1945 when Terrence Millin described the radical retropubic prostatectomy [272]. Surgery initially was associated with significant blood loss, incontinence, ED, and prolonged convalescence [273]. Breakthrough modifications to the surgical technique [274] have decreased the complication rate of total and stress-induced incontinence to less than 10% and significantly reduced ED without compromising oncological principles, leading radical prostatectomy to become the gold standard treatment for organ confined prostate cancer for several decades [275, 276, 277, 278]. However the above mentioned postoperative

RP: radical prostatectomy; XRT: radiation therapy; HA: hormonal ablation; WW: watchful waiting
complications may encourage choosing alternative treatments such as brachytherapy or external beam radiotherapy. Other additional anatomic, technologic and pharmacologic advances to minimize morbidity have been developed [273]. Within the past decade a major development has been the introduction of laparoscopic radical prostatectomy (LRP) and robotic-assisted laparoscopic radical prostatectomy (RALRP) [279,280].

c) Better diagnostic tools increase the prevalence of early diagnosed cases, impacting both the choice and goals of treatment

Until recently ED following radical prostatectomy was not an overwhelming concern, as most prostate cancers were detected in older men [281]. However, since the advent of PSA screening in the late 1980s, more young patients are being detected at an earlier stage, making both cure and quality of life important issues. There is some research on how patients trade preservation of urinary continence, bowel and sexual function versus more certain cure when given a choice in treatment modality [282, 283, 284]. Sexual function outcome following prostate cancer surgery is now considered a major issue.

d) Pathophysiology of post-RP Erectile Dysfunction (pRPED) and factors contributing to erectile function recovery

1. PATHOPHYSIOLOGY

Despite major advances in the understanding of mechanisms involved in pRPED (see chapter 20 for a comprehensive review on this topic), to quote the first step of this ladder is of justice: “The etiology of "impotence" after radical prostatectomy is unclear, although a variety of potential factors have been cited: neurogenic, psychogenic and possible vascular” [274, 277]; this is a literal quotation from the paper by Walsh and Donker, where they conclude: “Based on the findings in this study it is unlikely that potency can be maintained in men with locally extensive disease with capsular penetration. Rather the principles outlined seem to be more applicable to patients undergoing prostatectomy at the time of cystectomy or to patients with organ-confined prostate cancer. Recognizing that radical prostatectomy is more effective than external beam radiotherapy in the management of localized prostate cancer [285], it is incumbent upon urologists to perfect surgical techniques so that fears about the morbidity of the procedure do not discourage patients and physicians from selecting the optimal form of treatment. In this study 60 percent of the patients who were < 60 years old and who had tumor microscopically confined to the prostate were potent postoperatively. With further refinements in surgical techniques it may be possible to improve this record. If so, fears about impotence may be dispelled and physicians may take a greater interest in diagnosing prostatic cancer in young men at an early stage when it is still curable”. This statement written in 1982 was foresight indeed.

2. FACTORS AFFECTING ERECTILE FUNCTION RECOVERY

Although the main and well accepted pathophysiological issue is the neurological damage, the inconsistency between a “good surgical preservation procedure” and the “functional outcome” lead investigators to look at the basics, and consequently there are emerging points to be considered. Nowadays, the role of Accessory Pudendal Arteries (APA) [286] is under debate as a major precipitator of cavernous hypoxia in those patients in whom the cavernous nerves has been preserved. The cascade of events ending in cavernous fibrosis can start not only as a consequence of neural but of vascular damage as well. This point must be considered when a preservation procedure is undertaken. Besides these considerations, the following issues should be taken into account, when expecting/aiming erectile function (EF) recovery:

i) EF recovery is influenced by many factors [287, 288, 289] including:

a) Preoperative erectile function [290, 291]

b) Age and comorbidities [268]

c) Preservation of the neurovascular bundles [292, 291, 268]

1. Surgical technique of excellence does not refer necessarily to surgical approach, i.e.: open versus laparoscopic or robot-assisted, but to refinement on the procedure itself which is related to the surgeon’s experience (volume) [293].

3. INCIDENCE AND PREVALENCE OF ED ACROSS DIFFERENT SURGICAL TECHNIQUES

The current dilemma about the ED rate following RP is due to wide variation in the potency rates reported in the literature. Almost all the reviews conclude that the data are of limited value due to the lack of standardized variables in the available studies. The variables include: number of nerve-sparing procedures, single versus multi-surgeons series, volume of procedures, potency assessment, preoperative status, the use of erectile aids post-operatively, means of data collection and analysis. Despite these limitations, all the reports in the literature confirm that nerve-sparing surgery significantly increases the return of natural erections after RP [294]. The reported potency rates after bilateral nerve-sparing RP in most series varies from 53 to 86% [276, 295, 296, 297]. Contrary to assumed beliefs, better outcomes are related to surgeon’s experience and skills rather than to the method of surgical removal. Minimally invasive approaches, i.e. laparoscopic, whether robot assisted or not, do not seem to be relevant to the sexual outcomes [291, 273, 283, 298].
Our immediate task is to support the development of randomized trials incorporating consensus criteria on design and sexual function assessment. In the absence of such studies, relevant studies published within the last 10 years, have been identified through a comprehensive literature review and grouped in three categories:

1. Studies including preoperatively potent patients without use of erectile aids postoperatively: raw (true) pRPED incidence (Table 23).

2. Studies including preoperatively potent patients, but using or not using erectile aids post-operatively: pharmacologically adjusted pRPED incidence (Table 24).

3. Studies reporting only prevalence of post-operative ED are omitted, because of the limited value of their results.

Those interested in a wider scope of sexual dysfunctions after RP are encouraged to read the mentioned excellent reviews by Stanford 2000 [289], Trabulsi 2003 [290], Menon 2005 [308], Penson 2005 [311], Zippe 2006 [294], Miranda-Sousa 2006 [316], Burnett 2007 [268], and Sanda 2008 [317].

e) Therapy of post-surgical ED

Currently, no standard treatment or prophylaxis exists for pRPED. Neuro-protective and regenerative therapies, including immunophilin ligands, hold promise to reduce the morbidity of localized prostate cancer therapy [318]. In the meantime, several treatment modalities are available to manage sexual dysfunction following RP. These are used in addition to penile rehabilitation (see chapter 20), or when recovery of spontaneous erections fails.

Treatment options are [316]:

- First-line therapies including patient education, lifestyle modification, psychotherapy, oral therapy, and the use of a vacuum device.

- Second line therapies include intraurethral alprostadil and intracavernous injection therapy.

- Third-line options include penile prosthesis implantation.

Steps to minimize ED: In order to prevent cavernous tissue damage, the ultimate responsible for the true pRPED, the available evidence encourages to:

Aim to surgical technique of excellence:
- Maximal nerve preservation
- Avoidance of vascular damage
- Avoidance of thermal and electrical energy sources [319]
- Minimize cavernous ischemia.

Neural damage takes time to recover even when the nerves are preserved: up to four years [320, 295, 321], so penile rehabilitation (see chapter 20), must be considered in all patients aiming to resume spontaneous sexual activity after a radical prostatectomy.

Ejaculatory and other sexual dysfunctions after RP

Other distressing effects of treatment include: penile shortening (68%), loss of sexual desire (60-80%), less satisfying orgasms (64-87%), overall sexual dissatisfaction (61-91%) [322, 323]. Climacturia, or orgasm associated urinary incontinence (OAI), is a known complication of RRP. The exact rate of this problem is not well established and varies from 45% to 93% [324,325, 326].

Literature is scant providing information on the management of these problems. Some report on penile length preservation by means of vacuum devices begins to appear [327].

f) Conclusions and Recommendations (including level of evidence, when feasible)

Long survival from a localized prostate cancer is nowadays a reality. Quality of life, closely related to sexual function becomes an issue [317]. We conclude that ED following RP can be potentially either prevented or treated if the patients request such intervention. We note almost 50% of bilateral-nerve-sparing RRP patients freely decided not to start any ED treatment postoperatively [328]. Roughly 73% of patients who started therapy eventually discontinued it [328]. We note that patients who underwent RALP were more likely to be regretful and dissatisfied, possibly because of higher expectations of “innovative” procedure [329].

There is an urgent need to standardize data collection and reporting in order to improve our evidence for a better understanding and management of sexual function after RP. Our recommendations are as follows:

Means to minimize ED after radical prostatectomy are recommended: refining surgical technique including avoiding cautery to accessory pudendal arteries along with bilateral-nerve-sparing RRP is recommended [295, 289, 305, 313, 315]: Grade C.

Given some 50% of bilateral-nerve sparing RRP patients may not begin any ED treatment postoperatively [328], the couple rather than the individual should be considered when sexual function and dysfunction is addressed: Grade C.

We recommend urologists carefully portray the risks and benefits of new technologies during preoperative counseling to minimize regret and maximize satisfaction [329]: Grade C.
Table 23: Incidence of Erectile Dysfunction after Radical Prostatectomy (Non and Nerve Sparing Techniques) Patients pre-operatively potent, Erectile Function assessed without erectile aids post-operatively. [299, 300, 301, 302, 303, 304]

3. RADIOTHERAPY

a) Introduction

Despite the decrease in overall cancer incidence and mortality rates in developed countries since the early 1990s, cancer remains a major public health problem. Among men, the most common cancer affects the prostate and occurs more often in the older population [330]. In recent years, the number of patients diagnosed with prostate cancer (PC) has increased dramatically because of the widespread use of prostate specific antigen testing and the possibility for cure of early disease. Standard treatments for PC are radical prostatectomy, external-beam radiotherapy (EBRT), brachytherapy, hormonal therapy or observation. In recent years patient’s quality of life, including sexual functioning, plays a more significant role in decision making about treatment type. In the 1980s and 1990s penile prostheses and penile injections provided limited options for male sexual dysfunction. With the introduction of sildenafil (Viagra®) in 1998, media attention to erectile dysfunction (ED) made sexual problems more normative and increased acceptance of help-seeking [331].

b) Methods of Evaluating Erectile Dysfunction

The most practical and quickest way to evaluate ED is by using a questionnaire such as the International Index of Erectile Function (IIEF) [332]. The IIEF has been translated and validated in many countries, though it has not been specifically developed for cancer patients. In the published literature on post-radiation ED different questions have been used, but these were mainly incorporated into a more general questionnaire on toxicity of radiation treatment, or quality of life in general. For an extensive review of the clinical evaluation and symptom scales for sexual dysfunction assessment, see Chapter 6.

c) Definition of Potency

A clear definition of potency is mandatory in order to make meaningful comparisons of the different studies. The 2nd International Consultation on Sexual Dysfunctions, held in Paris is 2003, defined ED as the consistent or recurrent inability to attain and/or maintain a penile erection sufficient for sexual performance [333]. Rigidity of erections, presence of spontaneous daytime erections or morning/night erections are also important issues. It is also necessary to differentiate between ED and not being sexually active, often due to reasons not correlated to erectile insufficiency such as absence of a willing partner, or the lack of interest in sex. Psychological factors in irradiated patients may play a role in post-radiation ED and have to be kept in mind.

In most published studies, authors referred to the general terms potency or impotence without giving a proper operational definition. In some articles, a detailed definition of potency was provided, though this was often not comparable. Only very recent studies have used the IIEF questionnaire [332] or the shortened IIEF-5 questionnaire [334].

d) Etiology of Post-Radiation Erectile Dysfunction

An extensive and critical review on the topic has been published previously [335,336,337].

A study by Zelefsky and Eid [338] concluded that the predominant etiology of radiation-induced impotence was arteriogenic. Several more recent clinical studies investigated the relationship between the radiation dose to the neurovascular bundles, the penile bulb and the penile bodies and post-radiation ED [339, 340, 341, 342, 343, 344, 345, 346, 347,348, 349, 350, 351, 352, 353, 354] presenting contradicting results (Tables 25 and 26). Most studies have only analyzed few patients and the statistical power can be questioned. Post-radiation ED has more likely a multifactorial etiology, and is not only based on the general terms potency or impotence without giving a proper operational definition. In some articles, a detailed definition of potency was provided, though this was often not comparable. Only very recent studies have used the IIEF questionnaire [332] or the shortened IIEF-5 questionnaire [334].

radiation dose to one single anatomical structure. If this is the case, it is much harder to find a correlation between ED and the dose to a specific structure. Furthermore, it is very well possible that the structure responsible for ED has not been investigated yet (i.e. internal pudendal arteries). To date, no final conclusions can be drawn whether or not the radiation dose to the penile structures correlates with post-radiation ED. Even in a prospective, randomized trial such correlation was not found [353].

e) Incidence of Erectile Dysfunction after Radiotherapy

1. Incidence of Erectile Dysfunction after External-Beam Radiotherapy

An extensive review on the topic has been published previously [356]. Only studies that prospectively evaluated erectile functioning using validated questionnaires and using a proper definition of potency are useful to draw conclusions on the incidence of post-radiation ED. Two recent prospective trials have shown an incidence of ED in 30-40% of the patients treated by EBRT [357, 358]. Time elapsed since radiation is important: prospective studies show an increase of ED between one and two years after radiotherapy, but it does not seem to change after three years [357, 358].

LoE Level of Evidence
BT Brachytherapy
NVB Neurovascular Bundle
ED Erectile Dysfunction

Brachytherapy was originally introduced not only to limit the detrimental effects of EBRT on bowel and urinary function, but also to help preserve sexual function. The introduction of sophisticated 3D computer-assisted dosimetry, and the availability of intraoperative TRUS after the 1990s, led to a more accurate and reproducible implants. In general, after permanent seed implantations, ED rates ranged from 5 to 51%, with the highest percentages found after the combination brachytherapy and EBRT. The highest ED rates, ranging from 29 to 89%, have been reported combining the temporary Iridium-192 implants with EBRT.

EBRT = BT in combination with external-beam radiotherapy (EBRT)
n.a. = data not available
[^1] mean age for entire group;[^1] median
f) **Ejaculatory and other Sexual Dysfunctions**

A deterioration of sexual activity has been associated with the severity of ejaculatory dysfunction, particularly a decrease in volume or an absence of semen [375]. After radiotherapy, ejaculatory disturbances varied from a reduction or absence of ejaculate volume (2%-56%) to discomfort during ejaculation (3-26%) and haemospermia (5-15%). Dissatisfaction with sex life was reported in 25-60%, and decreased sexual desire in 12-58%. One study reported a decreased intensity of orgasm, decreased frequency and rigidity of erections, and decreased importance of sex [338, 373, 374, 339].

**g) Therapy of Post-Radiation Erectile Dysfunction**

Prior to the introduction of sildenafil, only one small study reported on the efficacy of intracavernosal injections (ICI) in the treatment of post-radiation ED [376]. All patients had erections sufficient for vaginal penetration with an ICI. Dubocq et al. reported a high satisfaction rate and low morbidity in 34 patients with a penile implant [377]. With the availability of oral drugs to treat ED, these methods of therapy are loosing popularity. The efficacy of sildenafil after radiotherapy in open-label studies has been reported in up to 90% of the patients. In the only randomized, double-blind trial performed so far, sildenafil improved erections significantly as compared to placebo; 55% of the patients had successful intercourse with sildenafil (18% with placebo) [382,383]. Similar results have been reported in one randomized, double-blind trial using tadalafil [384,385].

**h) Prevention of Post-Radiation Erectile Dysfunction**

Prevention is a difficult matter. If one accepts the hypothesis that radiation induces vascular damage, then decreasing the dose to pelvic vascular structures could decrease ED rate. As no reliable data are available to correlate the radiation dose in the penile structures and neurovascular bundles with the prevalence of post-radiation ED, to date no conclusions can be drawn. Possibly, reduction of treatment margins, the use of fiducials to visualize the prostate, more sophisticated radiation techniques such as the intensity modulated radiotherapy (IMRT), might all reduce the prevalence of post-radiation ED. However, prospective studies with large series of patients, and the use of standardized validated questionnaires, have to investigate this hypothesis.

**i) Conclusion**

The prevalence of post-radiation ED is high. There are still no conclusive data on EBRT techniques, field sizes, energy used and their specific influence on ED. Although vascular damage seems to play a role in post-radiation ED this has not confirmed so far. A multifactorial etiology has to be considered, taking into account age, comorbidity, previous prostate surgery, drugs, pre-treatment erectile function and hormonal manipulation. The definition of (im)potence advocated by the 2nd International Consultation on Sexual Dysfunctions should always be used [333], and ED evaluation should be standardized by using, prospectively, validated questionnaires on quality of life and sexual functioning, such as the IIEF. A better understanding of the etiology would allow for more specific therapeutic modalities. Finally, sexual counseling is an important aspect. Patients need to be correctly informed on the anatomy of the prostate, on the possible sequelae of radiation on their sexual life and functioning. Not only a functional penis but a functional couple, has to be the goal. Thus sexual desire, the importance of intercourse in their sexual experiences and both partners’ satisfaction with sexual life, has to be assessed as well.

**j) Recommendations**

We recommend to define ED using the definition advocated by the second international consultation on sexual dysfunction: Grade C.

Use internationally validated questionnaires and collect data on sexual functioning prospectively, because time since radiotherapy is an important factor: Grade C.

A likely multi-factorial etiology should guide treatment of ED: Grade C.

Take the time needed to discuss sexual matters after radiotherapy not only with the patient but with his partner: Grade C.

Phosphodiesterate-5 inhibitors are effective in about half of patients [382, 383, 384, 385]: Grade A.

4. **ANDROGEN DEPRIVATION THERAPY FOR PROSTATE CANCER TREATMENT AND SEXUAL DYSFUNCTION**

a) **Introduction**

Androgen deprivation therapy (ADT) is widely used for treating men with clinically localized or advanced-stage disease prostate cancer (PCa), and has served as both primary and salvage therapy in selected patient populations [386]. Classically, ADT was reserved for patients who had clinically evident metastatic disease or for those who were not candidates for more definitive local therapies, although the indications for early use of ADT are expanding [387,388,389].

Decreasing serum testosterone can have a significant negative impact on quality of life for patients treated with ADT due to adverse effects including decreased libido, osteoporosis, vasomotor flushing, fatigue, anemia, diabetes mellitus (DM),
metabolic syndrome, and altered body composition [386, 390, 391, 392, 393, 394]. Despite the induction of castrate testosterone levels with ADT and the potential for loss of libido and resulting ED, there is a subset of patients in clinical practice who maintain erectile and sexual function [395].

b) Pathophysiology of ADT related Sexual Dysfunction (SD)
Testosterone plays an important role in maintaining male sexual desire. Testosterone also modulates many aspects of the neurogenic vascular dilatation integral to the erectile response. Thus men who undergo ADT have a further decline in ability for sexual intercourse and a decrease in sexual desire compared with men who are not treated with ADT [396]. Sex steroid action in the brain results from the combination of rapid signaling as well as classic transcriptional regulation [397]. Amongst other actions, gonadal steroids act on brain regions involved in the control of sexual behavior and neuroendocrine regulation, modulating release of neurotransmitters including dopamine which is thought to modulate sexual desire. Available data from preclinical and clinical studies, suggest that in the corpus cavernosum, androgens regulate the multiple signaling pathways and the structure of cavernosal tissue. Androgens are involved in the regulation of: (i) NOS isoform expression and activity; (ii) phosphodiesterase-5 (PDE5) expression and activity; (iii) alpha adrenoceptor expression and function; (iv) smooth muscle cell growth and response to vasodilators; (v) connective tissue metabolism and deposition of the extra cellular matrix; (vi) differentiation of progenitor vascular-stroma cells into myogenic and adipogenic lineages; and in maintaining neural structure and function. Androgen reduction causes changes in tissue response to endogenous vasodilators causing reduced blood inflow (failure to fill); changes in the fibroelastic properties and expandability with poor compliance of the corpus cavernosum, resulting in increased blood outflow (failure to accumulate blood under pressure) and dysfunctional veno-occlusive mechanism, contributing to ED [398].

c) Incidence of SD across different treatment modalities
Heterogeneity in collecting data and defining outcomes makes the scant data on SD after ADT difficult to interpret and sometime surprising. We have reviewed data concerning:

i) Continuous Androgen Deprivation (CAD)
(1) Surgical
(2) Medical
   (a) LHRH agonists
   (b) LHRH agonists + antiandrogens: Combined Androgen Blockade (CAB)

ii) Intermittent Androgen Deprivation (IAD)
See Table 29 with relevant studies comparing sexual outcomes after ADT.

d) Management of ADT related SDs
Most standard treatments for ED such as oral agents, vacuum erection devices, intracorporal injection therapy, or placement of a penile prosthesis, are good options. Other forms of ADT, specifically antiandrogen monotherapy and intermittent androgen deprivation, have also been shown to be associated with significantly improved sexual function. In the study by DiBlasio [395] (2008) addressing treatment responsiveness, response rates were 33–80% with medical therapy, including 44% receiving PDE5 inhibitors monotherapy. The low desire as a consequence of ADT can improve during the "off treatment phases" when on IAD [401]. No specific data have been found on absent or delayed ejaculation.

e) Summary
In summary, studies demonstrate that sexual function is significantly impaired after ADT, and that these effects are similar for surgical versus medical ADT.

However, men receiving LHRH agonists reported more worry and discomfort and somewhat poorer overall health and were less likely to believe they are free of cancer compared to orchiectomy patients [395]. These results reflect treatment delivered to a heterogeneous group of patients in diverse health care settings but may provide representative information about the effects of hormonal therapy so as to guide treatment decisions.

In recent years the concept of IAD has passed from hypothesis to laboratory experiments and is now being investigated in randomized, controlled clinical trials. The potential benefits of IAD are an improvement in the ADT adverse event profile normally associated with CAD therapy, an increase in the patient’s overall QoL, and a prolongation of the time taken for the tumor to become androgen independent [401]. The whole question of allowing testosterone therapy for androgen deficient men with a history of prostate cancer is addressed by Committee 14.

f) Conclusions and Recommendations
Most endocrine-related health outcomes are similar after surgical versus primary hormonal therapy [399] (LOE 3). Adverse effects of ADT often mimic testosterone deficiency due to other causes. Symptoms such as hot flashes and sexual effects significantly affect quality of life [402] (LOE 2). We recommend the information comparing surgical and medical ADT is used by physicians and patients when making treatment decisions: Grade C.
We recommend further studies to help physicians carefully weigh the benefits against the morbidity associated with ADT and to optimize the management of adverse effects: Grade C.

II. TESTICULAR CANCER

1. INTRODUCTION

Testicular cancers are mainly germ cell tumors that are classified histopathologically into seminoma, nonseminoma and combined tumors. They account for about 1% of all male cancers [403]. Excellent cure rates have been achieved with greater than a 99% cure rate in the early stages by the standardization of treatment with surgery, radiation and platinum-based chemotherapy [404]. Since testicular cancer affects mostly young men aged 20-40 years, and these patients will survive many decades after successful treatment, the negative impact of the illness and its treatment on their sexual lives should be carefully addressed.

2. SEXUAL DYSFUNCTION

There are numerous studies reporting sexual dysfunction in patients with testicular cancer and after the cancer treatment. Nazareth et al [405] conducted a systematic review of literature from 1966 to 1999 and identified six controlled studies with end point data (table 30). They concluded, with cautions, that patients have increased risk for sexual dysfunction after testicular cancer treatment.

Jonker-Pool et al [406] conducted a meta-analysis of 36 empirical studies from 1975 to 2000 concerning 29 retrospective studies and 7 prospective studies with the mean follow-up of 6.9 years. The mean percentages for different sexual dysfunctions are summarized in table 31 for the entire patient population.

The outcomes of specific treatment modalities for testicular cancer were also analyzed but without comparing the retrospective with prospective data. This was due to the small number of patients in
the prospective studies who reported outcomes specified according to treatment modality (table 32). Obviously, patients’ sexual dysfunction varies after each treatment.

Interestingly, recent studies provide controversial results regarding the sexual function after the testicular cancer treatment. These studies are summarized in table 33.

3. PATHOPHYSIOLOGY

The mechanism of sexual dysfunction associated with testicular cancer and its treatment are complex. The known and proposed theories are summarized in table 34.

4. TREATMENT

Treatment of sexual dysfunction for testicular cancer survivors should follow the same principles as the treatment for patients without a history of testicular cancer. However, it is important to identify the psychological distress of testicular cancer and its treatment on patients and to include psychological therapy. Hormonal abnormalities should be identified and corrected unless there is a contraindication. All men undergoing orchectomy should be offered the option of testicular implantation and the realistic expectations of the testicular implantation should be discussed with the patients [413]. Because the

<tr>
<td>Nerve damage</td>
<td>EjD occurs in almost 100% of patients with bilateral radical RPLND due to the damage to the postganglionic nerves of the hypogastric plexus. Template RPLND with the nerve-sparing techniques can preserve the ejaculatory function. EjD can still occur in about 10-20% of patients after the use of current RPLND techniques[406, 409, 403]. More patients now have retroperitoneal surgery to debulk residual disease, and may end up with EjD because nerve-sparing is less effective in this context. [410] LOE: 3-4</td>
<td>It is suggested that RT could damage small blood vessels causing ED[405], but it is not known whether reported EjD after RT to bilateral para-aortic and ipsilateral hemipelvis to treat seminoma is associated with nerve damage[406].</td>
</tr>
<tr>
<td>Hormonal disturbance</td>
<td>Testicular cancer can cause hormonal disturbances with effects on gonadal function that independently influence sexual function[405]. In a cohort of 326 patients with cancer free &gt; 2 years, 55% and 49% of patients had elevated LH and FSH; 15% of patients had decreased testosterone and 7% of patients had abnormal estradiol levels. The correlation analysis revealed elevated LH and abnormal estradiol were significantly associated with sexual dysfunction[404]. LOE: 3</td>
<td>Platinum-based chemotherapy may contribute to the long term increase in gonadotropins and decrease in testosterone levels[411, 412]. However, a retrospectively study in 53 patients with a median following up &gt; 14 months found that chemotherapy for testicular cancer has no greater risk of developing a hormonal disorder than those following a surveillance strategy[408].</td>
</tr>
<tr>
<td>Body imaging effect</td>
<td>Correlation study revealed that changes in body image are statistically significant in association with negative impact on patients’ sexual life[407]. The appearance of normal male scrotum is important and orchiectomy per se can affect psychosexual function[413]. LOE: 3-4</td>
<td>Body image has been reported improved after testicular prosthesis implantation[403], but it is not known whether this would also significantly improve their sexual life.</td>
</tr>
<tr>
<td>Psychological effect</td>
<td>In a cohort of 326 patients with cancer free &gt; 2 years, more than 27% of patients had abnormal anxiety levels and more than 15% of patients had depression[404]. The symbolic nature of the testicular cancer in young men apparently will cause psychological distress[405], LOE: 3-4</td>
<td>There was no study specifically examining the interactions between psychological distress and sexual dysfunction in patients after testicular cancer treatment.</td>
</tr>
</tbody>
</table>
fertility outcome in testicular cancer patients varies so much between individuals, and because ultimate treatments are not always predictable at diagnosis, routine sperm banking is recommended before beginning chemotherapy or pelvic radiotherapy [414].

5. PREVENTION

Modified retroperitoneal lymph nodes dissection (RPLND) with nerve sparing surgery has proved to be and will continue, if indicated, to be the most effective preventive strategy to avoid EjD. Early psychological counseling should include accurate information about the sexual risks after specific treatment and psycho-sexual vulnerability that may evolve due to the intrinsic actual and symbolic danger of a genital tumor at a relatively young age. Study has shown that patients with testicular cancer who suffered sexual dysfunction reported extremely high needs for information and support [415]. Unfortunately, the latter was lacking for more than half of the patients both during cancer treatment and at the 5.9 year follow-up. Adequate information and support may prevent or reduce sexual anxiety and suffering.

6. CONCLUSION

With some conflicting studies, available evidence indicates that sexual dysfunction affects some patients after testicular cancer treatment. Higher level evidence is needed involving larger prospective controlled studies using standardized instruments and measures of sexual function before and after the treatment of testicular cancer. Nerve damage during the RPLND surgery is proven to be the responsible, yet preventable etiology in most cases for EjD. Hormonal disturbance maybe considered as a correctable cause for sexual dysfunction in some patients. Changes in body image are significantly associated with a negative impact on patients’ sexual life and all men undergoing orchiectomy should be offered the option of testicular implantation [407, 413, 403] (LOE 3/4): Grade C. Early psychological counseling should include accurate information and support regarding sexuality during and after testicular treatment: Grade C.

Routine sperm banking is recommended before beginning chemotherapy or pelvic radiotherapy; Grade C

III PENILE CANCER

1. INTRODUCTION

Penile cancer (PC) is rare in men in the USA and Europe, and accounts for 0.4-0.6% of all malignant diseases in men in these regions. However, it is a substantial health problem in developing countries, and can constitute up to 10% of malignancies in men in some African and South American countries [416]. In urban India, the age adjusted incidence rates vary from 0.7 to 2.3 per 100 000 people in the population-based cancer registries, and in rural India, the rate is three per 100 000 people - more than 6% of all malignant diseases in men [417]. The lowest incidence of PC has been reported in Jews [418]. It is a disease of older men, but is not unusual in younger men and has also been reported in children [419].

2. EFFECTS ON SEXUAL FUNCTION

Of all urogenital cancers, the one that most obviously jeopardizes sexual function is PC. It is an especially distressing disease because of its serious physical and psychosexual consequences. The conventional treatment for this cancer is partial or total penile amputation, radiation- or laser therapy. It appears that most patients can still enjoy a sexual life if laser treatment is used [420,421]. More invasive procedures reduce this likelihood [422]. If the lesion is early and noninvasive, conservative treatment with local resection, Mohs micrographic surgery, topical chemotherapy, external beam radiotherapy, brachytherapy, cryosurgery, or laser therapy can be used, with only marginal compromise of sexual function and satisfaction [423,424,425,426,427].

In partial penectomy, in spite of a reduction in the penile length, vaginal penetration is frequently possible as is the ability to reach orgasm and ejaculation. The main reason for not resuming sexual intercourse appeared to be related to feelings of shame owing to the small penile size and absence of glans penis found in 50% of sexually abstinent patients [422].

If total penectomy is necessary, the reason for not resuming sexual intercourse or masturbation is obvious [428], however, no studies have been found
addressing sexual function outcomes with regards to other sexual activities and satisfaction in these patients.

Surgical complications may also compromise resumption of sexual activity after amputation. Meatal stricture is the most frequent complication after partial penectomy. Excessive penile shaft skin has not been described as a complication; keeping it may give the post penectomy phallus an appearance of a short uncircumcised, but normal, penis. However, the excessive skin may interfere with function and require excision.

Few reviews have dealt with the quality of life and, in particular, sexual function of patients treated for PC. Table 35 shows the most relevant studies.

3. MANAGEMENT OF PC RELATED SEXUAL DYSFUNCTIONS

Given that PC most frequently appears later in life, some patients may develop ED after definitive treatment. This can be managed with current therapies, regardless of the therapeutic method used for the malignancy. The studies shown in Table 35 confirm that a high percentage of patients with partial penectomy maintain sexual function. This suggests that adequate follow-up possibly with a multidisciplinary team may improve sexual desire, function and satisfaction after partial penectomy, although this remains to be demonstrated [422].

4. SUMMARY

- Prevalence of PC varies widely between regions and races.
- Although PC is amenable for primary and secondary prevention, it has been ignored as a public health issue.
- Factors implicated in its etiology and suitable for intervention are: circumcision and poor genital hygiene.
- Conservative treatment, when feasible, should be aimed to preserve as much of the penis, hence sexual identity and activity.
- Partial penectomy seems to have a lesser impact on sexual function than expected.
- A proper follow up, including a multidisciplinary team should be considered, to optimize the outcome.
- The gap between “western” and “developing” countries, with regards to diagnose, treatment and outcomes, completely falls within the scope of this Consultation on Sexual Dysfunctions, raising the need for an effort on education on how to prevent PC incidence.

5. RECOMMENDATIONS

Pre-treatment education is recommended to minimize psychologically-based sexual dysfunction. Include confirmation that intercourse can occur with a short penis: Grade C.

Since penile cancer is a curable condition when diagnosis and treatment is implemented early, preservation of maximal penile shaft is advocated so as to allow continual sexual function [428, 423, 422]: Grade B.

Whether penectomy is partial or complete, multidisciplinary follow-up including clinicians trained in sex therapy is recommended: Grade C.

E. CANCER IN MEN AND WOMEN

1. PELVIC (NON GYNECOLOGICAL)

a) Introduction

Bladder cancer, usually transitional cell arising from the bladder mucosa, is the fourth most common cancer in men, although it is three times less frequent in women. The approximately two-thirds of tumors which do not spread beyond the bladder lining are treated locally, even when recurrent. When there is invasion of the bladder wall, radical cystectomy is indicated. Bladder cancer can spread locally into the prostate, vagina, or uterus. It may also metastasize to distant organs. Currently, metastatic bladder cancer cannot be eradicated. Regardless of the type of treatment, psychological concerns of cancer recurrence or of “being unclean” may add to sexual dysfunction from nerve damage and loss of sexual organs.

b) Intravesical Treatment

Superficial cancer is removed during cystoscopy, typically followed by chemotherapy or immunotherapy with Bacille Calmette-Juérin (BCG) instilled into the bladder [429]. There is little research on the impact of treatment for superficial cancer on sexual function in men or women. Intravesical therapy is typically followed by a week of pelvic pain [430] and sometimes temporary ED [431]. One small, cross-sectional comparative study suggested men and women receiving intravesical chemotherapy have similar sexual function as those receiving only cystoscopic tumor removal [432].

c) Pelvic Radiotherapy

Definitive radiotherapy is rarely used because long-term survival is much poorer than after radical cystectomy [433]. Radiation also typically decreases bladder capacity, causing problems...

with urinary frequency, urgency, and incontinence. However, some small retrospective studies found male sexual function to be less impaired after definitive radiotherapy than after radical cystectomy [434,435,436] (LOE 4). Definitive radiotherapy remains an option for patients who refuse radical cystectomy or whose health makes them poor surgical candidates.

d) Radical Cystectomy and Nerve Sparing to Preserve Erectile Function

Standard radical cystectomy also removes the prostate, seminal vesicles and pelvic lymph nodes. When cancer is multi-focal, especially when it is present in the bladder neck or urethra, the entire urethra may be removed. Recently, the need for urethrectomy has been challenged and in the future, the procedure may be done less often [437]. Although orgasm is preserved, it is different due to the loss of ejaculate after radical cystectomy. ED is usual.

Nerve sparing techniques to preserve erectile function after radical cystectomy were suggested by Walsh and Mostwin in 1984 [438]. To provide a context for the success of nerve sparing cystectomy, Schover et al [439] interviewed 112 men about to undergo radical cystectomy, with a mean age of 63 years. Seventy three men provided follow-up data 13 months post surgery: sexual inactivity increased from 20% before cystectomy to 50% at follow-up. Preoperatively, 35% had ED vs. 94% at follow-up. Table 36 summarizes the outcome of nerve-sparing cystectomy. Some procedures remove the whole prostate, attempting to avoid the neurovascular bundles lateral to its surface [438,440]. Other modifications include sparing the prostate, seminal vesicles and vasa deferentia so that both erectile function and ejaculation and fertility can be preserved [441]. Originally intended only for benign bladder conditions, this procedure has been adopted by some urologic oncologists for men with high risk superficial disease. It remains controversial since invasive transitional cell carcinoma is found at the apex of the prostate in 17-48% of men and another 29-40% have occult adenocarcinoma of the prostate found in the pathology specimens, which had not been suspected before cystectomy [442,443,444]. Although nerve-sparing appears to reduce the risk of ED, particularly if the entire prostate is spared, the risk of local recurrence is also elevated (LOE 4). A recent review of 252 cancer patients who had some form of prostate-sparing cystectomy also found a suspiciously high rate of distant metastases [444]. Recovery of erectile function may be enhanced after nerve sparing prostatectomy during radical cystectomy by the use of penile injection therapy or the oral phosphodiesterase inhibitors within a few weeks of surgery. This sexual rehabilitation may also include a counseling component, which was shown to improve patient satisfaction with treatment outcome [448].

e) Types of Urinary Diversions

It is presumed that having urinary continence will increase the likelihood of remaining sexually active. Unfortunately, it is impossible to conduct a randomized trial comparing ileal conduits with the two major competing diversions. The continent cutaneous diversion, often called the Kock or

Indiana pouch, has an internal reservoir for urine that is drained every few hours by putting a catheter into a smaller, “continent” ostomy opening on the abdomen. The continent ostomy requires careful adherence to a schedule of emptying the pouch with a catheter, and if leakage occurs, it is difficult to manage. A neobladder is the second option. The ureters are connected to a new bladder reservoir, created from a bowel segment, which is also attached to the remaining urethra so that urination can occur through the urethral opening for men or women. A major drawback of the neobladder is that many patients have some stress incontinence during the day and more severe lack of urinary control during sleep [433]. Since surgery to create a neobladder is longer and more complex than that to make an ileal conduit, reconstruction is significantly more common in patients who are younger, male, Caucasian, well-educated, treated at an academic center, and with less comorbidity [449]. Given the differing pros and cons of the three diversions, a recent review of the literature found no clear evidence for superiority of one method over another in terms of general quality of life (LOE: 3) [450] in agreement with Table 37 which summarizes evidence of impact of varying urinary diversions on sexual function or activity.

f) Modifications to Female Radical Cystectomy

Radical cystectomy has typically included removing the uterus, ovaries, and front part of the vagina along with node dissection. Because bladder cancer becomes more common with age, many women may not be sexually active at diagnosis. One older study [456] identified only 9 sexually active women out of 39 who had received radical cystectomy during a 38-month period. In these women, the vagina had been repaired without any tissue grafting, resulting in a narrowed or shallower vagina. Nevertheless, therapy including lubricants, topical estrogen, dilators, counseling, and pelvic muscle relaxation helped 7 to resume intercourse with no or only mild discomfort. Orgasmic response remains intact after radical cystectomy.

For women with cancer at the bladder neck urethrectomy is usually necessary and prevents construction of a neobladder [444]. Direct sexual consequences of urethrectomy have not been studied in women.

Surgeons have also tried to use more limited resection and nerve-sparing to improve women’s quality of life after radical cystectomy. Reports in the literature have been limited to small case series. One concern has been that traditional cystectomy may cause clitoral numbness [457]. A study of sensory thresholds in 16 women after radical pelvic surgery showed, however, that sensation was only reduced in the area of the proximal urethra, whereas sensation in the distal urethra was intact [458]. The pelvic nerve plexus that mediates sensation in the upper urethra is often damaged in surgery, but the

pudendal nerve, which innervates the lower urethra, clitoris, and outer third of the vagina, is not in the surgical field. As in men, type of urinary diversion appears to have little impact on women’s sexual function after radical cystectomy [457, 431]. The Cleveland Clinic group [459,460] have described a technique to preserve the neurovascular bundles on the anterior vaginal wall by using careful sharp dissection to separate it from the urinary bladder. It is unclear whether sparing the neurovascular bundles can help even postmenopausal women to have better blood flow into the vaginal walls with sexual arousal, and therefore more normal vaginal lubrication, or if the benefit is due to sparing more of the anterior wall so that vaginal size remains optimal. It is also important to acknowledge a selection bias, in that women more interested in maintaining sexual activity may opt for nerve-sparing cystectomy. Retrospective comparisons of women who choose one procedure vs. another may not be very enlightening. Table 38 summarizes different cystectomy types and their impact on female sexuality. Operations that spare neurovascular bundles and vaginal tissue may help preserve sexual function (LOE 4).

g) Recommendations/ conclusions

Research is needed on the sexual impact of repeated treatment for superficial tumors with cystoscopy/intravesical chemotherapy: Grade C.

With cystectomy, type of urinary diversion does not predict sexual activity or function [451, 452, 457, 453, 455, 461]: Grade C.

Nerve-sparing cystectomy has limited impact on erectile function [445, 446] (LOE 4). Grade C.

Prostate-sparing cystectomy reduces ED but also increase local and distant recurrence rates [440, 447] (LOE 4): Grade C.

2. COLORECTAL CANCER

a) Introduction

Treatment for colorectal cancer has the potential to interfere with sexuality in a variety of ways. Despite surveys indicating intact quality of life after colorectal cancer, specific assessment of sexuality consistently reveals high percentages of men and women discontinuing sexual activity or experiencing sexual dysfunction [462,463,464,465]. Furthermore, in prospective cohorts, other psychosocial and physical symptoms improve over time while sexual function remains impaired [462, 466,467,468]. When thirty long-term survivors of colorectal cancer were interviewed, the two most distressing problems associated with their cancer were pain and sexual dysfunction.

If the tumor is in the rectum, cancer treatments are more likely to impair sexual function. In a recent comparison, 86% of survivors of rectal tumors had sexual dysfunction compared with 39% of colon cancer survivors [469]. Intuitively one would expect a colostomy to impair psychosexual functioning more severely than surgeries that preserve the anus. In a retrospective survey of 476 cancer survivors who had lived a mean of 10 years with a colostomy, complaints about interference with sex were common. Fifteen percent of cancer survivors had become sexually inactive. ED was present in 79% of men [470]. Interestingly, 71% of those remaining active were satisfied with their sex lives. Unfortunately, surgery that reconnects the colon and rectum typically leaves survivors with bowel frequency and some incontinence. In fact a recent Cochrane review of 8 published studies found no clear advantage of...
sphincter-saving surgical procedures over colostomy on quality of life [471].

b) Assessing Sexual Problems after Colorectal Cancer Treatment

Two major quality-of-life inventories have been validated for patients with colorectal cancer, the EORTC QLQ-CR38 [472] and the FACT-C [473], each with a few items assessing sexual function. It remains difficult to compare rates and types of dysfunction across studies, however, because some researchers use idiosyncratic questionnaires and some use the more detailed International Index of Erectile Function [463, 474, 475] and Female Sexual Function Index [476, 463] scales, which measure sexual function in any adult population. Some general conclusions can be drawn, however.

c) Rates and Types of Sexual Dysfunction

Table 39 lists treatments for colorectal cancer, their hypothesized impact on sexual dysfunction, and evidence in the literature. Tables 39 and 40 summarize research studies that report the prevalence of sexual dysfunctions in men and women treated for colorectal cancer. Unfortunately researchers have focused on the physiological impact of cancer treatment without exploring the relationship between sexual function or satisfaction and other indices of quality of life [471]. It is probable that emotional variables, including premorbid psychosocial adjustment, social support, and socioeconomic status interact with physiological impairment in determining sexual outcomes. Even from a physiological standpoint, many men in the age group at high risk for colorectal cancer already have erection problems related to comorbidities that damage the penile vascular system and/or autonomic nerves, such as obesity, diabetes, smoking, or alcohol abuse [477, 463]. Some surveys have found older age to be a better predictor of sexual function than a specific type of colorectal cancer treatment [478, 479].

Although a number of surveys have concluded that men are more likely to have sexual dysfunction than women after treatment for rectal cancer [478, 477, 481, 494], few data are available for women. Many elderly women are not sexually active at the time of cancer diagnosis [477, 463, 478, 495]. Typically they lack a partner or their partner is ill or has erectile dysfunction. Women also appear more likely than men to give up sexual activity after cancer treatment [477, 463]. For those women who remain sexually active (Table 41), prevalence and types of problems appear similar to those in women treated for other pelvic tumors, such as cancer of the bladder, ovaries, or uterus [456].

Finally, a greater proportion of women in the cohorts refuse to complete questionnaires that ask about their sexuality. As Table 42 illustrates, in six recent surveys that provided information on participation from men vs. women in completing sexual items, response rates for men ranged from 52% to 100% compared to 27% to 70% for women [477, 463, 488, 485, 486, 479].

d) Anal Cancer and Sexual Function

Unlike colorectal cancer, anal cancer is a type of skin cancer that is strongly related to the human papilloma virus (HPV). Risk for these lesions increases when a person’s immune function is compromised: from Human Immunodeficiency Virus (HIV) [497], chemotherapy, immunosuppressive drugs for example. Since the advent of HIV, rates of squamous cell carcinoma of the anus have been increasing. Research has not yet examined the impact of anal cancer on sexual behavior or satisfaction. Since treatment usually involves simultaneous local radiation therapy and chemotherapy [498], receptive anal intercourse would probably become painful and alternative types of sexual stimulation might need to be substituted. Radiation induced vaginal stenosis is also likely.

e) Recommendations / conclusions

Avoid abdominoperineal resection if possible, since it has a worse impact on sexual function [463, 479, 482] (LOE 4): Grade C.

The combination of radiotherapy and surgery leads to more dysfunction than either treatment alone [464, 467, 463, 468] (LOE 2): Grade B.

Nerve-sparing with a laparoscopic total meso-rectal excision is promising in preserving erections [486, 489] (LOE 4): Grade C.

II. HEMATOPOIETIC CELL TRANSPLANTATION

1. INTRODUCTION

Over the past 20 years survival after hematopoietic cell transplantation has increased dramatically, making quality of life more salientse [499]. The typical preparation for transplantation of bone marrow or of peripheral blood stem cells is intensive chemotherapy and/or whole body irradiation, destroying the patient’s bone marrow so that no new blood cells can be made. Transplanted bone marrow or blood stem cells then restore the patient’s ability to produce new blood cells. The transplant material may be gathered before preparation from the patient (autologous transplantation) or is obtained from a donor matched to the recipient on human leucocytic antigens (HLA), proteins on the surface of blood cells (allogeneic transplantation). Increasingly, less intensive regimens are used, followed by infusing blood stem cells and using growth stimulating factors

<tr>
<td>Abdominoperineal resection (APR), complete removal of rectum and anus with creation of colostomy</td>
<td>ED from damage to inferior hypogastric nerve plexus and prostatic nerve plexus, diminished arterial flow to penis[480]; Damage to emission when sympathetic nerve pathways in the superior hypogastric nerve are interrupted higher in the pelvis, orgasm preserved but no ejaculate[481]; Partial resection of posterior vaginal or BSO can cause dyspareunia. Impact of colostomy on sexual activity[463]</td>
<td>Retrospective cohort studies: Male sexual problems worse after APR than other rectal surgeries [463, 479, 482]</td>
<td>3</td>
<td>Female sexual problems, especially vaginal dryness and tightness [463]</td>
<td>4</td>
</tr>
<tr>
<td>Low anterior resection (LAR) of the rectum with reanastomosis, sometimes including J-pouch to minimize urgency and incontinence</td>
<td>May be better than APR because entire rectum is not mobilized, but if done with older, blunt dissection, may be more likely to damage nerves involved in erection. Need to compare LAR and APR when both done using TME. Also no colostomy.</td>
<td>Male sexual problems better after LAR than APR, retrospective cohorts [483, 477]</td>
<td>4</td>
<td>No evidence</td>
<td>4</td>
</tr>
<tr>
<td>Total Mesorectal Excision (TME) mobilizing the whole rectum using sharp dissection from the pelvis before removing it. Can be done with LAR or APR.</td>
<td>Easier to identify and spare autonomic nerves involved in erectile function and antegrade ejaculation of semen; May also spare nerves important to female sexual function. Minimizes damage to pelvic arteries and veins[484]</td>
<td>Rates of ED after TME still range from 50% to 90%[463, 465, 477, 485]; Slight advantage for TME over older techniques in ED and antegrade ejaculation, but small, historical control[486]</td>
<td>4</td>
<td>In one very small cohort, women who had total mesorectal excision still had more sexual dysfunction than women with resection higher in the pelvis for colon cancer[487]</td>
<td>4</td>
</tr>
<tr>
<td>Laparoscopic TME</td>
<td>Laparoscopic approach may facilitate sparing of nerves involved in sexual function.</td>
<td>RCT laparoscopic vs. open rectal cancer surgery: More ED with former especially if surgery included complications or a conversion to an open procedure or was done with TME[488]; However, case series of laparoscopic TME for 48 men caused NO changes in IIEF scores Liang et al 2008 Smaller case series of laparoscopic TME report similar rates of preserved erections to those from open cases (75% and 58%, respectively[489, 491, 492].</td>
<td>4</td>
<td>Case series of laparoscopic TME in 44 women caused NO changes in FSFI scores[490]</td>
<td>4</td>

| Table 39: Colorectal Cancer Treatments and Their Impact on Sexual Function [463, 464, 465, 467, 468, 477, 478, 479, 480, 481, 482, 483, 484, 485, 486, 487, 488, 489, 490, 491, 492, 493] |
(usually granulocyte colony-stimulating factor) to increase stem cell production [499]. New techniques allow stem cells to be purified from the patient’s own blood, reducing the chance that a transplant will contain cancer cells [500]. Peripheral cells may also come from a donor or from umbilical cord blood that has been frozen soon after a baby’s birth. Since few people have stored their own cord blood, a matched donor is typically used. Cord blood is used most often for children, since it contains a limited number of stem cells [500].

2. GRAFT VERSUS HOST DISEASE

When a transplant is allogeneic, some degree of graft versus host disease (GVHD) often results, especially if the donor and patient are not well matched. The immune system attacks the patient’s own cells as if they were foreign, causing a variety of symptoms. Severe GVHD can be debilitating, but some degree of GVHD may actually mobilize the immune system to kill off any remaining cancer cells [501]. If peripheral stem cells from a donor are used along with a stimulating factor, chronic GVHD is especially common [502].

### 3. PHYSIOLOGICAL SIDE EFFECTS OF TRANSPANTATION ON SEXUAL FUNCTION, AND PREVALENCE AND TYPES OF PROBLEMS

Table 43 illustrates how the physiological impacts of hematopoietic transplantation affect sexual function. Tables 44 and 45 summarize literature in last 10 years reporting the prevalence of major types of sexual dysfunction for men and women after transplantation. Most studies have small numbers of participants. Only two are prospective studies with baseline measures of pre-transplantation sexual function, and only two include comparison groups that have not been transplanted. Limited conclusions can be drawn. Sexual function is affected more severely for women than for men. Although some recovery of sexual activity and pleasure occurs in the first two years after transplantation, survivors remain more likely than controls to experience sexual dysfunction even 5 to 10 years after their cancer treatment. The relative contribution of different physiological and psychological factors to these problems is still not adequately studied, but the presence of significant sexual problems after conditioning and

<td>Primary hypogonadism in men</td>
<td>Intensive chemotherapy, especially with alkylating agents; total body irradiation</td>
<td>Loss of desire for sex, ED, reduced semen volume Consider testosterone therapy if ED resistant to phosphodiesterase-5-inhibitors[503, 504].</td>
</tr>
<tr>
<td>Premature ovarian failure (POF) in women</td>
<td>Intensive chemotherapy, especially with alkylating agents, higher dose needed in younger women; after age 35, alkylating chemotherapy drugs typically cause permanent, premature menopause given depleted reserve of primordial follicles. The dose of radiation from TBI is also high enough to lead to premature ovarian failure[505, 506]</td>
<td>Loss of sexual desire, vaginal dryness and dyspareunia all common prior to actual transplantation due to premature ovarian failure from previous cancer treatment. Of 48 premenopausal women preparing for transplantation, 73% already had lost desire for sex and 48% were dissatisfied with their sex lives[507]. In women without specific contraindications to using estrogen replacement, either systemic or local treatments may help in treating vaginal atrophy. If vulvovaginal GVHD is present, 0.05% clobetasol propionate ointment may be added[508]. The safety and efficacy of testosterone therapy after POF is unclear[505]</td>
</tr>
<tr>
<td>Failure to begin puberty in children (male or female)</td>
<td>TBI or the chemotherapy drug busulfan are the most common antecedents of pubertal failure[509]. Direct radiation to the testes given to boys with leukemia to ensure no cancer cells are protected in those glands will prevent puberty. Although puberty is deferred during cancer treatment, or within a few years afterwards[509], a majority of females treated in childhood or adolescence retain sufficient follicles to be fertile, only to have an unusually early menopause[505]. In boys LH and FSH are often slightly elevated, but puberty occurs and testosterone remains in the lower normal range. It is unclear if these mild abnormalities lead to overt sexual dysfunction later in life.</td>
<td>Failure of spontaneous puberty is more common in girls than in boys. It is difficult to estimate the prevalence of failed puberty, since it varies with children's ages, type and dose of chemotherapy, and dose and field of radiation. Often treatments are combined. Reductions in recent years in treatment toxicity also may reduce the rate of gonadal damage.</td>
</tr>
<tr>
<td>Autonomic nerve damage</td>
<td>Neurotoxic types of chemotherapy (vincristine or platinum-based drugs) may cause damage to autonomic nerves, if given in high dosages, but evidence is only anecdotal[510]</td>
<td>May damage erection and/or ejaculation, but not even small cohort studies. No research on potential sexual impact in women.</td>
</tr>
<tr>
<td>Damage to pelvic vascular bed</td>
<td>TBI impairs the vascular supply to penis, vagina and vulva and the vascular supply to their autonomic innervation[511], but no research has examined the sexual consequences. TBI reduces uterine arterial blood flow and inhibits uterine growth, particularly when given before puberty[512] but effects on vaginal lubrication or expansion have not been studied.</td>
<td>May cause erectile dysfunction in men or reduced vaginal lubrication with sexual arousal in women. Much more research is needed. May be role for Phosphodiesterase-5-inhibitors to increase vaginal lubrication in women.</td>

<tr>
<td>-----------------</td>
<td>-------------------</td>
<td>---------------------------</td>
</tr>
<tr>
<td><strong>Graft vs. Host Disease (Male)</strong></td>
<td>Contribution of GVHD to male sexual dysfunction has been largely ignored. Case reports of genital GVHD causing inflammation of fascia and penile curvature[513] adherence of foreskin to the glans (phimosis)[514]. GVHD may be one cause of Peyronie’s Disease which affects 3% to 9% of all men[515, 516]. Out of five surveys of sexual function in men and women after hematopoietic cell transplantation, only one[517] included GVHD as a potential factor in sexual problems, finding a correlation with loss of sexual desire and pleasure, and inability to have sex. More recent studies have not investigated GVHD[518, 519, 520, 521]</td>
<td>Penile curvature, pain, and ED, or pain with erection due to failure of foreskin to retract. Men often puzzled and embarrassed by pain with erection and penile curvature, and do not seek medical help. Nelson and colleagues (2008)[515] documented that about half of men with Peyronie’s have high rates of chronic depression that does not decrease with time. It will be important in future research to see if genital GVHD in men is more prevalent than has been suspected.</td>
</tr>
<tr>
<td><strong>Graft vs. Host Disease (Female)</strong></td>
<td>Women with systemic GVHD often have vaginal inflammation and scarring, especially women receiving allogeneic peripheral blood stem cell transplants with growth factors: some 25% to 50% may be affected[522, 508]. Genital GVHD begins about 9 months post-transplantation with systemic GVHD almost always present. The earliest symptoms resemble provoked vestibulodynia, with redness on the vulva and exquisite tenderness around the vaginal introitus. If untreated, vulvar GVHD progresses into the vagina, where fibrous wisps of scar tissue attach to the vaginal walls, ultimately narrowing of the vagina by tough scar tissue (stenosis), and closing the vagina as the inflamed vaginal mucosal walls adhere to each other.</td>
<td>Pain with genital caressing and intercourse is common. If diagnosed early, genital GVHD can often be treated successfully with a combination of high-dose steroid topical cream and low-dose vaginal estrogen. Two recent case series of 29 women in an Australian cohort of 81 followed prospectively[522] and 29 American women referred for assessment of vaginal symptoms after transplantation[508] reported that all women responded to the local vaginal treatment, none needing surgery. Those who wanted to stay sexually active worked with vaginal dilators plus topical steroid and estrogen and were able to stretch the adhesions and open their vaginal canals.</td>

before transplant suggests that the long-term sexual dysfunction has complex causes. Not only may prior cancer treatment have damaged pelvic nerves and vasculature or reduced hormone production, but the intensive conditioning to prepare for hematologic transplantation, as well as the ongoing psychological stress exacerbate sexual problems. GVHD after transplantation may compound the dysfunctions further.

4. RECOMMENDATIONS

Men may become hypogonadal and require testosterone plus other medical treatments for ED [503, 504] (LOE 4): Grade C. After allogeneic transplants, women should watch for symptoms of vulvo/vaginal GVHD and seek early treatment with estrogen/steroids [522, 508] (LOE 4): Grade C. Local estrogen therapy is recommended for women with premature ovarian failure and dyspareunia. Systemic estrogen may be appropriate in some cases: Grade C.

We recommend giving information to men and women about sexual problems and rehabilitation before starting cancer treatment, with further assessment and counseling during planning for transplantation as well as at repeated follow-up visits: Grade C.

III. CANCER IN CHILDREN AND TEENS

1. QUALITY OF LIFE AND MARRIAGE IN SURVIVORS OF CHILDHOOD AND ADOLESCENT CANCER

Despite the increasing success of treatment for pediatric cancer in Western nations, men and women who survive these malignancies remain vulnerable to increased mortality from cancer recurrence, second malignancies, and late health effects of their cancer treatment [525]. Research on the quality of life of survivors of cancer in childhood and adolescence has rarely investigated sexual function, however. Rates of marriage have been compared with population norms. Survivors also are less likely to attain college degrees or be employed fulltime compared to population norms. Most have little idea that they may be at risk not only for infertility, but for sexual problems as well. A survey of 217 cancer survivors aged 18 to 40 at approximately 3-5 year follow-up from treatment found that about half desired counseling on sexuality, just as many as wanted assessment of infertility or counseling on adoption services [533]. Unmet needs were particularly acute in the group aged 18 to 29, whose age at diagnosis put them in the Adolescent and Young Adult (AYA) population that is now a focus of attention [534] (LOE: 4).

Even once these young people reach adulthood, research on sexual function seems to be off limits. In the past ten years, only two surveys of small, selected groups have been published. Relander and colleagues [535] used interview techniques and medical examinations to study 77 men treated for childhood cancer in Sweden at a median of 13-year follow-up. Eleven men were treated for low testosterone resulting from radiation for craniopharyngeal tumors, direct radiation therapy to the testes to treat leukemia, or high-dose alkylating chemotherapy agents. Only 2 of these men had "normal" sex lives, characterized by having desire for sex, being able to get erections, and being able to reach orgasm. Seventy percent of the 66 eugonadal men met criteria for being sexually functional, but this still suggests a higher rate of problems than expected among young men. A more recent Dutch study of childhood cancer survivors [536] included 31 young men and 29 young women with a mean age of 25. Although both genders were included, rates of problems were mainly cited for the group as a whole. In those over age 25, experience with sexual intercourse was significantly lower than age norms for the Dutch population. Being diagnosed during adolescence led to delays in sexual development in terms of dating, experimenting with intimate touch, intercourse, and for women, with masturbation. Although this sample also reported worse physical and mental health on the SF-36 than their peer group, general quality of life measures were not significantly associated with sexual function. Sexual problems were common: 41% reported low sexual desire, 45% sexual dissatisfaction, 44% feeling unattractive, and 14% feeling their cancer history interfered with their chance to have a future romantic relationship. Of note, these two surveys were conducted in
Northern Europe, where adolescent sexuality is not stigmatized as it is in the United States [537]. Clearly more detailed research is needed to enable clinicians to understand risk factors for sexual dysfunction after cancer in childhood and adolescence so that services can be directed to the subgroups most in need (LOE: 4).

3. TREATING SEXUAL PROBLEMS IN CANCER SURVIVORS

One intervention study used a psychoeducational model to counsel AYA patients about reproductive health issues [538]. A written workbook, using clip art and text layouts designed to appeal to teenagers and young adults included the following topics: male and female sexual anatomy and response, the impact of cancer treatments on sexual function and fertility, ways to develop a positive body image, making good decisions about whether or not to be sexually active, using contraception for safer sex and pregnancy prevention, being able to be assertive in sexual situations, and dealing with dating and relationships after cancer. Half of participants were randomized to a 3-month waiting list condition and half to 2 90-minute sessions of counseling from an expert psychologist, along with receiving the workbook. Questionnaires were administered at baseline, after the waiting list period, at the end of counseling, and at 3-month follow-up. Only 24 participants were recruited, and 3 could not complete the study because of illness. The only change during the waiting list period was an increase in emotional distress. However, gains at the end of treatment, and maintained at 3-month follow-up, included increased knowledge of the material, decreased general emotional distress, more positive body image, and less anxiety about sexuality and dating. Despite having the AYA programs of two large pediatric oncology centers participating, recruitment for this trial was very slow and difficult, limiting its generalizability (LOE: 3). In the future, it might be more acceptable to teens to use an internet-based or peer counseling model along with the material in the workbook.

4. RECOMMENDATIONS

Given the minimal research on sexuality compared to data on fertility and marital status, surveys of current young adult survivors are needed: Grade C.

F. CANCER IN WOMEN

I. GYNECOLOGICAL CANCERS

1. INTRODUCTION

Gynecologic cancer involving vulva, vagina, cervix, uterus, fallopian tubes or ovaries accounts for 13.4% percent of all cancers in women [539] with endometrial cancer being the most common: in the US some 40,000 women are diagnosed annually. In office endometrial biopsy or operative curettage for postmenopausal bleeding has lead to early diagnosis coupled with a favorable prognosis and a survival of 85-90% at five years. Surgical removal remains the mainstay of treatment for many gynecological cancers especially ovarian in origin. Pelvic radiation is often the primary or main adjunctive treatment for cervical and some endometrial cancers: external beam if often followed by intravaginal or brachytherapy. The majority of women (62-88%) are at high risk for developing vaginal agglutination and stenosis within the first 3 months after radiotherapy [540]. Recent studies demonstrate that between 30-63% of women who undergo treatment for cervical cancer experience some sexual complaint [541]. The sudden loss of ovarian hormones from surgery or chemotherapy also contributes to sexual dysfunction.

Surveys confirm the need to address sexual repercussions of gynecological cancer. Women with these diagnoses consider their sexual health to be one of the three most important aspects of quality health care [542] and while 74% in one study believed their physicians should discuss sex [543] such discussions did not occur in 62% of the time. Moreover, sexual dysfunction can be the primary source of distress from symptoms related to cervical cancer treatment [544]. However, data on prevalence and optimal treatment are scant especially for endometrial and fallopian tube cancers.

2. PREVALENCE

The prevalence studies (Table 46) of sexual dysfunction after specific gynecological cancers are often difficult to compare as sample size, oncological stages and follow up times are variable. Most studies are retrospective and do not have baseline sexual functioning. According to the National Cancer Institute, research shows that approximately one-half of women who have been treated for breast and gynecologic cancers experience long-term sexual dysfunction. Qualitative study highlights the importance of lost femininity and fertility and the fear of dyspareunia in women with endometrial and cervical cancer [545].

3. PATHOPHYSIOLOGY

The sexual side effects of treatment for gynecologic cancer are of multifactorial etiology and include direct and indirect mechanisms (table 47). Cancer treatment modalities and psychological reactions can both influence sexual function.

4. SPECIAL SURGICAL CONSIDERATIONS

Radical hysterectomy for cervical cancer is noted to have persistent negative ramifications on sexual desire whereas lubrication and other vaginal

concerns may dissipate over time, as noted in one study where the autonomic nerves in the cardinal and uterosacral ligaments were likely spared [541]. However, nerve sparing radical hysterectomy is in its infancy [563] but early data suggest neurovascular preservation leads to improved sexual function [548, 564].

Ovarian removal signifies both reproductive loss and the advent of menopause (see table for effects) [565] Bowel resections and anterior/posterior exenerations for advanced gynecologic malignancy can result in stomas, colostomies, and ileoconduits impacting on self image. Some surgical techniques are becoming less aggressive without impact on survival as oncological surgeons consider sexual health concerns: clitoral preservation surgery for vulvar cancer offers selected women decreased morbidity with preservation of sexual function [566]. There are on going studies of radical tracelectomy (which preserves fertility) for early cervical disease and subsequent sexual function. The emerging trend is to provide adequate cancer treatment, but with minimal surgical removal of tissue and to minimize long-term negative sexual consequences [567] In all cases, adequate preparation and information may facilitate sexual adjustment after surgical intervention [568].

5. PSYCHOLOGICAL CONSIDERATIONS
Sexual self schema, sexual self concept, create the cognitive view about sexual aspects of oneself derived from past experiences and often manifest in current experience. Sexual self schema may account for variance in predicting current sexual behavior in cancer survivors; those with positive sexual self concept may adapt more positively [546]. Recently studies have noted the success of brief psychosexual interventions and of addressing the informational and sexual needs of cancer patients [569, 570, 571]. Mindfulness training, that has been incorporated into a psychoeducational program for women with arousal disorder subsequent to gynecological cancer, has been effective in preliminary studies [572,573]. An effective method of treatment for sexual difficulties in cancer patients is through the coordinated provision of information, support, and symptom management [570], preferably at one site. Many cancer institutions have established comprehensive multi-disciplinary programs. The focus is on both the psychosexual and physical aspects of sexuality. Limited study has shown increased compliance with therapy and subjective improvement in sexual symptoms [574]. Palliative care providers can also be involved as they reassure patients and their partners that even at the end of life, when intercourse may not be feasible, physical sexual intimacy and emotional closeness can be encouraged.

6. FUTURE RESEARCH
Further randomized clinical trials are needed to

II. BREAST CANCER

1. INTRODUCTION
Breast cancer is the most common malignancy in women [576]. Some 2.5 million women in the United States are breast cancer survivors: the 5 year survival rate is estimated to be close to 90%. Twenty-five percent of new cases present before menopause and 15% present before the age of 45 [577, 578, 579]. Sexual concerns are distressing complications for women during their diagnostic, treatment, and survivorship phases of breast cancer. Etiological factors include premature menopause, premorbid sexual dysfunction and negative self-concept [580, 581] relationship discord and depression [582].
2. PREVALENCE:

Table 48 shows the prevalence of sexual dysfunction after a diagnosis of breast cancer.

Women of Asian [583] or African American [584] [585] descent may be less communicative about sexual health concerns and possibly more prone to sexual dysfunction after breast cancer, but this has yet to be determined. There is limited study on breast cancer survivors who are lesbian, bisexual or single.

3. PATHOPHYSIOLOGY OF DYSFUNCTION

Living with a diagnosis of breast cancer can negatively affect sexual self image and function. There may be fear of recurrence, hesitancy to start a new relationship with need to disclose medical details, fear of rejection by a partner, coupled with the stress and sadness of possible changed fertility, life plans and finances. However, studies conclude that major factors negatively influencing sexual are also treatment related, see table 49.

4. SPECIAL SURGICAL CONSIDERATIONS

Surgical excision may affect sexual image and impact sexual responsiveness. Sexual problems may be more significant immediately after surgery and some gradually decrease with time, but there is still a need to address sexual problems related to the breast surgery and possible iatrogenic menopause, especially in younger breast cancer survivors [587]. Up to 10% of women with breast cancer may have a genetic predisposition for the development of ovarian cancer because of BRCA gene mutations and some of these women may choose to undergo a risk-reducing bilateral salpingo-oophorectomy (RRBSO). In a recent study [590], women who underwent a RRBSO were negatively impacted, experiencing dyspareunia and reduced body image [591]. In addition many women choose to undergo prophylactic mastectomy of the breast unaffected by cancer fearing bilateral involvement or another primary breast cancer. Study of subsequent sexual function is scant but cosmetic results are not always favorable and may negatively impact sexual self esteem.

5. SPECIAL RADIATION CONSIDERATIONS

Radiation therapy may cause direct and indirect affects (see table 64) that promote sexual dysfunctions. Skin damage, fatigue, alopecia, diarrhea, nausea, vomiting and radiation-induced symptoms contribute to general malaise and negatively impact sexual desire and response. Studies are lacking with respect to Mammocyte®, a novel minimally invasive intramammary placement of radiation at the time of surgical intervention and its implications on female sexual function.

6. SPECIAL CHEMOTHERAPY CONSIDERATIONS

The probability that a woman will enter menopause as a result of chemotherapy increases dramatically at the age of 35. More than 40% of women receiving chemotherapy at the age of 40 become amenorrheic [592]. Weight gain with chemotherapy and hormonal manipulation has been linked to women's feelings of lost attractiveness [593]. Goodwin et al [594] noted a mean overall weight gain of 1.6 kg, with an average gain of 2.5 kg, in newly diagnosed breast cancer patients receiving chemotherapy, and a 1.3-kg gain in those taking tamoxifen.

7. SPECIAL HORMONAL THERAPY CONSIDERATIONS

Tamoxifen, a first generation selective estrogen receptor modulator (SERM), is prescribed to block estrogen receptors in the breast, but it also acts as a weak estrogen agonist on the uterine lining requiring monitoring for adverse endometrial effects. It is probably neither agonist nor antagonist in the vagina: studies that have looked at the impact of tamoxifen on sexual function have proven inconclusive [596].

Aromatase inhibitors (Anastrozole, Letrozole, and Exemestane) are rapidly becoming the mainstay of treatment for various stages of breast cancer. These drugs prevent the production of any estrogen and many women complain of vaginal dryness, moderate and severe dyspareunia, exacerbated menopausal symptoms, and loss of sexual desire [596]. Scientific data are limited. Management may include encouragement of non penetrative sex if non estrogen vaginal products to ease dyspareunia are insufficient.

8. PSYCHOLOGICAL CONCERNS

The literature confirms that many women adapt well after they learn of their diagnosis. Never the less, there is a subset of women who report continued anxiety, depression, and concerns regarding body image, fear of recurrence, post-traumatic stress disorder, and sexual problems well after treatment completion [592]. Sometimes women link prior negative sexual experiences, past sexual behavior (promiscuity, extra marital affairs or acquisition of sexually transmitted diseases) to their cancer diagnosis. Sexual well being in partnered women with breast cancer recurrence demonstrates substantial stress as they attempt to maintain their sexual lives. Younger and distant recurrence patients may have the greatest risk for sexual disruption. [597] The frequency of both intercourse and kissing declines significantly. Data demonstrate that sexuality declines after the recurrent cancer diagnosis and does not significantly improve over time.

The dynamics of relationships can be strained and changed with a cancer diagnosis. Survivors' levels of relationship distress, depression and age rather than hormonal levels have proved the most significant variables affecting arousal, orgasm, lubrication, satisfaction and sexual pain [598]. One study of women receiving ongoing anti estrogen therapy involved multiple regression analysis to determine what influenced desire, arousal, orgasm, pain and satisfaction. It was found that relationship factors predicted desire and a history of chemotherapy predicted problem-atic arousal, lubrication, orgasm and pain. However, there was no relationship between sexual function and hormonal levels including androgen metabolites [582]. The experience of chemotherapy rather than the resulting low hormones appeared to be highly detrimental to sexual function.

9. ASSESSMENT

Assessment of the breast cancer patient with sexual health concerns should be focused on the multimodal approach as outlined in the beginning of the chapter. Careful attention should be addressed to her relationship and social support network as well as her coping styles for her disease.

10. TREATMENT CONSIDERATIONS

It is imperative to counsel patients concerning possible sexual remedies including treatments for vaginal dryness [587]. Since breast cancer is often hormonally sensitive and tumor cells possess estrogen and progesterone receptors, treatment of menopausal sequelae with systemic replacement hormones is almost always contraindicated. The use of alternative medications, including serotonin reuptake inhibitors, antihypertensive medications, and environmental modifications (rhythmic breathing, acupuncture, avoiding spicy foods and alcohol, dressing in layers) may help decrease the intensity and severity of menopausal symptoms, though evidence of efficacy is limited. Sexual health resources to enhance body image (wigs, special lingerie, attachable nipples etc) should be widely available to help the survivor reclaim her sexual self esteem. The use of minimally absorbed local vaginal estrogen products remains an individual decision that requires informed consent and consultation with the oncology team [560, 599]. Several small reports [600] noted increased estradiol levels in women who take aromatase inhibitors and vaginal estrogen tablets. New lower dose tablets need further investigation and safety in breast cancer populations is lacking. Preliminary studies suggest that 0.5 G of Premarin Vaginal cream applied twice weekly has no endometrial effects and is not systemically absorbed; however it remains officially contraindicated in hormonally sensitive cancer survivors [560, 599]. Long term safety data are lacking such that the use of local estrogens for the treatment of vaginal atrophy after breast cancer women remains experimental: the amount of escape in to the systemic circulation has the potential to interfere with aromatase inhibition [575]. Non hormonal water based lubricants and moisturizers remain the primary treatment. Delivery of DHEA to the vaginal tissue may allow strictly local androgen action to benefit vaginal atrophy from aromatase inhibition and be a preferable choice in the future for women who must be strictly systemically estrogen-deplete [602]. A phase III RCT of 216 postmenopausal women without breast cancer, has confirmed maturation of epithelial cells and decrease in pH without significantly increasing serum estrogen or testosterone levels, with all steroid values remaining in the range seen in post menopausal women. All domains of sexual function improved [602, 603].
The safety of androgen replacement in the breast cancer population has not been adequately studied. There is a concern that testosterone can be aromatized to estrogen, which may reactivate or promote further tumor growth. The use of androgen replacement in estrogen deficient breast cancer patients was not effective for lowered libido in a recent randomized placebo controlled crossover clinical trial [604]. Future studies are needed to examine the safety and efficacy of androgens in this population. Psychosexual counseling and possible psychological therapies for sexual dysfunction should be offered to all breast cancer survivors with sexual complaints specifically addressing possible anxiety, stress, and mood changes from the imposed infertility.

11. Recommendations

Comprehensive assessment of sexual function is recommended given the multifactorial etiology and premorbid risk factors including past dysfunction, negative self-concept, depression, relationship discord as well as premature menopause [580, 581], Grade C.

Tamoxifen is likely sexually neutral [596], Grade C.

The clinically observed markedly negative impact of aromatase inhibitors on vulval vaginal health and coital comfort must be addressed: Grade C.

The short and long-term safety of minimally absorbed local vaginal estrogen for vaginal atrophy remains in question: their use is officially contraindicated by the FDA in the USA. The North American and the European Menopause Societies recommend individual decisions dependant upon each woman’s preference in consultation with her oncologist [560, 599]. We concur with these recommendations by the Menopause Societies: Grade C.

Local DHEA to allow tissue production of estrogen and testosterone without release of any sex hormones into the systemic circulation holds promise and research in this population is needed [601, 602, 603] (LOE 2): Grade C.

Non-hormonal water-based lubricants and moisturizers remain a safe treatment for dyspareunia: Grade C.

G. SEXUAL DYSFUNCTION AND PSYCHIATRIC DISEASE

I. INTRODUCTION

Sexual dysfunction should be acknowledged as a common and frequent symptom of psychiatric disease. Enquiry about possible changes of sexual performance including libido, arousal, orgasm, ejaculation, vaginal lubrication and erectile function should be made initially, before treatment is initiated. This information should be periodically reviewed in follow up visits in order to identify sexual problems and their acceptability to the patient and partner.

II. DEPRESSION:

1. DEPRESSION AND SEXUAL DYSFUNCTION

Depression is associated with low interest, lack of energy, low self-esteem as well as anhedonia. The associated deterioration of communication skills can impair personal relationships. Unfortunately patients frequently delay seeking help such that unsatisfactory sexual relationships are common. Social isolation and irritability can also contribute to decreased ability to initiate and maintain new intimate relationships.

a) Prevalence of sexual dysfunction from depression

Sexual interest is decreased in almost all depressive patients: it is a classical and frequent symptom. The Zurich Cohort study highlights a double prevalence of sexual dysfunction in depressed patients compared with controls (50% vs. 24%) [605]. Case controlled studies are shown in table 66. Approximately 40% of men and 50% of women with major depression suffer decrease in libido and problems regarding sexual arousal, as shown by specific questionnaires used to investigate sexual activity during the month prior to diagnosis. Orgasmic problems occur in a lower percentage, 15% to 20%, prior to taking the antidepressant drug.

2. ANTIDEPRESSANTS AND SEXUAL PROBLEMS

Selective serotonin reuptake inhibitors (SSRIs) venlafaxine, duloxetine and tricyclic agents (particularly those with a high serotonin reuptake blocker profile such as clomipramine) show a higher incidence of sexual dysfunction than other antidepressants that work through different mechanisms of action: bupropion [610], mirtazapine, moclobemide [611] tianeptine and agomelatine [612]. However, sexual dysfunction is the most frequent adverse effect of the serotonergic drugs [613, 614, 615, 616, 617, 618, 619]. This problem, which has a high incidence (30 - 50%), affects the patient’s quality of life and can lead to therapeutic noncompliance in long-term treatments, and was the most common side effect leading to a 50.8% dropout in the GAMIAN Survey [620].

Antidepressant drugs can deteriorate previous sexual activity by negatively affecting desire, arousal, orgasm, and ejaculation. Anecdotal reports also describe less frequent alterations such as penile anaesthesia [621] clitoral anaesthesia, painful orgasm [622], orgasm associated to yawning [623] priapism (associated with paroxetine and trazodone) [624], increased libido, spontaneous orgasm [625] and decreased ejaculation volume [626].

Only direct questioning will identify the real incidence of drug related dysfunction. Spontaneous reports are uncommon, even though this side effect can considerably affect drug compliance. In a specific study only 14% of the patients reported SD spontaneously but this increased to 58% when sexual questionnaires were used [613]. Patients are reluctant to speak about sexual problems with the physician because they are afraid of finding themselves in an embarrassing situation and they expect little help from their doctors in this regard [616].

a) Mechanisms involved in antidepressant-related sexual dysfunction

The normal sexual response includes the combination of neurogenic, psychogenic, vascular, and hormonal factors that are coordinated by hypothalamic, limbic system, and cerebral cortex centers (Table 67). Nowadays, it is accepted that human sexual function is influenced by the intervention of many neurotransmitters: dopamine, serotonin, noradrenaline, acetylcholine, GABA, oxytocin, arginine-vasopressin, angiotensin II, GRH, substance P, neuropeptide Y, and cholecystokinin-8, melanocortins among others. [616, 627] Dopamine enhances sexual function acting on D₂ receptors...
while serotonin inhibits sexual desire, ejaculation, and orgasm acting on postsynaptic 5HT2 receptors [616, 628, 629].

Although the central role of noradrenergic activity in human sexual activity is unclear, it is linked to the onset and maintenance of copulatory behavior in male rats. Blocking of the peripheral-adrenergic and cholinergic receptors in the genitourinary tract impairs sexual function [630]. Drugs with potent anticholinergic and/or α-1 receptor blocking action such as antidepressants (clomipramine) and some antipsychotic agents (risperidone) have a great capacity to impair sexual arousal. Reduction of nitric oxide (NO) activity has been related to SD secondary to antidepressant agents [631].

Table 51: Mechanism involved in Psychotropic related Sexual Dysfunction

- Increase of serotonin activity
- Anticholinergic effect.
- D₂ blockade
- Nitric Oxide Inhibition
- Alpha 1 blockade (priapism)
- Endocrine changes: Increase of Prolactin

b) Frequency of antidepressant-related Sexual Dysfunction

In agreement with previous studies which have shown frequencies of SD between 30% and 70% [613, 618], a very significant increase in SD incidence (59.1%) was found when patients were examined using the PRSexDQ Scale [614]. Only 24% of the patients with SD reported the problem spontaneously. Table 68 shows the overall frequency of SD for each of the antidepressants obtained by the Spanish Working Group using the specific PRSexDQ-SALSEX Questionnaire [612] and some important differences between them. Citalopram, venlafaxine, and paroxetine present the highest incidence values. A greater frequency of SD and sedation has been reported with paroxetine than with other SSRIs when a meta-analysis is used [632]. Citalopram and paroxetine are the most potent SSRIs. In this group of patients, fluoxetine had a slightly lower incidence of SD when compared with the other SSRIs [614]. The increase in serotonin activity is clearly related to low levels of libido and delayed or absent ejaculation and orgasm.

Moclobemide, a reversible MAO-A inhibitor has very little effect on sexual function, probably due to stimulation of dopaminergic activity and the absence of serotonergic effect.

Bupropion has shown little SD due to its dopaminergic mechanism of action. Clayton et al in a large sample of 6300 patients comparing SSRIs, buproprion, and placebo showed SD from bupropion to be no different from placebo [633]. Orgasmic dysfunction from bupropion is less than from SSRIs and also sexual dysfunction is less compared to venlafaxine [634]. Because bupropion is a selective norepinephrine and dopamine reuptake inhibitor with no serotonergic activity, other common antidepressant-associated side effects such as weight gain and sedation that could also impact sexuality, are absent.

Erectile dysfunction from serotonergic drugs is significantly less than orgasmic problems, suggesting a different mechanism of action perhaps not related to serotonin but rather to the peripheral adrenergic and cholinergic pathways. Paroxetine was associated with a significantly greater incidence of erectile dysfunction and insufficient vaginal lubrication [614]. This might be explained by the greater capacity of paroxetine to bind to the cholinergic receptors, as it is 5 to 160 times more potent in its cholinergic blocker capacity than the remaining SSRIs [635]. As well, it has been recently found that paroxetine is

a potent inhibitor of nitric oxide (as it inhibits oxide-nitric-synthase) both in vitro as well as in vivo [636].

Mirtazapine causes SD much less frequently (24.4%) than SSRIs and venlafaxine, and less severely [614]. However, erectile dysfunction occurs with the same intensity as with the other drugs, due to the different mechanisms involved in orgasmic and erectile function. Never the less, patients switched to mirtazapine because of SD related to other antidepressants may show improvement in all sexual items [637]. Although mirtazapine can improve sexual difficulties in depressed men and women, other adverse effects can appear (weight increase or somnolence). The global improvement found (64.7%), suggests that mirtazapine is a good therapeutic alternative in patients with severe SD secondary to other drugs, especially orgasmic problems [638].

Limited data suggest that duloxetine (with a dual serotonergic and adrenergic activity) has few sexual adverse events compared with paroxetine and escitalopram [639]. Agomelatine, a new antidepressant, an agonist of melatonin receptors MT1 and MT2, and antagonist at 5HT2C has shown a very low degree of SD [640,641]. A comparison of sexual functioning in depressed patients treated with either agomelatine or venlafaxine indicated that agomelatine 50 mg/day had a better sexual profile than venlafaxine XR 150 mg in remitted patients after 12 weeks of treatment in both orgasm and preorgasm measures; both treatments showed comparable antidepressant efficacy. Agomelatine caused significantly less sexual dysfunction, (similar to placebo, <10%), compared to paroxetine (>80%) in a sample of 90 healthy volunteers [641]. Due to its unique pharmacological profile, agomelatine has been shown to positively influence disturbed circadian rhythms in depressed patients by improving all phases of disturbed sleep and the overall quality of sleep, with a favourable impact on daytime alertness. Clinical studies suggest that this compound offers a novel approach to the treatment of depression combining efficacy, even in severe depression, with an extremely favourable side-effect profile including lack of sexual effects [641].

c) The need to use specific questionnaires to identify sexual problems

Recently validated questionnaires have been developed to measure psychotropic-related SD. The PRSexDQ-SALSEX, Psychotropic Related Sexual Dysfunction Questionnaire [642]; CSFQ Changes in Sexual Functioning Questionnaire [615], and ASEX Arizona Sexual Experiences Scale [643] have been used worldwide. SeeTable 53.

The “Psychotropic-Related Sexual Dysfunction Questionnaire” (PRSexDQ) has been used in samples of depressed and schizophrenic patients on medication [644]. Used in a direct clinical interview for the Spanish Group to Study Psychotropic Related Sexual Dysfunction, it has shown adequate feasibility and good psychometric properties. It consists of 7 items assessing 5 dimensions of SD according to severity or frequency: loss of libido, delayed orgasm or ejaculation, absence of orgasm or ejaculation, erectile dysfunction, vaginal lubrication dysfunction and patient’s acceptability of SD. In addition to scores for each item, an overall score may be obtained as a summated rating scale with items 3 to 7 ranging from 0 to 15 (severe SD).

d) Acceptability of sexual dysfunction by the patient and the partner

The acceptability of sexual dysfunction seems to be very relevant to the risk of dropouts, see table 54. As previously mentioned, data from large surveys show between 41.7% and 50.8% of the

total withdrawals are due to adverse effects. Thus, the use of alternative treatments that can decrease the frequency or intensity of SD in patients with poor tolerance, and at risk of discontinuing treatment, must be considered.

**e) Management Strategies for antidepressant associated sexual dysfunction.**

Past strategies have included waiting for spontaneous remission, dose adjustments, drug holidays, drug substitution, antidote therapy, and nonpharmacologic strategies, but their efficacy remains insufficiently proven or unknown [616, 645]. See table 55.

Gradual reduction of the dose may be useful in some patients especially in patients who are also experiencing other side effects. However, it should be attempted only in patients who have responded well to the medication, and clinician and patient must be watchful for any signs of relapse or discontinuation symptoms.

Drug holidays, in which a patient is advised to skip his or her antidepressant treatment for a day or two, can be effective but can also undermine treatment compliance and cause drug discontinuation symptoms or relapse of depressive symptoms.

Substituting one SSRI with another one may help alleviate sexual side effects; however, few patients (about 10%) benefit from this method of management [614]. Substituting SSRIs with drugs that work through a different mechanism of action, including bupropion [646], and mirtazapine [638] appears to be a more effective option. Patients on SSRIs for Generalised Anxiety Disorder were switched to Tiagabine (GABA agonist with anxiolytic effect) allowing remission of their SD [647]. The previously mentioned new antidepressant, agomelatine, may be a good alternative for patients suffering moderate to severe SD.

Agents currently used as antidotes that have been evaluated in placebo-controlled trials include drugs approved for the treatment of erectile dysfunction, such as sildenafil [648] or tadalafil [649]. A recent clinical trial with extensive exclusion criteria showed that sildenafil treatment of sexual dysfunction in women taking SSRIs was associated with a reduction in drug induced orgasmic dysfunction [650].

Sometimes no pharmacologic treatments alleviate the depression induced or the medication induced sexual dysfunction. Validating and explaining their sexual problems may be enough to help some patients, while others may require psychological treatments including CBT, sex therapy and mindfulness – see chapters 3 and 24

### III. PSYCHOSIS: SHIZOPHRENIA

#### 1. INTRODUCTION

Dependant on the course of their psychosis, patients suffering from schizophrenia have a variety of sexual difficulties. Patients with persistent illness tend to suffer significant sexual deterioration accompanied by other mental disturbances [651]. In contrast, patients with a good evolution of their disease maintain interest in their sex lives, although they have emotional difficulties in expressing their sexual needs [652,653]. Some 89% of chronically psychotic patients may have sexual dysfunction and this incidence may be related to the illness itself and how it affects the patients’ motivation, relationships with others, affective deficit, difficulties in finding or keeping a partner [654] or may be secondary to antipsychotic therapy. A significant group of patients are very dissatisfied when they develop sexual dysfunction following treatment, reducing compliance with treatment and clearly worsening the long-term prognosis [655].

2. SEXUAL DYSFUNCTION FROM ANTIPSYCHOTIC MEDICATION

a) Mechanism of antipsychotic drug induced sexual dysfunction

The most frequent dysfunctions are decreased libido, delay or lack of orgasm/ejaculation and arousal problems both in men and women. In general, antipsychotics that increase prolactin levels (haloperidol and typicals, risperidone, amisulpride, paliperidone) are associated with more sexual problems than those which do not (aripiprazol, quetiapine, ziprasidone and olanzapine). However, despite clozapine producing little or no change on serum prolactin concentrations, comparable and relatively high rates of sexual side effects were found for clozapine and haloperidol. Also, prolactin levels per se may not correlate with sexual dysfunction or psychosis control. Rather, the increased ability for emotional regulation from effective anti-psychotic therapy seems to benefit sexual function [656]. This finding also supports that, in addition to hyperprolactinemia, there are several possible mechanisms of antipsychotic induced SD including sedation due to histaminic blockade, cholinergic blockade, and adrenergic blockade [657]. Conventional antipsychotic drugs block D2 receptors on pituitary lactotrophes and so prevent inhibition of prolactin secretion by dopamine. The increase in prolactin levels also occurs at low doses and has a dose-dependent relationship as well. There is a greater prolactin elevation in women with chronic antipsychotic treatment at equivalent doses [658].

b) Prevalence of sexual dysfunction from antipsychotic medication

New atypical antipsychotics were expected to be associated with a lower incidence of sexual adverse events compared to conventional/typicals (chlorpromazine thioridazine) [659]. However, high rates of SD have been consistently reported with risperidone, ranking from 43% to 67% [660]. olanzapine, quetiapine, ziprasidone and aripiprazol exhibit a significantly lower incidence of SD as compared with risperidone. Moreover, olanzapine induced SD has been reported to be dose-related [658].

The disparity of incidence rates may be due to confounding factors such as difficulties in evaluating sexual function, use of small patient series and non-specific questionnaires and variably selecting sexually active and/or inactive subjects. When semi-structured sexual function interviews are used, SD frequency figures of between 49% and 63% are detected in treated schizophrenic outpatients [661]. In contrast, much lower frequency rates are found using the same methods in non-medicated psychotic patients, and in normal controls [662]. The highest figures for SD – 60% – (mainly erectile dysfunction and retrograde ejaculation) have been associated with thioridazine, decreasing to 25% with other antipsychotics[660, 663, 664, 665, 666, 667].

Sexual changes may include decreased libido, problematic ejaculation, orgasm, erection, vaginal lubrication, as well as priapism, menstrual disturbances, gynaecomastia, or increased breast size in women [644, 658, 668]. The frequency of SD in patients receiving antipsychotic medication is shown in Table 56.

c) Consequences of sexual dysfunction from antipsychotic medication

New atypical antipsychotics were expected to have a lower incidence of sexual adverse events compared to conventional/typicals (chlorpromazine thioridazine) [659]. However, high rates of SD have been consistently reported with risperidone, ranking from 43% to 67% [660]. olanzapine, quetiapine, ziprasidone and aripiprazol exhibit a significantly lower incidence of SD as compared with risperidone. Moreover, olanzapine induced SD has been reported to be dose-related [658].

The disparity of incidence rates may be due to confounding factors such as difficulties in evaluating sexual function, use of small patient series and non-specific questionnaires and variably selecting sexually active and/or inactive subjects. When semi-structured sexual function interviews are used, SD frequency figures of between 49% and 63% are detected in treated schizophrenic outpatients [661]. In contrast, much lower frequency rates are found using the same methods in non-medicated psychotic patients, and in normal controls [662]. The highest figures for SD – 60% – (mainly erectile dysfunction and retrograde ejaculation) have been associated with thioridazine, decreasing to 25% with other antipsychotics[660, 663, 664, 665, 666, 667].

Sexual changes may include decreased libido, problematic ejaculation, orgasm, erection, vaginal lubrication, as well as priapism, menstrual disturbances, gynaecomastia, or increased breast size in women [644, 658, 668]. The frequency of SD in patients receiving antipsychotic medication is shown in Table 56.

A major problem arising from SD is treatment non
compliance increasing the risk of relapse leading to significant healthcare, economic, family, and social consequences [669]. SD has recently been identified as one of the adverse effects that patients find most bothersome and that clearly compromises long-term treatment objectives [670]. Using specific Questionnaires it has been shown that patients, especially men (36% in one study), are very likely to drop out due to SD [644]. Much higher frequency rates are found when specific questionnaires (SALSEX) are used versus recording spontaneous reporting. Selecting patients who are sexually active will prevent falsely low prevalence rates of dysfunction (since patients who do not engage in sexual activity may not report/ be aware of adverse sexual effects); however, those who have discontinued due to sexual side effects will not be included.

d) Management of antipsychotic drug induced sexual dysfunction

There is minimal study to guide management. The efficacy of waiting for spontaneous remission, dose adjustments, drug holidays, drug substitution, antidote therapy and nonpharmacologic strategies, remains insufficiently proven or unknown [616, 645] (Table 57).

Spontaneous remission occurs only in a few cases and gradual reduction of the dose may be useful in some patients but relapses and discontinuation must be monitored. Drug holidays have been explored in anecdotal cases but undermine treatment compliance.

There is a lack of controlled data to support the use of antidotes such as amantadine, or cabergoline. The use of sildenafil shows significant improvement in erectile dysfunction [671].

Substitution may be helpful. Switching to olanzapine, quetiapine, aripiprazol or ziprasidone has decreased sexual dysfunction in observational studies [644, 658, 672]. When prolactin was measured an association between improved sexual function and decreased prolactin levels was found when risperidone was substituted for olanzapine [673].

IV. OVERALL CONCLUSIONS ABOUT SEXUAL DYSFUNCTION IN PATIENTS WITH PSYCHIATRIC DISEASE

- Sexual dysfunction may be present before psychotropic medication is initiated
- Direct and detailed examination of sexual function with specific scales is a decisive factor in the detection of dysfunction at treatment onset and in follow up
- The incidence of psychotropic drug related SD is underestimated and occurs mainly with serotonergic agents and hyperprolactinaemic drugs.
- Psychotropic drug related SD is associated with poor compliance with treatment
- There is a role for drug substitution to lessen sexual sequelae from medications in both depression and schizophrenia
- Phosphodiesterase inhibitors have a role as antidotes for psychotropic drug related SD
- Though minimally studied, non pharmacological therapy for sexual dysfunction during psychiatric disease may allow treatment compliance and improve quality of life

Table 57: Strategies for managing sexual dysfunction with antipsychotic medication
V. RECOMMENDATIONS WITH GRADES

Psychotropic drug related sexual dysfunction should be addressed given the known risk of non-compliance as well as impaired quality of life [620]: Grade C.

Sexual history using specific scales prior to initiating drug and at follow up is strongly recommended: Grade C.

Sexual side effects should be important factors when initially selecting long-term psychotropic drugs: select drugs with low risk of sexual dysfunction.: Grade C.

Though minimally studied, non-pharmacological therapy for sexual dysfunction during psychiatric disease may allow treatment compliance and improve quality of life: Grade C.

To lessen drug-induced dysfunction, choose olanzapine, quetiapine, aripiprazole, ziprasidone instead of risperidone, amisulperide or paliperidone, [642, 644]: Grade B.

Avoid serotenergic anti-depressants [633, 634, 614, 641]: Grade C.

It is a reasonable assumption that people who contract sexually transmitted infections (STIs) do not have sexual dysfunction and that those who are dysfunctional would not have the capacity to develop STIs. In this chapter we have put forward what we believe is a raft of compelling scientific evidence showing that these realms do, in fact, interact, often in causative fashion. Because sexual dysfunction symptoms may be found in up to half of non biased populations studies and the rates of STIs are measured in tens of millions, these issues potentially affect a sizeable proportion of sexually active men and women in most countries. To date, a systematic and broad review of the interaction of these two major themes has not been undertaken, but with the spread of HIV and other STIs worldwide, it is a timely mission that we have been asked to tackle. Although much of the material in this chapter has high grade references, the evidence base levels are low in some instances. This is due to the newness of the topic, a fact that positively opens many future possibilities for future research and improved evidence based levels.

I. OVERVIEW OF HIV AND HIV IN MEN

1. EFFECTS OF HIV ITSELF
   a) Introduction

The first cases of AIDS in 1981 described in young homosexual men in the US with severely impaired cellular immunity lead to the discovery of the human immunodeficiency virus - HIV [1] [2]. HIV is a novel retrovirus infecting CD4+ lymphocytes which are pivotal to cell mediated immunity. Those most affected in North America, Western Europe and Australia are men who have sex with men and intravenous drug users. Other marginalised populations are also at risk for example black and Hispanic residents of the United States. In the developing world, heterosexual sexual intercourse and vertical (mother to child) remain the primary routes of transmission [3].

Lack of any effective treatment for AIDS and HIV in the early years coincided with a reduction in the transmission of STIs due to a reactive increase in the use of barrier contraception and so-called “safe sex.” Unfortunately, since the advent of effective HIV treatment [highly active antiretroviral therapy (HAART)] in the mid 1990s, sexual behaviour has changed and the incidence of STIs has increased again; even among those who are HIV Infected [4] [5]. In developing countries, the incidence of HIV has been and remains explosive, and, without effective treatment and STI prevention measures, the outlook seems potentially devastating [3].

HAART generally produces a sustainable suppression of plasma HIV virus (viral load) and an increase in circulating CD4 cells. More than 25 antiretroviral drugs from six therapeutic classes are now available for the management of HIV infection and mortality in HIV infected patients now approaches that of the uninfected population [6].

Logically, it is untenable that men with sexual problems including erectile dysfunction, low sexual desire, and ejaculatory disorders should be at significant risk of STIs. Similarly, it is untenable that young, sexually active people who are at greatest risk of STIs should experience sexual problems. In reality, these paradoxical situations are common in clinical practice. In a nationally representative sample of HIV-infected outpatients in France, sexual difficulties were reported by 33.3%
of individuals; immuno-virological outcomes were not associated with sexual difficulties [7]. A study in London, UK demonstrated that Hiv infected MSM are 5 times more likely to report sexual problems than uninfected MSM and that those on HAART are more likely to complain of loss of sexual desire which is associated with endocrine abnormalities [8]. Furthermore patients on HAART with Sexual difficulties are more likely to report poor adherence to HAART [9]. Amongst Hiv infected MSM, there is a complex, but important organic and psychosocial interaction between recreational drug use, use of PDE5 inhibitors and poor condom use (and probably Hiv transmission) [10].

b) Hiv encephalopathy

The primary cause of Hiv encephalopathy (HivE) is the infection of the CNS caused by Hiv. If untreated, some 15-20 % of patients will eventually develop the disease [11]. Since the introduction of (HAART), the incidence of the disorder has decreased [12], [13]. Other terms used for this condition are AIDS dementia complex, AIDS dementia, Hiv dementia, and Hiv associated cognitive motor complex. HivE generally only occurs in the later stages of the Hiv infection when there is a profound immune suppression (CD4+ T-cells < 200/μl) [14] [15].

Hiv encephalopathy is a subcortical dementia which emerges over the course of weeks and months. Typical complaints are slowing of reasoning, forgetfulness, difficulties concentrating, lack of energy drive, mild depressive symptoms and emotional blunting. Impairment of alertness, neck stiffness and focal or lateralisning neurological signs (e.g. hemiparesis, aphasia) are not typical for Hiv associated encephalopathy. The coincidence of psychosis with HivE is rare. Focal and generalized epileptic seizures are rare manifestations of HivE [11] [13].

There are no systematic reviews of sexual functioning of Hiv patients with encephalopathy. Anecdotal reports by the authors had clinical pictures of low sexual desire, erectile dysfunction and sexual disinhibition. It is likely that patients with Hiv have altered neuropsychological functioning which may impact on sexual functioning. Hiv associated encephalopathy and other CNS manifestations are less likely in individuals on HAART and are more likely to improve on HAART [16], [17].

c) Adjustment disorders, depression and anxiety in Hiv

At the beginning of the AIDS pandemic, affective disorders such as depressed mood were seen in a considerable number of Hiv-1-infected individuals [18]. These disorders were a result of the poor physical condition of patients, brain involvement by the virus (e.g. encephalopathy), or a reaction to disadvantageous living conditions (losing friends, jobs, etc.). In the era of highly active antiretroviral therapy (HAART), mental illness related to physical weakness is declining [19].

A survey of patients in the US found that 54% of Hiv patients had Axis I psychiatric disorders, including 20% with major depression and 18% with depressive symptoms associated with adjustment disorder [20]. Patients with mild adjustment disorders resulting from bad news (i.e. giving the patient an Hiv diagnosis or the worsening of Hiv disease status) and patients with major depression may benefit from supportive psychotherapy. Regular meetings with a health provider to discuss feelings and to encourage treatment compliance are often of great benefit [21].

Anxiety and depression are common among persons living with Hiv, with a prevalence of nearly 50% in a U.S. screening sample of 2,864 Hiv-infected persons [22]. It is not known whether the introduction of HAART has led to a decline in depression and anxiety disorders among Hiv-infected persons, although recent studies showed that the incidence and prevalence of Hiv-1-associated dementia and minor cognitive motor disorders have significantly declined in the HAART era [13], [23]-[28]

The presence of depression and anxiety has been shown to be an important patient-related barrier to adequate adherence to HAART, as it has to adherence to medications for other disorders [29], [30]. Despite the consistent association between depression and HAART adherence behavior, there have been few detailed analyses of this issue. It is also possible that Hiv associated neurocognitive disturbances, which become more prominent as Hiv disease advances, might be responsible for non-adherence. However, to our knowledge, the relationship between adherence to HAART and neuropsychological performance has been assessed in only one recent study, which suggested a negative effect of neuropsychological impairment on adherence to antiretrovirals [31].

Men with Hiv who have multiple sexual problems were likely to suffer from major depression. Factors independently associated with multiple sexual problems among the Hiv-negative gay men were poorer general health and interpersonal isolation, whereas for the Hiv-positive gay men, they were adoption of avoidant strategies to cope with daily life stress, sexual risk-taking in casual encounters, and the use of antidepressants [32].

d) Endocrine

Hypogonadism was a well recognised clinico-pathological problem in the pre HAART era [33]. Hypogonadism is now less common among Hiv-infected men in the HAART era and is usually attributable to hypothalamic/pituitary dysfunction [34]. The prevalence and aetiology remains unclear,
however given its association with increasing age, the prevalence of hypogonadism may rise as Hiv-infected men survive to older ages [34]. Hypogonadism appears to be associated with decreased muscle mass quantity and function, changes in corporal fat mass distribution and quantity, secretion of adipocytokines and endothelial dysfunction. This may be due to the metabolic syndrome which is likely to be a feature of the lipodystrophy syndrome [35]. Hiv associated hypogonadism is also associated with sexual dysfunction, namely erectile dysfunction and low sexual desire [8], [34], [36], [37]. Furthermore, there is increasing evidence that men with Hiv complain of low sexual desire, particularly those on HAART who have raised estradiol levels [8], [36], [37].

2. DIRECT EFFECTS OF HIV INFECTION

**a) Lipodystrophy**

Lipodystrophy is a recognized side effect of older antiretroviral therapy [38]. Lipodystrophy is a pathological fat redistribution problem manifesting in central obesity and peripheral, including facial, fat atrophy. Lipodystrophy is associated with protease inhibitors and lipoatrophy is likely to be due to thymidine analogue reverse transcriptase inhibitors; however, the exact physiological mechanisms are unknown [38]. The psychological effects of lipodystrophy are potentially devastating. Patients fear disclosure and often exhibit features of depression, which can affect sexual function; self-image and self-esteem are compromised [39]. Aromatization of testosterone to estrogen in pathological lipodystrophic tissue has been noted as a biological mechanism for increased estradiol levels in Hiv-infected men [37]. Clinical trials demonstrating the role of aromatase inhibitors in preventing raised estradiol levels in lipodystrophic individuals have shown early encouraging results [36]. The incidence of lipodystrophy and lipoatrophy is decreasing due to newer antiviral agents.

**b) Neuropathy**

Peripheral neuropathy is a well-documented complication of both Hiv infection by direct viral toxicity and HAART, most notably thymidine analogue nucleoside reverse transcriptase inhibitors i.e. zidovudine-AZT [40]. There is little data on the relationship of peripheral neuropathy and sexual dysfunction in patients with Hiv. There is a significant association in this group of men with peripheral neuropathy and retarded ejaculation [41]. The relationship between retarded ejaculation and peripheral neuropathy is complex and often included. Although within the context of Hiv is likely to be an autonomic neuropathic process, other relevant causes of retarded ejaculation need to be considered [41], [42]. In non-Hiv settings, men with diabetes and consequent associated peripheral neuropathy have been reported to complain of retarded ejaculation [43].

**c) Iatrogenic low sexual desire**

Low sexual desire in the post-HAART era appears to be related to their Hiv therapy [44]-[46]. Experience in a previously reported study from a London Hiv centre showed that 2% of a convenience sample of unselected healthy MSMs admitted to low sexual desire, compared with 26% in Hiv positive men who were well but not on HAART and 48% for men with Hiv on HAART [8]. The mean estradiol level in the latter group was significantly raised (228 pmol/L). Clearly, the difference between 26% of non-HAART-taking men having low sexual desire and 48% of those taking HAART having low desire suggests there might be a causal relationship between HAART and raised estradiol levels [8]. Other workers have also found significant changes in testosterone and estradiol levels in men on HAART [37]. Using aromatase inhibitors in men with Hiv and low sexual desire has an effect suggesting that the organic mechanism is raised estradiol [36].

**d) New treatments**

Efavirenz, a commonly used antiretroviral agent since the late 1990s, has been shown to have CNS side effects; however, there does not exist any evidence for increased sexual dysfunction in controlled studies [47]. Currently, newer antiretrovirals are licensed on a yearly basis; however, effects on sexual dysfunction or interaction with current pharmaceutical agents used to manage sexual dysfunction are not systematically investigated. Protease inhibitors, cause increased plasma levels and clinical effects of all PDE5 inhibitors via the inhibition of cytochrome p450 liver isoenzymes [48]-[50].

3. PDE5I USE AND SEXUAL FUNCTION WITH PARTICULAR REGARD TO MSM

Common sense would suggest that MSM using PDE5i to maintain strong erections would lead to safer sex e.g. a man who feels his erection might fail whilst putting on condom would not do so and so have unprotected high risk sex but would have a hard erection under PDE5i cover and so feel able to use a condom. However, the current evidence appears contradictory to this concept. Rosen et al reported at the Bolger conference that PDE5i use is associated with recreational drug use (e.g. crystal meth or cocaine ) which in turn may lead to central excitement, but peripheral ( penile) vasoconstriction [10]. In order to overcome this recreational drug induced ED, MSM resort to PDE5i use, which seemingly in the USA is frequently obtained online, not via a physician, and with little or no safer sex counselling [10]. Furthermore, the disinhibition induced by these recreational drugs may well be enhanced by similar CNS effects of the PDE5is themselves [51]. A further problem is that PDE5i use has been shown to be much more likely to lead
to condom breakage and has also been suggested to lead to anal vasoengorgement in MSM with consequent facility of transfer of Hiv at anal sex [10]. Recent qualitative and quantitative work in MSM who have recently Hiv seroconverted shows that use of recreational drugs, past and current sexual assault and current depression are cumulatively associated with unsafe sex and Hiv acquisition [52]-[53]. Addressing these issues is important both to ensure good HAART compliance as well as safer sex [54]-[56].

The committee’s opinion is that intracorporeal alprostadil or Trimix for the treatment of ED should be injected further towards the glans than is usually recommended so that the puncture site is covered by the condom.

II CIRCUMCISION AS A STRATEGY TO REDUCE HIV INFECTION IN MEN

The merits of circumcision in the neonatal period or in later years have been debated for ages. Proponents of the procedure have argued that the public health benefits of circumcision including a protective effect against urinary tract infections in childhood, sexually transmitted diseases, penile cancer, and inflammatory conditions of the penis far outweigh the risks. Those against circumcision have traditionally held the view that this procedure poses an unnecessary surgical risk, that the benefits do not justify the potential exposure to risk, and question its ethical foundation. Three recent randomized studies in sub-Saharan Africa have conclusively demonstrated that circumcision is associated with a significantly decreased risk of Hiv infection in the male. The following is a summary of these more recent findings and their impact on forming current and future global health policy, as well as a brief review of the history, ethical aspects, and potential complications of circumcision.

1. HISTORY AND INTRODUCTION

Circumcision is believed to have originated in Egypt more than 6000 years ago and may be the “oldest” elective operation in the history of man [57]. Six millennia later, circumcision has resurfaced as a hotly debated topic and come to occupy center stage in public health policy directed toward the control of the Hiv epidemic. Recently, many “anti circumcision” activists have argued that the presence of foreskin and the associated Meissner’s corpuscles is necessary for maximized sexual pleasure and that removal of foreskin, especially in infancy and adolescence, is a form of unnecessary forced trauma [58] Detailed review of the merits of circumcision in relation to health benefits other than Hiv control is beyond the scope of this manuscript, but studies have shown reduced relative risk of urinary tract infections in boys, carcinoma of the penis, genital ulcer diseases, and human papilloma virus transmission in association with male circumcision [59]-[64].

2. CIRCUMCISION AND HIV RISK

The prevalence rates of Hiv are strikingly variable in different parts of sub-Saharan Africa, a finding that has been attributed to varying rates of male circumcision in different parts of the continent and the assumption that male circumcision reduced susceptibility to Hiv, syphilis and chancroid [65]. The protective effects of circumcision in preventing Hiv infection can be traced back to the observational studies performed in the 1980s [66]-[67]. In addition to these observational studies, the recommendations for MC in sub-Saharan Africa were based on three landmark, randomized controlled studies in Africa demonstrating unequivocally that non-ritual, properly performed circumcision can reduce Hiv acquisition by 50% or more [68]-[70]. The results of the first of these trials in Orange Farm, South Africa were published in 2005. In late 2006, the remaining two randomized controlled trials of male circumcision in Africa were terminated by the National Institutes of Health (NIH) due to a preponderance of evidence supporting the protective effect of circumcision against Hiv infection. In March of 2007, the World Health Organization (WHO) and UNAIDS issued statements recommending circumcision as an intervention in heterosexual men to reduce the risk of acquiring Hiv infection. The findings from these trials, published between 2005 and 2007, confirmed the considerable benefit of circumcision in reducing Hiv incidence in men [68]-[70]. Westercamp and Bailey identified thirteen studies from 9 countries in order to evaluate the acceptability of MC in sub-Saharan Africa and to assess factors that will influence uptake of circumcision in populations where circumcision is not routinely and traditionally performed. It was found that the level of acceptability was fairly homogeneous and consistent in the evaluated nations and that 65% of uncircumcised men were willing to undergo circumcision. Acceptability among female partners was similarly high with 81% of women willing to circumcise their sons and 69% of women favoring circumcision for their partners[71]. Today, much of the discussion and the challenges revolve around development of sound policy and budgetary planning for widespread implementation of circumcision in Hiv endemic areas.

3. BIOLOGICAL RATIONALE FOR PROTECTIVE EFFECTS OF MC ON HIV ACQUISITION

A number of investigators have looked at the biological rationale for the protective effects of circumcision against Hiv acquisition and have found the effect biologically plausible. The Langerhans’
cells, macrophages, CD4+ T cells, and dendritic cells are amply found in the foreskin and are all considered to be Hiv target/receptor cells. Other important factors supporting the biological protective effect of circumcision include exposure of the inner mucosa of the penile shaft to vaginal and cervical fluids, as well as mucosal breach of the frenulum and the distal shaft due to the minor trauma of intercourse. Other studies have documented the lower incidence of genital ulcer disease in the keratinized penile skin of circumcised men, yet another factor that may be protective against acquiring Hiv infection [72] [64], [70],[73]-[77].

4. POTENTIAL COMPLICATIONS AND ETHICAL ASPECTS

Muula et al performed a systematic review of complications of male circumcision in Anglophone Africa in March 2007 and included such factors as indications for MC, complications reported, age of patients and category of circumcisers. 8 articles and 2 abstracts were found to be suitable for the analysis and the prevalence of reported complications ranged from 0% to 50.1%. One study on hemophilic patients reported a very high complication rate of with 50.1%, but excluding this series, most of the reported complications in the reported studies were of only minor severity without serious sequelae. Interestingly, the prevalence of complications of MCs performed by physician surgeons was not significantly different than those performed by non-physician health professionals. Given the relatively short duration of the studies and inadequate long-term follow-up, it is evident that the information pertaining to at least some adverse events (i.e. keloid formation) may not be properly captured to date. The authors concluded that there is inadequate data to conclusively assess the prevalence of complications of MC in the region [78]. The overall complication rate reported in the 1,475 patients constituting the intervention arm of the South African randomized study was 1.8% which is not dissimilar to rates reported in the West and the industrialized nations [79]. The reality of complications associated with any surgical procedure, as well as the complexities of the various religious, cultural, and societal values pertaining to circumcision mandates careful attention to the ethical aspects of circumcision in Africa and the developing world. Some of the medical, legal, and ethical aspects of treating sexual dysfunction in the Hiv positive male have been previously addressed [10], [80], [81]. In the context of circumcision as it relates to Hiv prevention, attention to human rights and ethical considerations are paramount, especially as they relate to children. Stemple points to the nature of the disease typically affecting the marginalized and the poor, as well as the fact that the spread of disease can lead to further inequality and hardship, to encourage debate that is focused on informed consent and children’s rights [82]. He also urges an increase in the use of treaty-based judicial mechanisms and rewarding human rights compliance with preferential trade agreements [82].

5. CIRCUMCISION OUTCOMES AND EFFECTS ON SEXUAL FUNCTION

Implementation of policies for mass circumcision as a measure to control the Hiv epidemic has raised concerns about possible impairment of sexual function. A number of investigators have evaluated the effects of circumcision on a range of sexual satisfaction measures. Despite conflicting results in some of the historical observational studies, most recent papers do not show evidence of adverse effects on sexual function [83]. Senkul et al. evaluated the effects of adult circumcision on sexual function using the Brief Male Sexual Function Inventory (BMSFI) and ejaculatory latency time in men circumcised only for religious or cosmetic reasons. After a 12 week interval, the BMSFI evaluation and ejaculatory latency time measurements were repeated and it was noted that despite a post-circumcision increase in the mean ejaculatory latency time which the authors suggested can be considered an advantage, differences in the mean BMSFI scores were not statistically significant [84]. Similarly, a small prospective study of the effects of circumcision using the BMSFI administered before and after the procedure with a minimum 12 week follow up revealed no statistically significant difference in the BMFSI composite scores of reported sexual drive, erection, ejaculation, problem assessment, or overall satisfaction [85].

In the randomized trial of male circumcision performed in Rakai, Uganda, Kigozi et al investigated self-reported sexual satisfaction and function among 4456 sexually experienced Hiv-negative males. The study participants were randomized such that 2210 in the intervention arm had immediate circumcision and 2246 in the control arm had the procedure delayed for 24 months. Overall, less than 2% of the participants in either arm of the study reported problems with sexual satisfaction and function at 6,12, and 24 month follow-up. After a review of all analyzed domains, the authors concluded that sexual satisfaction and sexual function are not adversely affected by circumcision [86].

The effect of adult male circumcision on men’s sexual function and pleasure was also evaluated by the investigators of the previously reviewed Kisumu, Kenya, randomized controlled trial of circumcision to reduce Hiv. The arms of the study included immediate or delayed circumcision after 2 years similar to the Rakai trial. Both the circumcision and control groups had significantly decreased rates
of any sexual dysfunction from 23.6% and 25.9% at baseline to 6.2% and 5.8% at month 24 [87]. Changes pertaining to increased penile sensitivity were reported by 64.0% of the circumcised men and approximately half of the circumcision group reported significantly increased ease of reaching orgasm at month 24. These changes notwithstanding, the authors had concluded that male circumcision was not associated with sexual dysfunction [87]. The same group examined male circumcision outcomes among healthy, sexually active, uncircumcised, Hiv-seronegative men aged 18-24 in an African setting and reported 27 adverse events in 26 procedures (1.8%) out of a total of 1,475 procedures. It was further reported that among the study participants, 92% were “very satisfied” with the procedure outcome 3 months after the surgery [79]. (Table 1) below is a summary of these findings:

6. THE FUTURE AND GLOBAL HEALTH POLICY

Dickerman has authored an article provocatively titled: “Circumcision in the time of Hiv: when is there enough evidence to revise the American Academy of Pediatrics’ policy on circumcision?” where he strongly urges the Academy to issue more direct statements in support of the medical benefits of circumcision [88]. Comparative evaluation of the costs of neonatal circumcision in the United States in relation to later health benefits has confirmed that the post-neonatal circumcision is significantly (10X) more expensive than neonatal circumcision and that the latter will confer life-time benefits at little or no cost [89]. Although these findings are not directly applicable to the setting in sub-Saharan Africa, it is likely that the future trend for Hiv prevention will gradually evolve toward earlier circumcision. Any global policies for undertaking large scale circumcision programs must take into consideration the important ethical dilemmas as well as the delicate cultural sensitivities of each region. The landmark findings of the 3 randomized controlled trials on the protective effects of circumcision on reducing Hiv acquisition are major breakthroughs in the public health arena and will hopefully have a meaningful impact in areas ravaged by the epidemic. However, health care practitioners and global health policy engineers cannot overstress the dictum that circumcision will be most effective in disease prevention if combined with patient education and low-risk sexual behavior.

III. HIV IN WOMEN

1. INTRODUCTION

In almost all societies, women are disadvantaged compared to men to a greater or lesser extent. This has a significant impact on women’s health. Nowhere is this discrimination more vividly seen than in Hiv infection. Some of the sociocultural factors that prevent women from obtaining good quality health services and attaining the best possible level of health are included in the table below: [90]

It is estimated that up to 17 million women over the age of 15 are infected with HIV worldwide. Globally, this represents 50% of the disease burden. However, in sub-Saharan Africa, young women may be three times more likely to be infected than young men [91].

Women in high-income countries seem to find it particularly difficult to come forward to discuss their sexual problems, so that as few as 3% of women with sexual dysfunction have discussed these issues with a health care professional [92], [93]. Reasons given by women for non-consultation include a “perceived lack of perception or lack of bothersomeness of their problem”, not perceiving it as medical problem and embarrassment [94]. It may be surprising that as few as 4% of HIV health care providers in the UK ever ask their HIV positive female patients about sexual functioning [95]. This neglect of clinical care is likely underpinned by ignorance, lack of time and embarrassment [95], [96].

Sexual functioning issues in women with HIV in developing countries worldwide are more likely to be focused on male coercive sex and domestic violence[97]-[99]. Gender power differentials and poverty can force women to engage in unsafe forced sex in order to secure food and economic security for themselves and their children [99].

The best predictors of female sexual dysfunction (FSD) in general are lack of general emotional well being states found in conditions such as depression, anxiety and relationship difficulties [100], [101]. The evidence to date pertaining to FSD in HIV positive women bears this out, although important organic correlates may co-exist.

Overall, the literature on the interaction of HIV and FSD is sparse and not of the highest quality. The majority of the reported evidence comes from Europe and North America.

2. RATES OF SEXUAL DYSFUNCTION AND GENERAL ETIOLOGY.

a) Studies reported pre HAART

Small studies on socially disadvantaged and intravenous drug user women in the 1990s in North America suggested that FSD was commoner in women who were HIV positive compared to HIV negative, and that a sexual adjustment period after being told the diagnosis persisted for up to a year [102], [103]. In spite of needing to adjust to having HIV, 44% had resumed sexual intercourse after 4 weeks [103]. Hypoactive sexual desire disorder (HSDD)(DSM-III-R) was reported by 39% of such women over the previous 4 weeks in the absence of clinical depression [104]. Brown and colleagues carefully followed up 54 HIV-positive women from the US armed forces for over 5 years [16]. Heterosexual intercourse was the presumed mode of transmission in most cases. By their third follow up visit, 14 of the 28 still attending had developed HSDD (DSM III-R) for at least 4 weeks in the absence of psychiatric illness [105]. These rates of HSDD appear significantly higher than the 16% recently reported in a large general population study[106]. However, it is questionable whether HSDD reported for only 4 weeks is clinically meaningful [107].

b) HAART era- quantitative studies

Denis and Hong, in an Australian study in 2003 compared 43 HIV+ to 73 non HIV women from a community sample. They pointed out that the two groups were not ideally matched, particularly in regard to the level of psychosocial stress that HIV itself can impart. Using an adapted version of the Sexual Function Questionnaire (SFQ) for women they found the HIV + women had significantly lower total SFQ scores, plus lower scores on a number of the subscales including sexual interest, activity, satisfaction and orgasm [108]. Two clinically based European surveys [20],[21] suggest that such sexual problems, particularly low desire, might be caused either directly by protease inhibitors (PIs) or as a secondary effect via iatrogenic lipodystrophy (see below)[46], [109]. Unfortunately the data for women in these studies are not reported separately. A recent Italian cohort study demonstrated a strong correlation between FSD and self reported non adherence to HAART (the authors offer a number of explanations for this including medication side effects and advancing HIV disease)[9]. Two further studies on women with HIV; one European cross sectional and the other from New York comparing cross sectional data pre and post HAART do not show that PIs or indeed any antiretrovirals have any great impact on women’s sexual dysfunction or psychosocial status [110], [111]. This contention is supported by data that women in general in the HAART era perceive these medication as beneficial and in a positive light compared to the pre-HAART era [112].

Three recent cross-sectional studies show strong associations between FSD and psychiatric illness (Table 3) [110], [113], [114].

c) HAART era- qualitative studies

Further understanding of the psychosocial issues that underpin FSD in the HAART era has been explored in recent qualitative studies [115], [116] (Table 4).

3. GENERAL PSYCHOSOCIAL MANAGEMENT

Studies looking at socially disadvantaged HIV-positive women in North America suggest that focus groups may enhance the social support of these patients, and that using psychological coping styles rather than physical coping mechanisms (i.e. enhancing positive cognitions rather than attending to practical issues) may be associated with significantly less distress and depression [117], [118].

4. OTHER ISSUES

a) Genital arousal

There are good theoretical reasons as to why genital arousal in HIV+ women might be impaired i.e. genital arteriosclerosis and impaired vascular response because of autonomic neuropathy. However, there are no studies directly addressing these issues. Indirect evidence comes from a number of studies such as the large Women’s Interagency HIV study in the USA where insulin resistance was found to be significantly associated with HIV (compared to HIV negative women) - particularly with use of the NRTI stavudine [119]. Arteriosclerosis has been found to be associated with HIV infection itself, likely via local cytokine release, the duration of infection, age, abnormal fat distribution, nadir CD4 count and protease inhibitors [120], [121]. Screening for autonomic neuropathy by history suggests it is a not uncommon problem in women and men in a population with a mean CD4 count of just over 300 [122].

b) Body image

The pathogenesis of HIV associated lipodystrophy is multifactorial. However, the protease inhibitors have been incriminated in fat accumulation and the nucleoside analogue reverse transcriptase inhibitors with lipoatrophy [123]. A recent pan USA cross sectional study involving 183 HIV+ women and 142 well matched negative controls however demonstrated that peripheral fat atrophy (face, cheeks, arms, legs, buttocks) occurred in 28% of the HIV women but only 4% of the controls. Central (visceral) hypertrophy was present in around 60% of both groups, was associated with HAART use, and was not associated with peripheral atrophy [124]. Two further HIV negative matched cross sectional studies in women from the USA confirmed that lipodystrophy is significantly associated with poor body image and depression and may result in patients stopping HAART [125]-[127]. In an African setting fat redistribution (facial and buttock atrophy and abdominal adiposity) can render these women easily recognisable, and hence significantly effects psychological and social domains of the quality of women’s lives to the extent that they feel stigmatised and marginalized socially and sexually [128]. Exercise training (level 1) and facial lipofilling with either autologous fat or polylactic acid infiltrates (level 3) can result in a marked improvement in self image and self esteem [129], [130].

### c) Sex hormones

When HIV disease becomes advanced in women, low body mass index is associated with significant reduction in free testosterone [131]. An early studies suggested that iatrogenic visceral lipodystrophy was associated with significantly raised free testosterone levels, but this was not confirmed in a later study of similar design [132], [133]. In terms of sexual desire and arousal, it is likely that some women are more sensitive than others to falling levels of androgens [134]. Replacing testosterone in women with HIV associated weight loss appears to be safe and well tolerated at least in the short term (level 2) and significantly increases muscle strength (level 2) [135, 136]. Its effect on sexual responses in women are not known.

It has been argued that oestrogens may be protective against Tat protein induced inflammatory pathways in human vascular endothelium induced arteriosclerosis, and may be protective against HIV dementia [137], [138]. However, oestrogen containing contraceptives may interact with antiretrovirals and consideration should be given to this therapeutic scenario in each individual case, along with consideration of dual methods of contraception [139].

d) Unsafe sex

A French cohort study followed up 176 men and 47 women over a median of 24 months who initially had primary HIV infection. Sexual behaviour at risk for transmission of HIV (SBR) was defined as inconsistent use of condoms at sex, compared with always using condoms. SBR rates for women were higher than for men, but mostly occurred with seropositive partners. After a mean of 5 year follow up, 21% of patients had had SBR with a casual partner (9% at study outset). SBR sex with steady partners however remained constant at about 5%. Other risk factors for SBR were the onset of lipodystrophy and anxiety/depression [140].

Adolescents who had acquired HIV non sexually either at birth or via transfusion appear to have little knowledge of safer sex, and in an African context are both marginalized by short stature and low weight as well as worrying if they can ever marry [141], [142].

However, condom use in post menopausal women with HIV does not appear to decrease after the menopause, unlike typical HIV negative women [143].

In a recent UK study 80% of women who attended a clinic for emergency contraception after unprotected sex had not heard of post exposure HIV prophylaxis [144].

5. HUMAN PAPILLOMA VIRUS (HPV) AND SEXUAL DYSFUNCTION

Human papilloma virus (HPV) causes benign condylomata or genital warts and is known to have oncogenic strains. More than 120 HPV subtypes have been identified. Of the 120 subtypes of HPV, 30 infect genital epithelium. HPV is spread through direct skin-to-skin contact during oral, genital, or anal sex with an infected partner. Genital warts can
be caused by strains 6, 11, 30, 42, 43, 44, 45, 51, 52 and 54. However, types 6 and 11 are responsible for 90% of genital warts cases [145]. Most infected individuals do not develop genital warts: the rate of subclinical infection is high. HPV is also associated with cervical cancer and anal cancer; types 16 and 18 account for 70% of HPV associated cancers including oral cancers [146]. The incidence of HPV infection has increased in the last 35 years, likely the result of earlier age of initial sexual contact and an increased number of sexual partners [145]. The estimated prevalence rate of HPV genital infection in the US adult population is 10-20 percent. The incubation period of HPV varies from 3 weeks to 8 months, with a mean of 2-3 months after initial contact [145].

There are now two prophylactic vaccines for HPV; a bivalent vaccine Cervarix which induces protective immunity against HPV 16 & 18; and a quadrivalent vaccine, Gardasil, a quadrivalent vaccine inducing protective immunity against HPV 6, 11, 16 & 18 [147], [148]. There is also unpublished evidence that these vaccines reduce both the incidence and virulence of genital cancers in men. Public health officials in Australia, Canada, Europe and United States recommend vaccination of young women against HPV to prevent cervical cancer and genital warts and possibly oral cancers.

There is currently conflicting data to link sexual problems including emotional distress in men and women with HPV infection [149]-[153]. In practice, many clinicians managing men and women with genital warts realize the association between genital warts and changes in sexual functioning and relationship issues. Clearly more research is required.

6. GENITAL HERPES

Genital herpes (GH) is usually caused by type 2 herpes simplex virus (HSV) but type 1 is becoming an increasingly common cause nowadays [154]. A recent population study in the USA estimated that 17% of those between the ages of 14 and 49 had acquired HSV type 2 [154]. Up to 90% of those who acquire HSV type 2 antibodies have never knowingly had a clinical outbreak of GH [155]. Symptoms can be severe in a primary outbreak, particularly in women, where fever, headache, malaise and myalgia are reported in up to 70% of cases [156]. Classically, the lesions progress from erythema to vesicles to pustules, and then break down to form erythematous-bordered painful ulcers [156]. The ulcers heal by crusting in non moist areas. About 30% of patients have a milder clinical course, likely either because of pre-existing HSV 1 or HSV 2 [156].

Routine diagnostic testing is either via cell culture or nowadays, increasingly commonly in house polymerase chain reaction testing [157].

Patients are usually in too much pain to even consider intercourse during a primary infection. Untreated, the symptoms can persist for weeks, but antivirals such as acyclovir can resolve the symptoms within days. Recurrences of genital herpes are less common where the initial infection was HSV type 1 [158].

Many patients have frequent recurrences. These are usually confined to a small area of the genitals and rarely persist for longer than 7 days even if untreated. It is not so much the pain of the genital lesions that may prevent some patients from having intercourse but rather the concern of transmission even if they do not have any current outbreak. Other important patient issues are the stigma of having a sexually transmissible disease as well as the psychosocial and psychosexual issues that may accompany recurrences in some vulnerable patients.

There is little doubt that recurrent GH is associated with psychological distress and psychosexual problems. However opinion differs as to whether these problems are the result of the stress of having genital herpes, caused by pre-existing stressors or a combination of the two [159],[160]. Many patients with recurrent GH complain of feeling low in mood, tense and having sleep disturbances for a day or two prior to a recurrence. This may be because of release of systemic cytokines prior to the clinical manifestations of the recurrence [159].

Disclosure to partners may be problematic. Patients with recurrent GH appear less likely to tell partners their diagnosis if they perceive them as "casual" and if they are depressed. Decisions to inform partners are more based on perceived likelihood of discovery and honesty rather than control of transmission [161].

Patients who have frequently recurrent GH need to be empowered with information regarding their illness and likely transmission to others. Even if they abstain from intercourse at outbreaks there is about a 5% chance per year that the partner will acquire GH (via asymptomatic shedding of virus) [162]. This rate can be halved if the patient takes continuous antiviral prophylaxis and is significantly decreased with regular condom use [162], [163]. Patients should be told that even if the recurrence is not in the genital area e.g. buttock region, that asymptomatic genital shedding of virus is a common contemporaneous event [164].

Continuous antivirals for patients with regular and frequent recurrences, such as acyclovir, valacyclovir or famcyclovir will significantly decrease the clinical outbreak rate, increase the quality of the patient's life in general, decrease anxiety, illness concern and the chance of transmission at sex [162], [165], [166]. It is
of psychological distress compared to those who did not suffer sexual abuse in the past [179]. A Danish study of 277 men and women based in general practice showed that 10% of those who found out they were CT positive ended their current acquisition onto others rather than themselves [175]. Both qualitative research and a thematic analysis of the literature strongly suggest that CT positive patients are at increased risk of psychological distress [176], [177]. In particular, women tended to blame themselves for acquiring CT and feel stigmatised, whereas men are less concerned in general about CT, less willing to disclose to partners and tend to project the blame of infection onto others rather than themselves [175]-[177]. A Danish study of 277 men and women based in general practice showed that 10% of those who found out they were CT positive ended their current relationship as a direct result of the infection [178]. A history of past sexual abuse in patients with recurrent bacterial STIs was associated with a higher degree of psychological distress compared to those who did not suffer sexual abuse in the past [179].

Consistent and correct condom usage has been shown to confer a statistically significant degree of protection against bacterial STIs such as CT and Gc [180]. CT and Gc are the most likely organisms to cause acute PID but other conditions such as bacterial vaginosis (see BV section) and Mycoplasma genitalium may be involved [181], [182]. Gonococcal PID is usually more severe, but less likely than CT to cause long term sequelae. The incidence of PID in women who are CT infected ranges from 5% to 30% [183]. The important outcomes of PID are pelvic pain, infertility and ectopic pregnancy. Deep dyspareunia may or may not be present with background pelvic pain- it is associated with anxiety, depression and a history of sexual abuse [184].

Young women may continue to have intercourse in spite of dyspareunia because they feel sexual intercourse affirms them being a normal woman and to satisfy their partner’s sexual needs [185].

Tubal infertility can be associated with distress, anxiety, depression and relationship problems. In one study of tubal infertility about a third of women felt this had a negative effect on their sex lives [186].

7. CHLAMYDIA TRACHOMATIS (CT), GONORROEA (GC) AND ASSOCIATED PELVIC INFLAMMATORY DISEASE (PID)

Recent WHO estimates estimate the prevalence of CT in European women as between 2.7% and 8.0%, with rates of up to 13% in African countries [172]. Rates for Gc world-wide ranged from between 0.1% and 3.5% and resulted in a total of 62 million cases between 1995 and 1999 [173].

Mass screening programs are important in order to decrease the prevalence of CT and its complications. Careful assessment of 20,000 men and women randomly screened from general practice in the UK showed that the screening process did not have a negative impact on psychological well being where the results were negative; in fact they suggested that the process can lead to a general decrease in anxiety [174]. Both qualitative research and a thematic analysis of the literature strongly suggest that CT positive patients are at increased risk of general anxiety, fear of infecting their partner and concern about infertility [175]-[177]. In particular, women tended to blame themselves for acquiring CT and feel stigmatised, whereas men are less concerned in general about CT, less willing to disclose to partners and tend to project the blame of acquisition onto others rather than themselves [175]-[177]. A Danish study of 277 men and women based in general practice showed that 10% of those who found out they were CT positive ended their current relationship as a direct result of the infection [178]. A history of past sexual abuse in patients with recurrent bacterial STIs was associated with a higher degree of psychological distress compared to those who did not suffer sexual abuse in the past [179].

Consistent and correct condom usage has been shown to confer a statistically significant degree of protection against bacterial STIs such as CT and Gc [180]. CT and Gc are the most likely organisms to cause acute PID but other conditions such as bacterial vaginosis (see BV section) and Mycoplasma genitalium may be involved [181], [182]. Gonococcal PID is usually more severe, but less likely than CT to cause long term sequelae. The incidence of PID in women who are CT infected ranges from 5% to 30% [183]. The important outcomes of PID are pelvic pain, infertility and ectopic pregnancy. Deep dyspareunia may or may not be present with background pelvic pain- it is associated with anxiety, depression and a history of sexual abuse [184].

Young women may continue to have intercourse in spite of dyspareunia because they feel sexual intercourse affirms them being a normal woman and to satisfy their partner’s sexual needs [185].

Tubal infertility can be associated with distress, anxiety, depression and relationship problems. In one study of tubal infertility about a third of women felt this had a negative effect on their sex lives [186].

IV SEXUAL DYSFUNCTION AND CHRONIC PROSTATIS/CHRONIC PELVIC PAIN SYNDROME (CP/CPPS)

1. INTRODUCTION

In spite of the known impact of prostatitis-associated symptoms on sexual dysfunction, limited data is available to suggest a proven association between the two entities. Since a high percentage of men with prostatitis-like symptoms do not have a known infectious or inflammatory prostate-related etiology for their symptoms , the investigation of the relationship is complicated and must be based on the generally accepted definition of the National Institutes of Health(NIH) prostatitis panel (Table 5) [187], [188]. The evaluation of the effects of prostatitis on sexual function should take into consideration the adverse effects of drug therapy of CP/CPPS on sexuality, as well as the more interesting direct interactions between prostatitis symptoms and disorders of libido, erectile function and ejaculation. In this context, it is noteworthy that some investigators are convinced that “prostatitis” does not necessarily impair sexual function, whereas others suggest a rather strong association [189], [190]. The failure to demonstrate a concrete link between sexual dysfunction and prostatitis may be based on the following two factors: a) The use of unaccepted classifications of “prostatitis” and b) analysis of a generally dysfunctional or disturbed sexuality without clear definition of the different entities. An acceptance of the new prostatitis definition and a clear identification of the items of disturbed sexuality are necessary to improve the understanding of the association.
2. PROSTATITIS – CLASSIFICATION AND RELATED UROGENITAL INFECTIONS INFLAMMATIONS.

The NIH classification of prostatitis syndromes is supported by the International Prostatitis Collaborative Network (Table 5) [187].

Type I, Acute Bacterial Prostatitis is a severe infection with fever, inflammatory host response, and voiding disturbances excluding active sexuality. Type IV prostatitis is considered an asymptomatic inflammatory condition in patients in whom white blood cells are found in prostatic tissue or in prostatic secretions and is thus difficult to relate to sexual dysfunction. Therefore, when considering disturbed sexuality, only type II Chronic Bacterial Prostatitis and type III Chronic Prostatitis/Chronic Pelvic Pain Syndrome have to be considered.

Chronic Bacterial Prostatitis (NIH II- typically caused by coliform bacteria) is a rare disease in about 5 percent of all men presenting with “prostatitis” symptoms which are indistinguishable from CP/CPPS [188], [191]. Recurrent UTIs in the history and the evidence of bacteriospermia in semen are other clinical findings common for this entity [192]. In CP/CPPS (NIH III), men with “prostatitis” symptoms, mainly pelvic pain, are classified to the inflammatory (NIH III a) or non-inflammatory (NIH III b) group. The differentiation is made by the finding or exclusion of leukocytes in the urine after prostatic massage, EPS or in semen [187], [188], [191], [192]. It is an ongoing debate whether both entities are really to be considered as different [193], [194]. There remain also major concerns regarding the validity of the NIH-CPSI questionnaire as instrument for diagnosis, classification and severity of CP/CPPS [193], [194]. The WHO has pointed out that the symptoms of CP/CPPS may relate not only to pathology in the prostate but also to the whole male pelvic genital region, especially to the epididymides and the seminal vesicles [195]. There is little direct evidence that sexually transmitted bacteria such as Chlamydia Trachomatis or Mycoplasma species cause CP/CPPS, in part due to problems of urethral contamination of prostatic secretions [187], [196-198]. Hopefully, the interaction between IL-8 and antichlamydial mucosal IgA in the ejaculate provides a new opportunity to establish a better organ-related diagnosis of potentially sexually transmitted infections of the prostate in the future [196].

3. ANALYSIS OF THE LITERATURE

We searched the PubMed database covering the last 8 years (English-German) using the search terms: urogenital infections, prostatitis, chronic urethritis, Chronic Bacterial Prostatitis, CP/CPPS, MAGI, ejaculate infection, ejaculate inflammation, sexual dysfunction, erectile dysfunction, libido disorders, sexual excitation, ejaculatory dysfunction, premature ejaculation, ejaculatory pain, loss of ejaculate volume. Furthermore, all supplements (2000-2008) were included. These topics have been looked through for items addressing sexual disorders in their relation to infections/inflammations of the urogenital tract.

These searches identified a total of 62 articles. This was followed by a review of the titles and abstracts following the modification of the US Department of Health and Human Services (1992)* giving an evidence-based guideline. 51 papers met the criteria for inclusion. Astonishingly, no systematic reviews or meta-analyses could be included.

Most of the papers detailed results of case series and cohort studies (Level 2 and 3 evidence).

4. SEXUAL DYSFUNCTION AND "PROSTATITIS" SYMPTOMS

Early anecdotal experience in the 1980s suggested a significant association between "chronic prostatitis" and sexual dysfunction [199]. Later on, these postulated interactions between chronic prostatitis, the psychological and physical health status and the direct influence on sexual activity were addressed in two overviews [200], [201]. In 2005, Lutz et al were the first to analyze systematically the interaction between urogenital (pelvic) pain and sexual function [202]. The authors used the NIH-CPSI with a cutpoint of >4 in the pain score and the Brief Male Sexual Function Inventory [193], [203]. In this study men with significant “pelvic pain” had a higher chance of suffering from ED than patients without pelvic pain (level 3 evidence). Recently, Marszalek et al analyzed the prevalence of CP/CPPS in an urban population (Vienna) in association with erectile function [204]. The study confirmed a significant correlation between CP/CPPS symptoms measured by the NIH-CPSI and erectile dysfunction measured.

NIH (National Institutes of Health)
by the IIEF (level 2 evidence). Using the same questionnaires Qiu et al. were not able to confirm such a significant correlation (level 3 evidence) [205, 206].

4 studies analyzed the percentage of ED measured by the IIEF in men suffering from CP/CPPS according to NIH criteria (Table 6). Anderson et al. analyzed 146 patients with CP/CPPS defined by NIH criteria and stated erectile dysfunction in 45%, meaning a percentage of 31 percent (level 3 evidence) [207]. Liang et al. analyzed the prevalence of sexual dysfunction, meaning erectile dysfunction and premature ejaculation in “prostatitis” patients demonstrating a prevalence of ED in only 15% (level 3 evidence) [208]. Most of these patients revealed erectile dysfunction and/or problems with premature ejaculation: 7.7% suffered from both pathologies. In a recently published study from China, 296 participants seeking help for CP/CPPS have been evaluated, 72.3% reported sexual dysfunction (level 3 evidence) [209]. In this study, in most of men ejaculatory dysfunction was common and in men, reporting both ED and ejaculatory difficulties, worse CP/CPPS symptoms and a reduced quality of life became evident (level 3 evidence). Finally, one study from Italy has to be mentioned. This study included not only men with CP/CPPS, but also men with CBP. The authors demonstrated an incidence of ED in about 23% of the patients (level 3 evidence) [210].

In conclusion, symptoms of sexual dysfunction, especially ED, do occur in between 15 to 72 percent of all patients seeking help for “prostatitis” related symptoms. This is particularly notable in cases of CP/CPPS. A significant correlation between severity of ED and increasing CP/CPPS symptoms remains debatable. Unfortunately, age-matched control studies including the general accepted risks for ED are not published in this context to date. Until an evidence-based confirmation of this association becomes available, it is difficult to ascertain the validity of the proposed links between the two conditions.

Another very important concern is the interaction between CP/CPPS symptoms and ejaculatory dysfunction. As already mentioned, two Chinese studies demonstrated the relevance of premature ejaculation (PE) in symptomatic prostatitis patients [208], [209]. This finding was later corroborated by a study from Turkey where a modern definition of PE using the intravaginal ejaculation latency time was utilized: 77% of all men with CP/CPPS suffered from this disorder (level 3 evidence) [211]. In a very similar study from Italy, Screponi et al. reported a high incidence of “inflammatory prostatitis signs” in men with PE [212]. Their findings are more controversial and debatable due to the use of poorly-defined “prostatitis” diagnostic tools (no evidence).

Besides PE, “prostatitis” patients may be bothered by ejaculatory pain [213]. Despite lack of concrete evidence, many patients may be encouraged to refrain from ejaculation when suffering from this condition [189]. Conversely, other investigators have suggested that improvement of prostatitis symptoms may follow better prostatic fluid drainage with regular sexual activity and increased ejaculatory frequency [214] (no evidence).

5. “PROSTATITIS” AND BPH

The impact of infection/inflammation on the pathogenesis of BPH is the subject of ongoing discussions. It is well known that histologically proven inflammation can be demonstrated in the majority of BPH pathologic specimens and that the presence of inflammation may be a predictor of progression outcomes of BPH (level 1 evidence) [215]. The interaction between chronic immune response and fibromuscular growth of BPH is one possible explanation for the similar pathogenesis [137]. A second arguably more important pathway may be the similar cytokine expression by epithelial and stromal prostate cells in men suffering from BPH and CP/CPPS [216]. In men presenting with LUTS, an important diagnostic goal is to establish or to exclude the pathogenesis of the symptoms as being related to BPH [217]. Usually, the AUA Symptom Index or the IPSS are recommended for symptom assessment. A recommendation for special questionnaires pertaining to other items such as altered sexual function is not routinely given [217]. The Alf-One study elegantly demonstrated the direct interaction between severity of LUTS and sexual dysfunction, especially ejaculatory disorders (level 2 evidence) [218]. The key message of this study and consecutive papers is that in sexually active men with LUTS suggestive of BPH, those with painful ejaculation have more severe LUTS, more frequently suffer from ED, and have reduced ejaculatory
6. THERAPEUTIC CONSIDERATIONS.

The 6th International Conference on New Developments in Prostate Cancer and Prostate Diseases in Paris 2005 summarized all types of therapy based on an evidence-based approach for all types of prostatitis and CP/CPPS [188]. In this context, it seems to be the consensus that only therapeutic strategies reducing symptoms, especially against pelvic pain, are of relevance in relation to changes of sexual function. The use of alpha-blockers has to be addressed since one study demonstrated a special benefit on painful ejaculation in LUTS patients. In patients with CP/CPPS, alpha-blockers are often prescribed as the first therapeutic choice for several reasons [222], [223]. Besides the proven efficacy for LUTS, the blockage of alpha-adrenergic receptors located in the nervous system has been discussed as a possible strategy in long-term pain syndromes [224]. Furthermore, a direct effect on neurogenic inflammation has been noted [223]. Concerning CP/CPPS, a new randomized study using alfuzosin did not demonstrate a reduction of symptoms in comparison to placebo (level 2 evidence) [225]. This outcome is contrary to the widespread use of alpha-blockers in all types of prostatitis and especially not in concordance with several trials in the last decade. Nevertheless, there is similarity to the study of Alexander et al who did not find a reduction of symptoms in a 4-arm study using a fluoroquinolones, tamsulosin, both drugs or placebo (level 2 evidence) [226]. Discussing these negative findings, Weidner argued in 2004 against the efficacy of alpha-blocker therapy due to highly variable treatment periods, different populations, and inhomogeneous inclusion criteria of the different studies [227]. In conclusion, it is questionable whether the effects of alpha-blocker therapy are thoroughly directed against the symptoms that comprise CP/CPPS. A subgroup of men with proven subvesical obstruction and/or proven CBP (NIH II) may benefit from alpha blockers, but adverse effects on ejaculatory function typical for at least some alpha-blockers have to be taken into account. Unfortunately, all other types of treatment of CP/CPPS have been evaluated without a clear effect on sexual symptoms in comparison to placebo including phyotherapeutic agents such as pollen extract, quercetin or saw palmetto [223], [228]. Unfortunately, a new randomized study with pollen extract in patients with inflammatory CP/CPPS did not show an improvement of the mean sexuality domain of a life satisfaction questionnaire, although compared to placebo, the pollen extract significantly improved total symptoms, pain and quality of life (level 2 evidence) [229]. These results are to be interpreted as a weak interaction between CP/CPPS symptoms and disturbed sexuality.

Concerning the combined use of alpha-blockers and a PDE 5-inhibitors in men suffering from LUTS and ED, it seems to be the consensus that this combination may be more effective than each drug administered alone [230]. Stimulated by these results, different authors speculate on the benefit of PDE 5-inhibitors in CP/CPPS. A relaxation of prostatic duct smooth muscles increasing the washout of prostatic reflux products interacting with pain receptors was suggested as one beneficial pathway [231]. Furthermore, the better arterial vasodilatation provided by the degradation of cGMP into GMP catalyzed by cyclic nucleotide phosphodiesterase enzymes in the prostate has been suggested to be useful in the treatment of CP/CPPS [231], [232]. Unfortunately, recently published studies concerning the interaction of the effect of PDE 5-inhibitors on CP/CPPS symptoms and disturbed sexuality do not show significant effect either due to the study design or to the missing correlation between CP/CPPS symptoms and ED (Table 7) (no evidence).

V. SEXUAL, SOCIO-CULTURAL AND ECONOMIC ISSUES OF HIV WITH PARTICULAR REFERENCE TO SUBSAHARAN AFRICAN WOMEN

1. INTRODUCTION

Every day, over 6800 persons become infected with HIV and over 5700 persons die from AIDS, mostly because of inadequate access to HIV prevention and treatment services [91]. AIDS continues to be the single largest cause of mortality in sub-Saharan Africa and of the global total of 2.1 million [1.9 million–2.4 million] adult and child deaths due to AIDS in 2007, 1.6 million [1.5 million–2.0 million] occurred in sub-
Saharan Africa. There are an estimated 11.4 million [10.5 million–14.6 million] orphans due to AIDS1 in this region [91].

Women and young people are especially vulnerable to HIV. Half of all new infections occur in young people aged 15-24 and young women account for 62% of the 11.8 million people living with HIV [233].

Differences in the spread of the epidemic can be accounted for by a complex interplay of sexual behavior and biological factors that affect the probability of HIV transmission per sex act and sexual behavior patterns are determined by cultural and socioeconomic context [234]. In sub Saharan Africa the subordinate position of women, impoverishment and decline of social services, rapid urbanisation and modernization, wars and conflicts have contributed to extensive spread of HIV [234].

In addition to these macrocosmic parameters there are microcosmic influences to this epidemic. Stulhofer’s study on Croatian youth indicates that peer pressure, sensation seeking, personal risk-assessment, behavioral intention, condom use at first sexual intercourse and sexual victimization were significant predictors of sexual risk taking behaviors [235]. An integrated sociobehavioral approach to communication as a means of prevention of HIV/AIDS is thus of vital importance [236].

2. THE FEMINIZATION OF HIV

In sub Saharan Africa, young women (15-24 years) are approximately three times more likely to be HIV infected compared to young men of the same age [237]. 50% of infected people worldwide are women and half of new infections occurred between spouses with women often at risk from their main male partner [238]. This has been described as the “feminization of HIV/AIDS” [238].

Gender based violence (GBV) is the most significant reason for women’s greater vulnerability to HIV. It is partly explained by women’s inability to negotiate the terms and conditions of sex as well as very high levels of sexual and domestic violence [239]. A study of more than 1500 South African women indicates that “women with violent or controlling male partners are at increased risk of HIV infection. [239]” A review of research articles from 1996 to 2002 found 9 studies showing that women who experienced sexual coercion were more at risk of HIV transmission [239]. Ackermann looked at the social factors that make South African women vulnerable to HIV infection and concluded that the degree to which women are able to control various aspects of sexual lives is critical to HIV prevention [240]. The high rate of rape, the unfavorable economic position of women and the inability to insist on condom usage render these women powerless to protect themselves against HIV/AIDS [240], [241]. Poor women are especially vulnerable to coercion from and compliance to their male partners [236].

A study examined gender attitudes and sexual violence-supportive beliefs (rape myths) in a sample of South African men and women at risk for HIV transmission. The authors speculated that women’s risks for STI/HIV are the product of partner characteristics and male dominated relationships. Some of these men’s characteristics include a sexual assault history and rape myth acceptance, along with alcohol and other drug use history [241]. Studies conducted in the USA show that women in violent or abusive relationships are less likely to use condoms, more likely to incur abuse as a result of requesting condoms and more likely to contract a STI than women who have not been in violent relationships [241].

This is supported by research conducted in a township in Cape Town [241]. A total of 40% of the women surveyed had been sexually coerced. They were significantly more likely to have exchanged sex to meet survival needs, to have had multiple male sex partners, greater rates of unprotected vaginal intercourse, lower rates of condom use, more sexual

AIDS cases due to the perinatal transmission of HIV infection, by year of diagnosis, 2001-2005, United States [233].

Contacts involving blood and greater rates of STI’s. This suggests that the potential for women to reduce their risks for STI/HIV is seriously limited by socially constructed gender roles and sexual scripts [241].

Intimate Partner Violence (IPV) or “Femicide” is violence perpetrated by an intimate partner [237]. Globally between 10 and 69% of women report physical abuse by an intimate partner at least once in their lives. Between 6 and 47% of adult women worldwide report being sexually assaulted by intimate partners in their lifetime. Between 7 and 48% of girls and young women age 10-24 years report their first sexual encounter as coerced [237]. Gielen et al reviewed 35 US studies on the intersection of HIV and IPV. HIV positive women appear to experience any IPV at rates comparable to HIV negative women.
from the same underlying populations. However their HIV positive women’s IPV seems to be more frequent and more severe than women who are HIV negative. Their research suggest interventions need to focus on both causal pathways of IPV and HIV [242].

The intersection of IPV, GBV and HIV is explained by biological as well as socio-cultural and economic factors [237]:

a) Direct transmission through sexual violence [237]

The biological risk of transmission of forced coercive sexual intercourse with an HIV infected partner is determined by type of exposure (vaginal, anal or oral). HIV risk increases in presence of other STI’s and also degree of trauma, vaginal lacerations and abrasions that occur when force is used. Vaginal tracts of younger women are immature and tear easier during sexual intercourse thus increases risk. Two studies form USA suggest that while women who are raped are at high risk for pre-existing STI, sexual assault itself presents a small but substantial additional risk of acquiring STI (236).

b) Indirect transmission through sexual risk taking

Studies show that women’s experience of violence is linked to increased risk taking. This includes multiple partners, non-primary partners or engaging in transactional sex [237]. In Zimbabwe, Kenya, South Africa and Zaire increasing financial insecurity that exists among female –headed households makes transactional sex a “rational means of making ends meet [236].” Jewkes and colleagues have shown that women who enter transactional relationships are more likely to be HIV positive. They may be more vulnerable as they tolerate unfaithful partner and also seek out additional concurrent sexual relationships for themselves [243].

In more than two thirds (68%) of households women or girls are the primary caregivers for those sick with AIDS related Illnesses [239]. Similar trends are present in parts of Asia and Latin America [236]. Sexual abuse during childhood and forced sexual initiation during adolescence are associated with HIV risk taking among women. In USA several studies show that experience of childhood sexual assaults is associated in adults with early sexual initiation, anal sex, sex with unfamiliar partners and low rates of condom use [237].

c) Indirect transmission through inability to negotiate condom use.

Suggesting condom use with a resistant partner has dire consequences for women: threatens his masculinity, raises his suspicions about the woman’s monogamy or sexual history. Dunkle and Jewkes found that traditional men’s gender roles lead to “more negative condom attitudes and less consistent condom use” [239]. Women find themselves vulnerable to further violence, being rejected and potentially loosing partner’s financial support. This was confirmed in a study conducted in South Africa by the international Centre for Research on Women [241]. A study from USA African-American women who had physically abusive partners were four times more likely to be verbally abused and nine times more likely to be threatened with physical abuse when they asked their primary partner to use condoms compared to those who did not have partner abuse 237. In a South African study women who experienced forced sex were found to be nearly six times more likely to use condoms inconsistently than women who did not experience coercion. And women with inconsistent condom use were 1.6 times more likely to be HIV positive [237]. However another South African study found that women who were physically abused prior to the past year were 1.5 times more likely to ask their current partner to use condoms than women who were not abused [237]. As these have been cross sectional studies measures of condom use and violence have differed across studies. Thus it is difficult to draw definite conclusions about how partner violence is linked to condom use. Condom use is economically dependent as evidenced in Thailand. They experienced initial success with this structural intervention that enforced 100% condom use in collaboration with sex workers, brothel owners, clients of sex workers and the police. But the Asian financial crisis caused widespread unemployment. This worsened the economic situation for women and youths [238]. Girls, women and sex workers found it difficult to insist on condom use. Evidence suggests that when faced with economic duress women are more likely to acquiesce to intercourse with no condoms when offered more money by men [238].

d) Indirect transmission by partnering with riskier/older men

A review of over 40 studies from sub-Saharan Africa suggests that a significant proportion of adolescent girls have sexual relations with men five to ten years older than themselves [237]. Emerging evidence form a study conducted among women (16-23 years) in South Africa suggests that women who have partners older than them (i.e. age difference of three or more years) have 1.6 fold higher odds of being HIV infected. Young women with older partners are 1.5 times more likely to experience physical and sexual violence than women with partners in their peer age group [237]. Several studies highlight that men’s use of violence is linked to their own sexual risk taking. This increases both their and partners risk of HIV/STI’s [237]. In India a study showed that men who had extra marital sex were six times more likely to report sexual abuse of their wives than men.
who remained faithful [237]. The men in this study who reported an STI were 2.5 times more likely to report abuse of wives than men who did not report an STI. Thus these researchers concluded that abusive men were more likely to engage in extra marital sex, acquire STI, and place their wives at risk for STI possibly through sexual abuse [237].

e) Violence as a consequence of being Hiv positive.

Between 16-86% of women in developing countries choose not to disclose their HIV status to their partners [237]. Disclosure is essential as it ensures HIV positive person get access to services including prevention of mother-to-child transmission (MTCT) antiretroviral treatment (ART) and psychosocial support. In most studies between 3-15% of women report negative reactions from disclosure. Blame, abandonment, anger and violence result. Between 16-51% of women in studies from Tanzania, South Africa and Kenya say they do not disclose their status due to their fear of violence [237].

A study was conducted in South Africa to examine if non-disclosure of HIV positive status placed sexual partners at risk. Sample was 69 sexually active, heterosexual, married (62%), cohabitating (38%) patients recently diagnosed as HIV positive. Results showed that 78% had not disclosed and 46% had no knowledge of their partner’s serostatus [244]. These non disclosures were more likely to be male, to not have used a condom during their last sexual encounter, to have used alcohol heavily before sex, to have multiple sexual partners and to have engaged more frequently in sexual intercourse in the six months prior to the study [244].

Kalichman’s study on risk behaviors of men and women living with HIV/AIDS is disturbing [245]. Across populations one in three persons with HIV/AIDS continues practicing HIV transmission risk behaviors. This behavior is related to relationship factors, economic conditions, emotional states, substance abuse and personality dispositions. From this study it appears that risk behavior is increasing with HIV negative partners and partners of unknown HIV status. Kalichman’s study observed that risk practices are also affected by perceptions of how ART’s may affect infectivity [245].

Similarly a study by Marks and Crepaz (14) of 206 HIV positive men (41% homosexual, 35% bisexual, 24% heterosexual) showed that 25% of the men engaged in unsafe sex and 48% of the total sample withheld disclosure from the partner. Risky behavior patterns repeat what has been noted in other studies: alcohol and drug use before sex, having a HIV unknown partner, being less emotionally involved with one’s partner and testing seropositive in the previous 3 years [246].

A cornerstone of HIV prevention in South Africa is voluntary HIV antibody counselling and testing (VCT), only one in five South Africans aware of VCT have been tested. Kalichman’s study results on 224 men and 276 women living in a black township in South Africa showed that individuals not tested for HIV demonstrated significantly greater AIDS related stigmas; greater shame, guilt and social disapproval to people living with HIV.

f) Mother-to-child (perinatal) HIV transmission

HIV transmission from mother to child during

(Strengthening the Linkage between Reproductive Health and HIV/Aids Program, by Elizabeth Lule, Population and Reproductive Health Advisor)
pregnancy, labor and delivery, or breastfeeding is called perinatal transmission [247].

VCT testing allows pregnant HIV women ARV’s to reduce the risks of MTC (perinatal) transmission. However a study by Gaillard et al shows that a major obstacle to compliance is partner disclosure [248]. Only a third of the 290 HIV infected women included in an intervention study to reduce mother-to-child transmission of HIV in Mombasa, Kenya, informed their partners of their results. Despite careful counselling, 10% subsequently experienced violence or disruption of their relationship.

g) Women who have sex with women (WSW)
The belief that female same sex relationships are low risk of contracting HIV and other STI’s continues to dominate. WSW who are in both same sex and heterosexual relationships needs attention [249]. Data on HIV risk faced by WSW are scarce. Several surveys have reported that that certain groups of WSW engage in risky behavior such as unprotected sex with men, unprotected sex or sharing sex toys with women and injection drug use [250]. Self reported HIV rates among lesbian women in a study show that 8% of those tested were positive [249]. In Post-apartheid South Africa, a large number of lesbian black women have fallen victim of hate crimes and violent sexual attacks, being victim to “conversion rapes” some of which have led to HIV infection or even death [249]. Numerous studies indicate higher prevalence of BV, hepatitis C and HIV risk behaviors in WSW [251], [252]. These data support the hypothesis that sexual exchange of vaginal secretions is a possible mechanism for acquisition of BV. A study by Marazzo JM et al indicates that Genital HPV infection and squamous intraepithelial lesions are common among WSW [252]. In summary women’s physiological susceptibility due to hormonal changes, vaginal microbial ecology and physiology plus a higher prevalence of STI’s, and it is understood that behaviors that put WSW at risk for HIV need attention [253].

3. SEXUAL BEHAVIOR AND HIV/AIDS/STI’S

Although HIV has been identified as the etiological agent causing AIDS, transmission of this virus depends on human behavior related largely to sexuality and drug use [239]. It is important not to assume that individuals make rational decisions when engaging in sexual activity. It is impulsive and driven by physiological needs [236]. Add to this “contextual personal” and socio cultural variables such as gender and racial/ethnic culture and the complexity of HIV/AIDS becomes clearer [236].

Concurrent partnerships are a major contributing behavior that places people at risk. Morris’s study examined how concurrent partnerships amplify the rate of HIV spread. Their results indicate that concurrent partnerships exponentially increase the number of infected individuals and the growth rate of the epidemic during its initial phase. Adimora and Schoenbach’s study similarly found that mathematical modelling demonstrates that concurrent sexual partnerships spread transmission of HIV through sexual networks more effectively than does serial monogamy for the same total number of sexual partners [254], [255]. Helen Epstein gives an excellent description of concurrency and the effects of sexual networking on HIV transmission as an explanation of why HIV rates are so high in Africa [243].

4. THE VULNERABILITY OF MEN AND HIV/AIDS/STI’S

Although the first cases of AIDS were reported in gay men little is known about the current prevalence of HIV among lesbian, gay, bisexual, transsexual (LGBT) and now that the dominant mode of transmission is seen as heterosexual, and women at most risk, less data exists on heterosexual men and HIV/AIDS.

Decker et al did a study on sex purchasing and HIV among a clinic based sample of US men [256]. They found that men engaging in sex purchasing were more likely to be HIV/STI infected and thus represent a risk to the sexual health of both commercial and non-commercial sex partners. In summary heterosexual men put their close partners at risk through lack of awareness of their actual HIV status, practicing unprotected sex with close committed partner whose status is also unknown, intravenous drug user and sex purchasing [257].

Dunkle and Jewkes name the following as male factors that increase their risk for HIV [239]:

1. Men and low condom use
2. Men and VCT: Recent national studies in South Africa found that only one in five South Africans aware of VCT have been tested and that men accounted for only 21% of all clients receiving VCT3. Men and ART: A study conducted at Johannesburg General Hospital indicated women accessing ARV’s outnumbered men 2:1. Men were also likely to use ARV’s later in the disease trajectory than women.
4. Men and alcohol: World Health report noted that South African men were more likely to be “heavy drinkers”. Alcohol is a risk factor for GBV and HIV
5. Men and male circumcision (see section on this topic above)
6. Men and partner reduction: surveys suggest that the spread of HIV is accelerated where men have multiple concurrent partners and practice unsafe sex [243], [254], [255].
5. MEN WHO HAVE SEX WITH MEN (MSM)

Recent studies demonstrate that unprotected anal sex between men is a factor in HIV prevalence. In Zambia one in three surveyed tested MSM tested HIV positive; in Kenya 43% of MSM were living with HIV; in Senegal HIV prevalence rate of 22% was found among 463 MSM surveyed [258].

Lieb et al examined estimated numbers of MSM in Miami-Dade County by race, ethnicity and mortality rates. An estimated 63,020 men aged >=18 in the country are MSM with mortality rates higher for black men than other races [259].

Mckellar et al tested MSM aged 15-29 years for HIV at 263 randomly selected sampled venues in 6 US cities from 1994-2000. Of 5649 participants 10% tested positive for HIV. Of these 77% overall were unaware of their infection [260]. A study was conducted with MSM who use the internet to meet sexual partners. 53% used condoms consistently, 47% reported having sexual partners that were older >4 years. In this study MSM engaged in behaviors such as unprotected anal intercourse that place them at risk for HIV /STI's [261].

Research into MSM in Africa is limited. Johnson reports that most Africans have also engaged in sex with women [262]. Once again myths make men more vulnerable to HIV, as does economic exchange, and inconsistent condom use. Sexual abuse of MSM is common.

In summary, management and prevention requires all people get tested, use condoms, and choose partners carefully. In addition long term sustained strategies should address the social, cultural, economic, and political factors that influence the spread of HIV/AIDS.

<tbody>
<tr>
<td><strong>1. HIV</strong></td>
</tr>
</tbody>
</table>

**RECOMMENDATIONS**

- early diagnosis of HIV associated sexual dysfunction is important in the context of HIV infection and HIV units should have provisions to diagnose/manage or refer to specialists as indicated.
- physicians caring for both HIV infected and HIV negative msm should be aware of the likely psychosocial interaction between recreational drugs, pde5 inhibitors, unprotected sexual behaviour and HIV transmission
- Level of evidence 3, Grade B

HIV encephalopathy

- There should be recognition that there is a likely association between HIV encephalopathy and sexual dysfunction.
- Level of evidence 3, grade B
- Specialist management of HIV associated sexual dysfunction should be in collaboration with HIV physicians
- There should be recognition that there is an interaction between HAART and sexual dysfunction
Level of evidence 3, grade B

Endocrine:

Patients with HIV and endorinopathy should have an assessment of sexual functioning.
Level of evidence 3, grade B

Direct Effects of HIV infection

Lipodystrophy

Recognition of possible association between HIV lipodysrophy and sexual dysfunction is important
Level of evidence 3, grade B

Neuropathy

- Physicians looking after HIV patients should recognize that associated neuropathy may include symptoms of sexual dysfunction
Level of evidence 3, grade B

Iatrogenic low sexual desire

- HIV patients with low sexual desire should be formally assessed for endocrinopathy
Level of evidence 3, grade B

New treatments

Caution and vigilance using newer anti-HIV therapy should include assessment of sexual function
Level of evidence 4, grade C

Circumcision as a strategy to reduce HIV infection in men

1. Male circumcision reduces the risk of acquisition of the HIV virus in HETEROSEXUAL men
Level of evidence: Level 1
Grade of recommendation: Grade A

2. Heterosexual Male circumcision is not associated with behavioral disinhibition and engaging in high risk sexual behavior
Level of evidence: Level 1
Grade of recommendation: Grade A
3. There is a paucity of literature pertaining to the complications of male circumcision in Africa. The available literature does not allow a complete comparison among various studies as there is great heterogeneity with regard to indications, follow-up duration, and the skill set level for the circumcisers.

Level of evidence: Level 3
Grade of recommendation: Grade B

4. Adult male circumcision can be performed in the developing country setting with acceptable outcomes and complications rates similar to those observed in developed nations.

Level of evidence: Level 3
Grade of recommendation: Grade B

HIV IN WOMEN
- Female Hiv infection is associated with sexual dysfunction.
  Level of evidence 3 Grade C.
  - All women with HIV should have a sexual dysfunction screen.
  GRADE B

2. GENITAL HERPES
- All patients with primary and recurrent GH should be seen and counselled about the condition
  level of evidence 4 Grade C
- Those with frequent recurrences of GH should be assessed psychologically and psychosexually and given appropriate treatment for any co-existing psychological illness
  level of evidence 4 Grade C
- Patients with frequent recurrences of GH should be assessed regularly by a clinician and can have their sexual functioning and quality of life enhanced by giving continuous antiviral cover
  level of evidence 1 Grade A

3. CHLAMYDIA TRACHOMATIS (CT), GONORRHOEA(GC), AND ASSOCIATED PELVIC INFLAMMATORY DISEASE (PID)
- Chlamydia trachomatis (CT), gonorrhoea(Gc), and associated pelvic inflammatory disease (PID) are associated with sexual dysfunction.
  Level of evidence: 4
  Grade C

4. HUMAN PAPILLOMA VIRUS RECOMMENDATIONS
HPV infection is likely to affect sexual function, however more research is needed.
Level of evidence: 3 Grade C

5. SEXUAL DYSFUNCTION AND CHRONIC PROSTATITIS / CHRONIC PELVIC PAIN SYNDROME (CP/CPPS)
- Acute bacterial prostatitis (abp) interferes with sexual function due to the severity of the acute disease
  Level OF EVIDENCE 1 Grade A
- CBP may be associated with ejaculatory pain
  Level OF EVIDENCE 4 and ED Level OF EVIDENCE 3.
  Grade C
- CP/CPPS is associated with ED in 15 to 72 %
  Level OF EVIDENCE 3 Grade C
- Premature ejaculation has been described in 77% of men with cp /cpps
  Level OF EVIDENCE 3 Grade C
- Therapy of CP/CPPS is limited by a 40% placebo effect.
- An improvement of symptoms with PDE-5 inhibitors remains debatable.

6. SEXUAL, SOCIO-CULTURAL AND ECONOMIC ISSUES OF HIV WITH PARTICULAR REFERENCE TO SUBSAHARAN AFRICAN WOMEN MANAGEMENT INTERVENTIONS
MACROCOSMIC:
1. Programs targeting gender attitudes and norms should be supported. For example, the subordinate position of women must be acknowledged and addressed.
  EVIDENCE LEVEL 3
  RECOMMENDATION GRADE C
2. Economic empowerment of women. For example micro finance.
  EVIDENCE LEVEL 4
  RECOMMENDATION GRADE C
3. Role of health services in addressing gender based violence should include strengthening the
MICROCOSMIC:

1. Early coital debut should be delayed as it is a significant predictor of Hiv.

EVIDENCE LEVEL 2
RECOMMENDATION GRADE B

2. Negotiation and disclosure skills should be taught in school programs.

EVIDENCE LEVEL 3
RECOMMENDATION GRADE B

3. VCT should be vigorously encouraged at every clinic, and educational seminar. VCT should be widely accessible. There should be increase demand for availability of VCT.

EVIDENCE LEVEL 3
RECOMMENDATION GRADE B

4. Stigmatizing attitudes towards people living with AIDS should be discouraged to promote VCT.

EVIDENCE LEVEL 3
RECOMMENDATION GRADE C

5. Hiv prevention strategies must be blended with Hiv/AIDS care services.

EVIDENCE LEVEL 3
RECOMMENDATION GRADE B

6. Sexual assertiveness, condom self efficacy for women and parental monitoring, traditional morality, Hiv knowledge, and talking about sex with partners should be taught and encouraged.

EVIDENCE LEVEL 4
RECOMMENDATION GRADE C

7. More interventions should be targeted towards male clients of sex workers.

EVIDENCE LEVEL 3
RECOMMENDATION GRADE B

8. Prevention interventions are needed to address behaviors that put WSW at risk for Hiv infection.

EVIDENCE LEVEL 4
RECOMMENDATION GRADE C

9. Pap smears must be encouraged for WSW.

EVIDENCE LEVEL 4
RECOMMENDATION GRADE C
10. Disclosure must be encouraged.

EVIDENCE LEVEL 3
RECOMMENDATION GRADE B

11. “Knowledge gaps” should be filled and seen as primary intervention in communication campaigns.

EVIDENCE LEVEL 3
RECOMMENDATION GRADE B

12. Knowledge and appropriate attitudes are necessary for bringing about risk reduction behavior but they are not sufficient.

EVIDENCE LEVEL 4
RECOMMENDATION GRADE C

INTRODUCTION

Sexual function incorporates physiologic processes and regulation of the central and peripheral nervous systems, the vascular system, and the endocrine system, similar but different in men and women. Recent advances in sexual medicine research have led to an increased understanding of the underlying molecular factors and mechanisms governing the display of sexual functions. Understanding the molecular basis for penile erection has led to treatment of erectile dysfunction with oral phosphodiesterase type 5 (PDE5) inhibitors. Little is known, however, about the physiology and regulatory biology of the erectile/arousal response. Scientific investigation in this field is needed to increase knowledge and foster development of the future line of treatments for all forms of sexual dysfunction. This paper addresses the current knowledge of the major cellular and molecular targets of biologic systems responsible for sexual function. Scientific discovery is critically important for developing new and increasingly effective treatments in sexual medicine. Future treatment targets include growth factor therapy, gene therapy, stem and cell-based therapies, and even regenerative medicine. All directions should be vigorously explored and considered for future management sexual disorders.

I. CNS TARGETS FOR MALE SEXUAL DYSFUNCTIONS

1. INTRODUCTION

The use of drugs that act on the central nervous system (CNS) is possible and fascinating although a very complicated strategy for the therapy of several male sexual dysfunctions (erectile dysfunction, [ED], hypoactive sexual desire disorder [HSDD], and premature ejaculation [PE]). This strategy is feasible only when neural pathways, which originate from the CNS and control the vascular and muscular structures of the genital apparatus, are intact. Among neurotransmitters and neuropeptides which control sexual behaviour and its various phases and components at the CNS level, the best known are dopamine, serotonin, oxytocin, nitric oxide (NO) and adrenocorticotrophic hormone-melanophore-stimulating hormone (ACTH-MSH) derived peptides [1 - 24]. Cannabinoid (CB1) receptors, endogenous vascular growth factor (VGF)-derived peptides and growth hormone (GH) secretagogues have been recently added to this list [25 - 32]. This makes these compounds and their receptors valuable targets for the therapy of male sexual dysfunctions (33).

2. CNS TARGETS FOR ERECTILE DYSFUNCTION

a) Dopamine and Dopamine Receptors

Dopamine agonists are perhaps the best known compounds that facilitate penile erection in male mammals, including man. Apomorphine is the best known dopaminergic agonist commercially available and labelled for the therapy of ED (34) activates dopamine receptors of the D2 family in order to facilitate penile erection [35-37]. Molecular biology studies have shown that D2 receptors may be divided into D2 (long and short variants), D3 and D4 receptor subtypes [38]. Recent studies revealed that selective D4 agonists or partial agonists induce penile erection when injected systemically or into the paraventricular nucleus of the hypothalamus (PVN), with a potency similar to that of apomorphine (Figure 1). Perhaps most importantly for therapeutic use in men, some of these compounds are ineffective in mammal models...
of emesis [39]. This reopened the research aimed at the identification of new dopamine agonists, which are capable of inducing penile erection after systemic administration and are devoid of emetic properties. These studies make central D4 receptors one of the most promising central targets for the therapy of ED and suggest that the synthesis of selective pro-erectile D4 agonists may provide a valuable strategy for the treatment of this sexual dysfunction.

Figure 1. D4 Receptor agonists [PD 168887 (PD), PIP-3A (PI)] induce penile erection when injected into the PVN: comparison with apomorphine and prevention by L-745,870 (L), a selective D4 antagonist, or haloperidol (H), a D2 antagonist, given into the PVN. DA agonists were dissolved in the appropriate vehicle (V) and injected into the PVN at the dose of 100 ng each. DA antagonists were dissolved in the appropriate vehicle and injected into the PVN 15 min before the DA agonists. Each value is the mean ± SEM of 7 rats per group. * P < 0.01 when compared to vehicle-treated rats, # P < 0.01 when compared to the corresponding group treated with DA agonist alone (Student's t test)

b) Oxytocin and Oxytocin Receptors

Oxytocin is one of the most potent compounds discovered to induce penile erection when given into the PVN, mediated by the stimulation of oxytocinergic receptors located there as well as the hippocampus and spinal cord (40) (Figure 2). Unfortunately, oxytocin given systemically does not cross the blood brain barrier in amounts capable of inducing penile erection, and it is unfeasible to treat ED by injecting oxytocin or other drugs directly into brain nuclei controlling penile erection. The only way to overcome this problem is to synthesize molecules (possibly non peptidergic) that pass the blood brain barrier and have the same potency and selectivity of oxytocin when given systemically at central oxytocinergic receptors. The synthesis of such non peptide molecules, however, would be very complicated and expensive.

c) CNS Oxytocinergic Neurons

Drugs that stimulate neurotransmitter/neuropeptide receptors located in the cell bodies of oxytocinergic neurons in the PVN can facilitate or inhibit penile erection by activating or inhibiting oxytocinergic neurons at level of the PVN [40]. The most promising are dopamine receptor agonists of the D2 family, or the D4 receptor subtype without emetic properties. Other neurotransmitter/neuropeptide receptor agonists or antagonists meant to facilitate erectile response by increasing oxytocin neurotransmission would have to be given directly into the PVN in order to avoid other side effects often incompatible with sexual activity. The CB1 receptor antagonist, SR 141716A, may induce penile erection by increasing the release of glutamic acid in the PVN, in turn activating oxytocinergic neurons mediating penile erection [41] (Figure 3).

d) Melanocortins and Melanocortin Receptors

The stimulation of central, mainly hypothalamic melanocortin (MC) receptors by ACTH-MSH peptide or non peptide molecules is another way to facilitate erectile function [42], melanotan II and its carboxylate derivative PT-141, new a-MSH analogues with high agonist and antagonist potency and selectivity at specific receptor subtypes, induce penile erection in men when given subcutaneously [43]. The increase in intracavernosal pressure induced by α-MSH is not antagonized by a classical oxytocin receptor antagonist in contrast to that induced by oxytocin [44-46]. In contrast, the pro-erectile effect of tetrahydroisoquinoline (THIQ) [47], a non-peptide putative MC4 receptor agonist induces penile erection when injected in male rats. Although the role of oxytocin in the pro-erectile effect of ACTH-MSH peptides and non peptides may be very modest, the ability of these derivatives to induce penile erection after systemic administration makes MC3 and MC4 receptors a valuable target for ED and these compounds new possible therapeutic agents for ED treatment.

3. CNS TARGETS FOR HYPOACTIVE SEXUAL DESIRE DISORDER

a) Dopamine, Oxytocin and their Receptors

Hypoactive sexual desire disorder often occurs with erectile dysfunction, and is not always associated with low levels of testosterone [48 - 50]. In these cases drugs that act at the CNS level may represent a successful strategy for the therapy. Different neurotransmitters are known for their ability to increase or decrease sexual motivation and sexual arousal, the best known being dopamine. The nucleus accumbens is the brain area in which dopamine is thought to act to facilitate sexual motivation and sexual arousal [51]. Male rats exposed to an inaccessible receptive female often show non-contact erections, pheromone-dependent penile erection episodes indistinguishable from those induced by drugs and/or neuropeptides. Recent studies have shown that extracellular dopamine also increases in the medial
Figure 2. Oxytocinergic neurons as a target for the central therapy of ED. These neurons originating in the PVN and projecting to extra-hypothalamic brain areas, mediate penile erection. When activated by neurotransmitters such dopamine, excitatory amino acids, NO, oxytocin, hexarelin peptide analogues, VGF peptides or by the blockade of CB1 receptors in the PVN, facilitate penile erection, while when inhibited for instance by GABA or opioid peptides this sexual response is reduced. Appropriate references are cited in the References list.

Figure 3. The pro-erectile effect of SR 141716A, a CB1 receptor antagonist, when injected into the PVN is mediated by the blockade of CB1 receptors located in GABAergic synapses impinging on glutamatergic synapses that stimulate oxytocinergic neurons mediating penile erection. Such a block reduces GABA release increasing glutamic acid release that activates in turn oxytocinergic neurons to facilitate penile erection. Alternatively, SR 141716A may block CB1 receptors exerting an inhibitory control on glutamic acid release, and which are located in the above glutamatergic synapses. Whatever mechanism operates in the PVN, this facilitates glutamic acid release increasing oxytocinergic neurons mediating penile erection. Both mechanisms have been identified in other brain areas rich in CB1 receptors. Appropriate references are cited in the References list.
preoptic area [52] during copulation and in the PVN not only during copulation but also during non-contact erections. Finally, dopamine agonists injected into the PVN not only induce penile erection but also increase extracellular dopamine in the nucleus accumbens. This increase is negated by oxytocin antagonists injected intracerebroventricularly or into the VTA, where mesolimbic dopamine neurons originate [4, 51].

If a neural circuit connects the mesolimbic and incerto-hypothalamic dopaminergic systems where oxytocinergic neurons originate, it may be involved in the integration of neural activities controlling of consummatory (erectile – ejaculatory) and anticipatory (motivational and rewarding) aspects of male sexual behaviour in physiological contexts. Dopamine may contribute to modulating the activity of incerto-hypothalamic dopaminergic neurons in the PVN, which causes either penile erection (via activation of oxytocinergic neurons projecting to the spinal cord) or sexual motivation and reward (via activation of oxytocinergic neurons projecting to the VTA) (Figure 4).

Thus, this neural circuitry may be a valuable target for drugs capable of increasing its activity, and dopamine agonists represent a valuable strategy for the therapy of both ED and HSSD, as they act both in the nucleus accumbens and in the PVN. However, considerations against these drugs are the emetic properties of D2 agonists and their potential to produce marked dependence and addiction by increasing dopamine release (e.g., amphetamine-like drugs) from or by inhibiting dopamine reuptake (e.g., cocaine-like drugs) in central synapses. Oxytocin and oxytocin receptors also might be targeted for activating this neural circuitry, although the capability of oxytocin receptor agonists crossing the blood brain barrier seems still far from being realized.

4. CNS TARGETS FOR PREMATUR EJACULATION

a) Serotonin and Serotonin Receptors

Stimulation of serotonin receptors of the 5HT2 subtypes is often followed by inhibition of seminal emission and ejaculation in many animal models...
II. PERIPHERAL PHARMACOLOGIC TARGETS FOR ED

1. INTRODUCTION

Penile erection is initiated after central processing and integration of peripherally and/or centrally generated stimuli (e.g. tactile, visual, olfactory, and imaginative). The signals generated by peripheral penile tissues depend on the balance between factors that control the degree of contraction of the smooth muscle of the corpora cavernosa (CC) and the penile vessels, in turn determining the functional state of the penis. Many details of neurotransmission, impulse propagation and intracellular transduction of signals in penile smooth muscles have been described [61-63], but information on the peripheral control mechanisms involved in erection is rapidly expanding, and new details are continuously added. This review summarizes new information on some established and some new potential targets for drugs potentially useful for control of penile erectile mechanisms.

2. PERIPHERAL NEUROMEDICATION

The different structures of the penis receive sympathetic, parasympathetic, somatic, and sensory innervation [61-63]. The nerves contain different transmitters, and the nerve populations have been categorized as adrenergic, cholinergic, and non-adrenergic, non-cholinergic (NANC), dependent on the transmitter content. However, it should be stressed that these nerves often contain more than one transmitter or transmitter/modulator generating enzymes, such as NO synthases (NOS) and heme oxygenases (HO) [64-67]. One important population of nerves in the CC contains not only acetylcholine (ACh), but also NOS, vasoactive intestinal polypeptide (VIP), and neuropeptide Y [68,69]. If co-released, the different transmitters/modulators may interact, implying that the end result may be more complex than would be suggested from an experimental situation, where often the effect of a single agent is investigated.

It is not only the nerves, but also the endothelium of the CC and vessels of the penis, that produce and release transmitters and modulators that can influence the contractile state of the CC smooth muscle. In addition, they may also have other important functions. There is no question that among the contractile transmitters, noradrenaline (NA) plays an important role, and that for CC relaxation NO derived from nerves and endothelium is a major factor. These transmitters, their receptors and their signalling pathways remain to be the main targets for drugs meant for the treatment of ED. However, other transmitters/modulators, either directly or indirectly, can affect the CC and penile vessels and change the balance between relaxation and contraction and thus influence penile function [70-72].

a) Acetylcholine and Cholinergic Receptors

The importance of parasympathetic nerves for producing penile erection is well established [61-63]. Penile tissues from humans and several animal species are rich in cholinergic nerves [73,74] from
which ACh can be released by transmural electrical field stimulation. ACh released from these nerves acts on muscarinic receptors located on CC smooth muscle and on the endothelium of sinusoids and vessels. Four muscarinic receptor subtypes (M₁₋M₄) were shown to be expressed in human CC [76-77]. The receptor on smooth muscle was suggested to be of the M₂ subtype [76-77], whereas that on the endothelium was of the M₃ subtype [77]. ACh causes endothelium-dependent relaxation of CC, penile arteries, circumflex and dorsal vessels *in vitro* [61-63]. In isolated CC cells, carbachol consistently produces contraction. This means that relaxation induced by ACh can be produced either by inhibition of the release of contractant factors, e.g., NA, and/or by the release of relaxation-producing factors, e.g., NO.

It is important to stress that ACh also acts on nicotinic receptors. Bozkurt et al. (2007) analyzed the presence of neuronal nicotinic ACh receptors in rabbit CC tissue and possible mechanisms underlying nicotine’s potentiation of electrical field stimulation-induced relaxation [78]. The authors showed that nicotine acts on the nicotinic ACh receptors located on nitrogic nerves, thereby evoking release of NO from these nerve terminals. Since most nitrogic nerves are cholinergic, it may be speculated that ACh, released by the parasympathetic stimulation causing erection, acts not only via stimulation of ACh, released by the parasympathetic stimulation nerves are cholinergic, it may be speculated that ACh, released by the parasympathetic stimulation causing erection, acts not only via stimulation of 

**b) Noradrenaline and Alpha Adrenoceptors**

Noradrenaline (NA), released from adrenergic nerves, stimulates α-adrenoceptors (ARs) in the penile vessels and CC, producing contraction. It is generally accepted that this tonic activity keeps the penis in the flaccid state [79]. Both α₁- and α₂-ARs have been demonstrated in human CC tissue, but available information supports the view of a functional predominance of α₁-ARs. This may be the case also in the penile vessels, although a contribution of α₂-ARs to the contraction induced by NA and electrical stimulation of nerves cannot be excluded.

The mRNAs of all subtypes of α₁-AR have been shown to be expressed in human CC [81-82]. Their results demonstrated the presence of α₁A-, α₁B-, and α₁D-ARs, and they suggested that the NA-induced contraction in this tissue is mediated by two or possibly three receptor subtypes.

An additional α₁-AR subtype with low affinity for prazosin (α₁L), and which probably represents a conformational state of the α₁A-AR, has been suggested to be of importance in human penile erectile tissues. In rats, α₁B-, and α₁D-AR subtypes seem functionally relevant for erectile function, and α₁B-, and/or α₁L-AR subtype selective antagonists were suggested to represent advantages in the treatment of ED [83]. The distribution of α₁-AR subtypes in the penis and systemic vessels, however, may not be the same in rats and humans, and the method of study may influence the results. For example, Hussain and Marshall [84] found that the α₁D-AR predominated in several systemic rat vessels *in vitro*, which may not be the case in humans [85]. Similarly, Tong and Cheng [86] found α₁A-ARs to be responsible for the contractile response of rat CC, which does not seem to be in agreement with the *in vivo* data.

Expression of mRNA for α₁A-, α₁B-, and α₁D-ARs in whole human CC tissue has been demonstrated. Radioligand binding revealed specific α₁-AR binding sites, and functional experiments showed that the selective α₁A-AR agonist, UK 14,304, induced concentration-dependent contractions of isolated strips of human CC smooth muscle [87-88]. Whether or not these α₁-ARs are of importance for the contractile regulation of tone in CC smooth muscle is still unclear. Prejunctional α₁-ARs have been shown to inhibit stimulus-evoked release of NA from nerves in the human CC. Stimulation of prejunctional α₁-ARs in horse penile resistance arteries was also shown to inhibit NANC-transmitter release [89]. This might be one of the mechanisms by which NA maintains detumescence.

Morton and co-workers assessed the response of dorsal and cavernous penile arteries on alpha-AR-selective agonists and antagonists in the rabbit [90]. They found a predominant, functional α₁A-AR population with little evidence of other α₁-AR subtypes in cavernous arteries; there seems to be evidence for the presence of α₁D-AR in dorsal arteries. The authors concluded that α₁A-AR-agonists with affinity for both α₁A-AR and α₁D-AR would potentially have pro-erectile properties, with the combination of these perhaps being most effective.

**c) Endothelins and Endothelin Receptors**

Endothelins (ETs) have been demonstrated in penile erectile tissues and may contribute to the maintenance of CC smooth muscle tone [61-63]. In the endothelium of human CC tissue, intense
ET-like immunoreactivity has been observed; immunoreactivity has also been observed in the CC smooth muscle. Binding sites for ET-1 have been demonstrated by autoradiography in the vessels and in CC tissue. As both ET_A and ET_B receptors have been found in human CC smooth muscle membranes, it cannot be excluded that both receptor subtypes are functional [91].

ET-1 potently induces slowly developing, long-lasting contractions in different smooth muscles of the penis: CC, cavernous artery, deep dorsal vein, and penile circumflex veins. Contractions can also be evoked in human CC tissue by ET-2 and ET-3, although these peptides have a lower potency than ET-1. The contractions induced by ET-1 are dependent on both transmembrane calcium flux (through voltage-dependent and/or receptor-operated calcium channels) and on the mobilization of inositol trisphosphate- (IP_3-) sensitive intracellular calcium stores [92-93].

Becker [94] investigated the plasma ET levels in 33 healthy adult males and in 25 ED patients. In the healthy males, no changes in ET-1/2 levels were observed in the systemic and cavernosal blood during penile tumescence, rigidity and detumescence. However, in the patients, mean plasma ET-1/2 levels during penile flaccidity and detumescence were found to be higher in the systemic circulation than in the cavernosal blood. However, Becker [94] concluded that their data did not support speculations regarding the involvement of ET-1 in the pathophysiology of ED. El Melegy [95] found significantly greater mean plasma levels of ET-1 in the venous blood of patients with ED than in controls. They also found that patients with organic ED had significantly higher levels of ET-1 in both venous and cavernosal blood than had those with psychogenic ED, and suggested that ET-1 could be a clinical marker of diffuse endothelial disease manifested by ED.

Mumtaz [96] assessed the effect of ET-1 and its possible role in the a1-AR pathway during the erectile process using organ bath studies on rabbit CC smooth muscle. ET_A receptors were found to play a greater role than ET_B receptors in the ET-1-induced contraction. The a1-AR-dependent pathway did not involve ET_A or ET_B receptors. In a rat model of chronic cocaine administration, Kendirci [97] found significantly increased plasma big-ET-1 levels in the cocaine treatment group compared with control animals. In the penis, cocaine administration significantly increased ET_A receptor expression compared with saline controls, while ET_B receptor expression was not altered. Cocaine-treated rats showed also significantly decreased endothelial NOS (eNOS) expression and NO production. The authors concluded that cocaine administration significantly reduces erectile function in rats and that the pathophysiologic mechanisms likely involved include increased plasma big-ET-1 levels, increased penile ET_A receptor expression and reduced penile eNOS expression.

In addition, ETs may function as modulators of the contractile effect of other agents, e.g. NA. They may also act as long-term regulators of CC smooth muscle tone and modulate cellular proliferation and phenotypic expression. ET-1 has been hypothesized to be directly involved in end-organ damage in salt-sensitive forms of hypertension. In support of this hypothesis, Carmeiro [98] found that activation of the ET-1/ET_A pathway contributed to mineralocorticoid hypertension-associated ED. ET_A receptor blockade may thus represent an alternative therapeutic approach for ED associated with salt-sensitive hypertension and in pathological conditions where increased levels of ET-1 are present. Even if much available in vitro information suggests that ETs may be of importance for erectile physiology and pathophysiology, the role of the peptides in vivo is unclear [99]. So far, the only published pilot clinical study with selective ET_A receptor antagonists failed to show enhancement of erectile responses in men with mild-to-moderate ED [100].

d) Dopamine and Dopamine Receptors

The importance of dopamine and dopamine receptors in the CNS for penile erection is well established. However, the role of dopamine receptors in the CC and penile vessels is less certain. Hyun [101] found dopamine D1 and D2 receptor gene expression in rat CC. In situ hybridization signals for dopamine D1 and D2 receptor mRNAs were localized to CC and dorsal vessels, and Western blot analyses showed peripheral dopamine D1 and D2 receptor proteins. Immunohistochemically, peripheral dopamine D1 and D2 receptor proteins were detected in dorsal nerves, dorsal vessels and CC smooth muscle of the rat penile tissues. D’Emmanuele di Villa Bianca [102] demonstrated that both D1 and D2 receptors were expressed in the human CC, D1 receptors being two-fold more abundant than D2 and that both receptors were mainly localized on the smooth muscle cell component. They concluded that apomorphine had a peripheral relaxant direct effect as well as antiadrenergic activity, and that human CC possessed more D1-like (D1 and D5) than D2-like (D2, D3 and D4) receptors. Both D1- and D2-like receptors were mainly localized on smooth muscle cells and the relaxant activity was most probably mediated by D1-like receptors partially through NO release from endothelium.

Apomorphine may thus not only amplify sexual and copulatory behaviour but also, by a complementary role, amplify neurogenically mediated erections by acting in the periphery [103]. On the other hand, Matsumoto [104] investigated the role of peripheral
dopamine receptors for regulation of penile erection. They found that in the rat isolated CC, pre- and postjunctional effects of apomorphine appeared to involve dopamine D1- and D2-like receptors, as well as α-adrenoceptors. At relevant systemic doses of apomorphine, however, peripheral effects of the compound were unlikely to contribute to its proerectile effects in rats.

### e) Serotonin and Serotonin Receptors

Serotonin (5-hydroxytryptamine: 5-HT) pathways in the brain are known to be involved in the induction of penile erections in rats [61-63], and Kimura [105] presented evidence that the 5-HT<sub>2C</sub> receptor in lumbosacral spinal sites mediates not only dopamine–oxytocin–5-HT action but also melanocortin action on penile erections.

The importance of peripheral 5-HT receptors is less well established. Finberg and Vardi [106] demonstrated an in vivo 5-HT-mediated inhibitory action on penile erection in rats due to vasoconstriction of the cavernosal arteries. Also, Esen [107] showed that the in vitro 5-HT-mediated contractile response in human penile veins was augmented in patients with venoocclusive disease. The involvement of 5-HT<sub>1A</sub>, 5-HT<sub>1B</sub>, and 5-HT<sub>2A</sub> receptors [108, 109] in contracting cavernosal smooth muscle was shown in animal studies. Furthermore, 5-HT<sub>1A</sub>, 5-HT<sub>2A</sub> and 5-HT<sub>1C</sub> receptors were implicated in human erection [110, 111]. Lau [112] further confirmed that the peripheral 5-HT pathway may play a part in the erectile process via 5-HT<sub>2A</sub> receptor-mediated contractile and 5-HT<sub>1C</sub> receptor-mediated relaxant activities. It cannot be excluded that neurally released 5-HT is an important contractile neurotransmitter in the erectile process. If so, doxazosin, ketanserin, and 5-HT<sub>1A</sub> and 5-HT<sub>1C</sub> receptor antagonists may be useful as a form of combination therapy to treat ED.

### f) ATP, Adenosine and Adenosine Receptors

ATP and other purines were shown to decrease both basal and phenylephrine-stimulated tension in isolated rabbit CC preparations [113, 114]. It was suggested that ATP is a NANC transmitter in the CC, and that purinergic transmission may be an important component involved in the initiation and maintenance of penile erection [113]. However, none of the purines tested facilitated or inhibited the response of CC smooth muscle to electrical field stimulation, and therefore their role may be in the modulation of erection rather than acting as neurotransmitters [114]. ATP injected intracavernously in dogs was found to produce increases in intracavernous pressure and erection [115]. This effect, which was unaffected by atropine and hexamethonium, could be obtained without changes in systemic blood pressure. In addition, adenosine produced full erection on intracavernous administration [116].

The relaxant activity of ATP may be mediated either by its interaction with ATP receptors, or by adenosine generated through the endonucleotidase-mediated breakdown of ATP. Adenosine was suggested to act through stimulation of receptors belonging to the A<sub>2A</sub> subtype [117]. Filippi et al. [118] found that ATP acted as a potent and NO-independent relaxant agent of human and rabbit CC. They also showed that the ATP effect was partially attributable to the metabolic breakdown of ATP to adenosine but was also due to a direct stimulation of P2 receptors, seemingly different from the classical P2Y and P2X receptor subtypes. Shalev [119] showed that human CC strips can be relaxed by stimulation of P2Y purinceptors via NO release. This relaxation was mediated by an endothelium-dependent mechanism. They suggested that purines may be implicated in physiological erection in man. However, the roles of ATP or adenosine in the physiological mechanisms of erection still remain to be established [120 – 122].

Adenosine produces its effect on target cells by binding to four specific G-protein-coupled receptors: A<sub>1</sub>, A<sub>2A</sub>, A<sub>2B</sub>, and A<sub>3</sub>. Each receptor has a unique affinity for adenosine and a distinct cellular and tissue distribution. A<sub>1</sub> and A<sub>3</sub> receptors are coupled to adenylyl cyclase by the inhibitory G-protein subunit (G<sub>I</sub>) and hence serve to lower intracellular levels of cAMP. A<sub>2A</sub> and A<sub>2B</sub> adenosine receptors are commonly coupled to adenylyl cyclase by the stimulatory G-protein subunit (G<sub>S</sub>) and serve to increase intracellular cAMP [120]. As pointed out by Dai et al. [120], adenosine has several features making it an excellent candidate for contributing to normal and abnormal penile erection: it is a potent vasodilator with a very short half-life (<10 seconds), and it generates erection via cyclic nucleotide second messengers.

Adenosine-mediated cAMP induction activates protein kinase A and results in decreased calcium calmodulin-dependent myosin light chain phosphorylation and enhanced smooth muscle relaxation [124]. Studies in several animal species, including humans [125] showed that intracavernous injection of adenosine resulted in tumescence and penile erection [126, 127]. More recently, Tostes [128] presented data suggesting that adenosine-induced relaxation in mouse CC is mediated through activation of both A<sub>2B</sub> and A<sub>3</sub> adenosine receptors. Mice lacking adenosine deaminase (which is necessary for the breakdown of adenosine) showed priapic activity involving A<sub>2B</sub> receptors [129]. Consistent with these reports, a recent study demonstrated that ED in men in some cases may be due to endothelial A<sub>2B</sub> receptor dysfunction [130]. However, not all forms of ED are associated with impaired adenosine signaling. For example, Carneiro et al. [122] showed that adenosine actions are preserved in ED seen in obese and Type II diabetic da/db mice, suggesting that increased CC responses to adrenergic nerve stimulation are not
due to impaired negative modulation of sympathetic neurotransmission by adenosine in this diabetic model.

**g) Prostanoids and Prostanoid Receptors**

Human CC tissue has the ability to synthesise various prostanoids and the additional ability to metabolize them locally [131 - 133]. The production of prostanoids can be modulated by oxygen tension and suppressed by hypoxia. Corresponding to the five primary active prostanoid metabolites (PGD$_2$, PGE$_2$, PGF$_2$, PGI$_2$, and thromboxane A$_2$ (TXA$_2$)), there are five major groups of receptors which mediate their effects—the DP, EP, FP, IP, and TP receptors. cDNAs encoding representatives of each of these groups of receptors have been cloned, including several subtypes of EP receptors.

Penile tissues may contain most of these groups of receptors; however, their role in penile physiology is still far from being established [131-133]. Prostanoids may be involved in contraction of erectile tissues via PGF$_{2\alpha}$ and TXA$_2$, stimulating thromboxane (TX) and EP receptors and initiating phosphoinositide turnover, as well as in relaxation via PGE$_1$ and PGE$_2$, stimulating EP receptors (EP2/EP4) and initiating an increase in the intracellular concentration of cAMP [134 – 136]. Prostanoids may also be involved in the inhibition of platelet aggregation and white cell adhesion, and there is evidence suggesting that prostanoids and transforming growth factor-β$_1$ (TGFβ$_1$) may have a role in the modulation of collagen synthesis and in the regulation of fibrosis of the corpus cavernosum [137].

Brugger [138] characterized the pharmacological and physiological activity of novel subtype-selective EP and DP receptor agonists using isolated human and rabbit penile cavernosal tissue in organ baths and in vivo measurements of intracavernosal pressure in rats and rabbits. They found no consistent correlation between the pharmacological profile (receptor binding and second messenger assays) of the EP agonists and their effect on cavernosal tissue tone. However, they found that a potent DP1-selective agonist, AS702224, caused penile erection. They concluded that the DP1 receptor mediates relaxation in human cavernosal tissue and stimulates pro-erectile responses also in both rat and rabbit.

**h) Endocannabinoids**

Little information exists concerning the peripheral effect of cannabinoids on CC tissue. Ghasemii [139] investigated the effect of the endogenous cannabinoid anandamide on the NANC relaxant responses to electrical field stimulation in isolated rat CC. They showed that anandamide has a potentiating effect on NANC-mediated relaxation of rat CC through both CB1 and vanilloid receptors. Furthermore, they demonstrated that the NO-mediated component of the NANC relaxant responses to electrical stimulation is involved in this enhancement. The same group studied the effect of biliary cirrhosis on NANC-mediated relaxation of rat CC and the possible roles of endocannabinoid and NO systems in this model [140, 141]. NANC-mediated relaxation was enhanced in CC strips from cirrhotic animals. Anandamide potentiated the relaxations in both groups. Either AM251 (CB1 receptor antagonist) or capsazepine (TRPV1 receptor antagonist), but not AM630 (CB2 receptor antagonist), prevented the enhanced relaxations of cirrhotic strips. Both the non-selective NOS inhibitor, L-NAME, and the selective neuronal NOS (nNOS) inhibitor, L-NPA, inhibited relaxations in both groups, but cirrhotic groups were more resistant to the inhibitory effects of these agents. Relaxations to sodium nitroprusside (NO donor) were similar in tissues from the two groups. The authors concluded that cirrhosis potentiates the neurogenic relaxation of rat CC probably via the NO pathway and involving cannabinoid CB1 and TRPV1 receptors.

Western blotting of CC tissues in this and other studies demonstrated the existence of CB1 receptors in CC strips of rat and rhesus monkey [142]. In contrast to rat CC tissue, relaxant responses to electrical stimulation were not altered in the presence of anandamide at 10 nM- 30 μM in monkey CC strips. Further studies are needed to elucidate the role of the endocannabinoid system in erectile tissue.

**i) Nitric Oxide and the Guanylate Cyclase/cGMP Pathway**

It is widely accepted that NO plays an important role in the relaxation of the CC smooth muscle and vasculature (143 - 146). In vitro, several investigators have shown that both ACh- and neuronally-mediated relaxation in animal and human corpus cavernosum involves the release of NO, or a NO-like substance (143). Both the nerves (nNOS) and the endothelium (eNOS) of the corpus cavernosum may be the source of NO, the former initiating erection, and the latter providing sustained maximal erection (147 - 149). The relative contribution of the different forms of NOS to erection has not been definitely established. However, more than one isoform of nNOS may be involved (148).

Mice lacking both eNOS and nNOS have erections, show normal mating behaviour, and respond with erection to electrical stimulation of the cavernous nerves (150, 151, 148). Surprisingly, isolated corporal tissue from both wild-type and NOS-deleted animals have demonstrated similar responses to electrical stimulation. However, Hurt et al. (146) showed that alternatively spliced forms of nNOS are major mediators of penile erection.

cGMP signals via different receptors in eukaryotic cells, including ion channels, phosphodiesterases,
and protein kinases. At present, the molecular targets which are activated by cGMP in order to execute the relaxation of penile smooth muscle are not known. Two different cGMP-dependent protein kinases (cGK I and II) have been identified in mammals. Inactivation of cGKI in mice abolishes both NO/cGMP-dependent relaxation of vascular and intestinal smooth muscle and the inhibition of platelet aggregation, causing hypertension, intestinal dysmotility, and abnormal hemostasis (152). Sadeghipour et al. (153) suggested that lithium, by interfering with the NO pathway in both endothelium and nitroergic nerve, can result in impairment of both the endothelium- and NANC-mediated relaxation of rat CC.

Male cGKI-deficient mice seem to have very low reproductive capability, likely due to the markedly reduced ability of their CC tissues to relax in response to NO, whether it is neuronally or endothelially released or exogenously administered (154). Analysis of the NO/cGMP-induced relaxation clearly shows that cGKI is the major mediator of the cGMP signaling cascade in murine CC tissue. Its absence cannot be compensated for by the cAMP signaling cascade (154). Taken together, these findings suggest that activation of cGKI is a key step in the signal cascade leading to penile erection.

Bivalacqua et al. investigated the expression of cGMP-dependent protein kinase (PKG)1α and PKG1b in the CC and evaluated the effect of adenoviral gene transfer of PKG1a to the erectile compartment on erectile function in a rat model of diabetes (155). They found PKG1a and PKG1b activities to be reduced in the erectile tissue of the diabetic rat. Gene transfer of PKG1α to the penis restored PKG activity and erectile function in vivo in diabetic rats. They concluded that gene therapy procedures targeting PKG1α might be an interesting future therapeutic approach to overcome diabetic ED resistant to oral pharmacotherapy.

Angulo et al. evaluated the influence of protein kinase C (PKC) activity on penile smooth muscle tone in tissues from diabetic and non-diabetic men with ED (156). They found that overactivity of PKC in diabetes is responsible for enhanced contraction and reduced endothelium-dependent relaxation of human CC smooth muscle. Thus, the authors concluded that such alterations can result in ED.

**j) Other Gaseous Mediators**

Carbon monoxide (CO) and hydrogen sulfide (H₂S) are together with NO considered to be the principal peripheral pro-erectile gasotransmitters that are released chiefly by cholinergic nerves and the sinusoidal endothelium to relax corporal smooth muscle through the cGMP pathway.

A significant, positive effect of the hemoxygenase (HO)/ CO system on penile erection has been reported in several studies, and its potential roles as molecular target in treatment of erectile dysfunction was reviewed by Shamloul (157). He noted that none of the studies examined the role of HO/CO system in aging animals; aging being considered the most important risk factor for ED. Furthermore, only one study tested the role of HO/CO system in erectile function. The author concluded that the HO/CO system may have an important role in many male sexual functions including penile erection, but that further studies are needed to precisely delineate the extent to which the HO/CO system plays a role in the physiology and pathophysiology of male sexual dysfunctions.

**k) Phosphodiesterases**

Phosphodiesterases (PDE) have been shown to be relevant for the erectile response by affecting cGMP and cAMP signaling in the penis. Specifically, their role is to degrade cyclic nucleotide second messenger products, thereby limiting their mode of action which result in CC tissue relaxation. The most prominently described PDE, PDE5, is well recognized as a primary pharmacologic target, and orally administered PDE5 inhibitors have indeed been successfully used for the treatment of ED (158). New concepts surrounding PDE5 biology as it relates to erectile function have centered on alternative mechanisms beyond direct pharmacologic inactivation for temporary erectogenesis (159). Scientific studies have suggested that this target could be applied for the treatment of various erectile disorders. The role of PDE5 is influenced by its gene regulation, and cyclic nucleotide-inducible promoters as well as enhancers precede the 3 PDE5A isoform mRNAs present in human penile CC (160). The inducibility of PDE5A promoters by cyclic nucleotides, as would be the case with increased cGMP levels in the penis resulting from the use of PDE5 inhibitors, offers a potential basis by which PDE5 expression and activity can be increased. Androgenic influences may also affect PDE5 function in the penis (161, 162), but the effect may be indirectly mediated by the influence of androgens on NOS function, which possibly induces cGMP production. These insights indicate that regulatory factors of PDE5 expression and activity in the penis critically determines the biological role of the enzyme.

**l) The RhoA/Rho-kinase Pathway**

A major mechanism of the calcium sensitization of smooth muscle contraction is through the inhibition of the smooth muscle myosin phosphatase (MLCP). The resulting myosin phosphorylation and subsequent smooth-muscle contraction therefore occurs without a change in sarcoplasmic calcium concentration. Several studies have revealed important roles for the small GTPase RhoA and its
The RhoA/Rho-kinase-mediated calcium sensitization is important for regulation of smooth muscle contraction, increased RhoA/Rho-kinase activity may lead to abnormal contractility of the corpora cavernosa. Evidence has been presented that elevated RhoA/Rho-kinase activity contributes to the pathogenesis of diseases such as diabetes and hypertension, and possibly to other conditions associated with ED, such as hypogonadism and aging. Several studies have suggested that NO inhibits RhoA/Rho-kinase activity, but the detailed mechanisms by which this regulation occurs are yet to be determined.

Vignozzi et al. (169) investigated the effect of testosterone on RhoA/Rho-kinase signaling in diabetes and found that overexpression of RhoA/Rho-kinase signaling contributes to diabetes-related ED. Moreover, treating hypogonadism associated with diabetes may maintain erectile function also by normalizing RhoA/Rho-kinase pathway upregulation.

One of the proposed mechanisms responsible for diabetes-related ED is overactivity of RhoA/Rho-kinase signaling, as seen in experimental models of diabetes. Morelli et al. (170) investigated whether the statin, atorvastatin, ameliorated diabetes-related ED. Streptozotocin-induced (8 weeks) diabetic rats and alloxan-induced (8 weeks) diabetic rabbits received atorvastatin (5 mg/kg daily) for the last 2 weeks. In both diabetic models, atorvastatin did not affect glycemia, lipid plasma levels, and the hypogonadal state. In diabetic rats, atorvastatin ameliorated the erectile response to electrical stimulation of the cavernous nerve and normalized sildenafil’s effect on erectile function. In penile tissue from diabetic animals, atorvastatin completely restored the diabetes-induced hypersensitivity to Y-27632 and prevented RhoA membrane translocation/activation. The authors concluded that atorvastatin improved diabetes-related ED and restored sildenafil responsiveness, most probably by inhibiting RhoA/Rho-kinase signaling. Gao et al. (171) suggested that impaired erectile function with aging in Sprague-Dawley rats is associated with the imbalance between nNOS and Rho-kinase activity and that the Rho-kinase inhibitor, Y-27632, could improve the erectile function in old Sprague-Dawley rats through adjusting this imbalance.

It has been shown that the Rho/Rho kinase calcium sensitizing pathway has been implicated in the pathogenesis of ED as well as systemic atherosclerosis. Park et al. (172) investigated whether chronic treatment with an oral Rho kinase inhibitor, fasudil, could prevent the development of both vasculogenic ED and pelvic atherosclerosis in a rat model. They found that the Rho/Rho kinase pathway is substantially involved in the development of ED and pelvic atherosclerosis, both of which could be prevented by chronic treatment with fasudil, and suggested that Rho-kinase might be considered a novel target for the prevention of vasculogenic ED.

Theoretically, suppression of an increased RhoA/Rho-kinase activity is an attractive therapeutic principle in ED. However, the ubiquitous occurrence of the Rho/Rho-kinase pathway limits the use of Rho-kinase inhibitors. If regulators of RhoA/Rho-kinase uniquely expressed in penile tissue can be demonstrated, they may be targets for drugs. This will potentially lead to the development of new therapeutic agents for the treatment of ED. Demir et al. (173) investigated the relationship of adrenergic responses in CC tissues in the presence of bladder outlet obstruction (BOO) using the α₁-AR receptor antagonist, doxazosin, and the Rho-kinase inhibitor, Y-27632. The contractility of human CC was increased in the presence of BOO; Doxazosin and Y-27632 generated effective CC smooth muscle relaxation in the presence of BOO. Doxazosin and Y-27632 may therefore be alternatives for the treatment of ED associated with benign prostatic hyperplasia.

### III. GROWTH FACTOR TARGETS FOR ED

#### 1. INTRODUCTION

The management of sexual disorders is not limited to traditional pharmacotherapy, in reference to drugs administered with targeted actions involving molecular mediators and their signaling mechanisms. Clinical therapeutics in this field will most certainly
exploit a growing understanding of the roles of diverse biological constituents involved in the sexual response. These constituents can be characterized across tissular, cellular and molecular levels, and they have relevance with respect to homeostatic, proliferative and regulatory requirements of sexual organs. In the penis, for example, the biology of growth factors has suggested alternative approaches to manage ED. Growth factor interventions for this organ refer to “targeting” the biologic properties of its cellular components, including nerves, endothelium and smooth muscle, either to facilitate mechanisms involved in the erectile response or to revitalize penile erectile tissues toward a functionally intact level in the face of injury or disease. In this subsection, we describe growth factor therapy applying the ED paradigm as a likely direction for therapeutics in sexual medicine.

2. NEUROMODULATION

Neuromodulatory therapy for ED implies a treatment strategy that is specific for the neurogenic loss of erectile function, arising from neurological disease, pelvic surgery and other conditions disturbing the neurological mediation of penile erection. The role of growth factors for neuromodulatory treatment has origins in the scientific disciplines of neurogenesis and neural development as well for prevention of neuronal cell death, with a purported basis to facilitate or augment the endogenous recovery of injured nerve tissue. Often used terms characterizing this general area of study are neuroprotection, neuroregeneration and neurotrophism. Particular emphasis for the application of neuromodulatory therapy in sexual medicine owes to the interest in preserving erectile function in men undergoing treatments for prostate cancer and other pelvic malignancies in which ED regularly occurs as a consequence of surgically traumatized cavernous nerves (174, 175).

Neurotrophins (neurotrophic factors) are secreted products both of the end organ for nerve terminations and Schwann cells, glial cells of peripheral nerves. Their source is generally restricted to Schwann cells following peripheral nerve injury, and upon release they target the nerve cell body and support survival of the nerve and stimulate its axonal regeneration. Neurotrophins interact with specific plasma membrane receptors in nerve cells activating Akt (protein kinase B) and/or mitogen activated protein kinases (e.g., ERK, JNK and p38), which regulate downstream effectors in neuronal proliferation and survival pathways. The range of their effects includes neuronal proliferation, differentiation, and changes in cell motility, structure and phenotype.

Neurotrophic molecules of particular interest in neuromodulatory applications for the penis include both classic neurotrophins as well as atypical neurotrophic factors. In experimental rat models of cavernous nerve grafting, nerve growth factor (NGF) and acidic fibroblast growth factor (FGF) enhance nerve function recovery in the penis and facilitate electrophysiologically induced erectile responses (176, 177). Basic FGF, insulin-like growth factor (IGF)-1 and transforming growth factor-β have been prominently localized in rat corporal tissue and associated with neurite outgrowth-promoting activity (178, 179). Brain-derived neurotrophic factor (BDNF) has shown particular importance as a neurotrophic factor for the penis based on its potent penile nerve recovery effects after adeno-associated virus transfer in a rat model of cavernous nerve injury (180). Recent in vitro and in vivo evidence has pointed to the important role of the JAK/STAT signaling pathway in mediating the effects of BDNF-induced functional recovery (181 - 183).

Additional interest has turned recently to glial cell-derived neurotrophic factors (GDNF) such as neurturin, persephin and artemin for neuromodulatory objectives in the penis. Prominent among these is the agent neurturin, again based on studies involving parasympathetic nerve regeneration in vitro and erection recovery in vivo using the cavernous nerve injured rat model (184, 185). GDNF delivered using a herpes simplex virus vector has been further shown to promote erection recovery in the animal model of cavernous nerve injury (186).

The atypical neurotrophin vascular endothelial growth factor (VEGF) has interestingly caused intrapenile nerve growth, besides having an angiogenic potential, in a rat model of traumatic arteriogenic ED (187). IGF-1 and IGF binding protein-3 complex regenerate penile nerve fibers and promote erection recovery in the rat model of cavernous nerve injury (188). Sonic hedgehog (SHH), a smooth muscle protein involved in penile development but also a neurotrophin secreted by Schwann cells, has been implicated in cavernous nerve regeneration in rats and may particularly serve to limit apoptotic effects in cavernous smooth muscle (189). Growth differentiation factor-5, a member of the TGF-β superfamily and a tissue developmental regulator like SHH, has been found to exert neurotrophic erection recovery effects in cavernous nerve injured rats (190).

The discovery of immunophilins in nerve tissue that operate as specialized receptors for neuroprotection and neuroregeneration has led to their investigation as a basis for therapy for conditions ranging from neurodegenerative disorders to peripheral nerve injury (191, 192). Excitement has surrounded the development and study of ligands specific for immunophilins, such as the immunosuppressants FK506 and rapamycin and particularly their non-immunosuppressive derivatives (e.g., GPI1046, FK1706), for this purpose. Basic scientific work has suggested that their modes of action involve anti-apoptosis, anti-oxidation and cellular repair.
the CC to include increasing endothelial cell content (193). This field of investigation has been brought to conditions of penile neuropathy associated with cavernous nerve injury both experimentally induced in animal models and clinically following radical prostatectomy (193 - 195, 185). Although erectile function recovery effects have not yet been observed at the clinical level unlike that shown preclinically, it remains of interest to explore further the possible utility of this treatment for clinical indications.

The cytokine hormone erythropoietin has been shown recently to have impressive neurotrophic effects for penile nerve function preservation. In both animal models of cavernous nerve injury and in men undergoing radical prostatectomy who were involved in a small, non-blinded clinical trial, the hormone exerted potent protective effects on erectile function (196, 197). The basis for this effect is understood to engage cell survival and anti-apoptotic mechanisms and possibly involve JAK/STAT signaling. Additional trials are warranted to evaluate the possible use of this therapy at the clinical level.

Stimulatory conditions for neurotrophic effects in the penis are also suggested as clever approaches to protect cavernosal tissue against risk for impairment. For instance, hyperbaric oxygen therapy promoted erection recovery in a rat model of cavernous nerve injury, with an effect that preserves cavernosal smooth muscle content and apparently involves heightened NGF and endothelial NOS function (198).

3. ANGIOGENESIS AND VASCULOPROTECTION

Investigational efforts have been given to understanding the functional and structural biology of the cavernosal tissue and penile vasculature and establishing ways to preserve and restore these tissue components for ED management. The notion to develop this scientific area is hardly trivial and attempts to address frequent pathogenic etiologies for ED of vasculogenic origin including hypercholesterolemia and atherosclerosis.

Great interest has been given to the potential application of angiogenic cytokines to promote erectile function. VEGF, a direct-acting specific endothelial cell mitogen and angiogenic factor, has been most significantly studied in relationship to genital vasculature. Splice variants for this cytokine have been verified in both rat and human cavernosal tissue (199, 200), and their expressions are downregulated in the corpus cavernosum of hypercholesterolemic rats and rabbits (201 - 203). In animal models of vasculogenic ED, intracavernous delivery of VEGF, by way of direct protein infusion or gene transfer, has effectively restored erectile function (9, 187, 201, 204). In line with effects of VEGF shown in other vascular systems, erectogenic responses were associated with multiple mechanisms operating in the CC to include increasing endothelial cell content (187, 201, 205) and causing both eNOS upregulation (7) and direct activation by Akt phosphorylation (9). Basic FGF has also been shown to exert angiogenic effects while also directly stimulating VEGF function in cavernosal tissue of the hypercholesterolemic rabbit (206, 207). Similarly, angiopoietin-1 has been demonstrated to have erectogenic effects and stimulate both angiogenesis and eNOS function in the CC of the hypercholesterolemic rat (202). These observations suggest an advantageous role for therapeutic angiogenesis in the treatment if not prevention of vasculogenic ED.

Targeting cytokine regulation in the penis has received additional attention as a strategy to treat vasculogenic ED. Interest has turned to pro-inflammatory cytokines, well described mediators of endothelial dysfunction. One such cytokine is tumor necrosis factor-alpha (TNF-α), which has been implicated in many cardiovascular diseases (e.g., hypertension, diabetes mellitus, metabolic syndrome) and is elevated in patients with ED (with or without cardiovascular disease). The suppression of eNOS expression by TNF-α constitutes a mechanism for its effect. As a direct investigation into this area, Carneiro et al studied erection responses and molecular mechanisms operating at the penile level in genetically engineered mice lacking the TNF-α gene (208). These mice exhibited improved erections in vivo and in vitro (i.e., increased NO-dependent cavernosal tissue relaxation and diminished sympathetically mediated effects) in association with increased protein expressions of both neuronal and endothelial NOS enzymes in CC tissue compared with control animals (208). This information suggests that anti-TNF-α therapies may be effective in treating forms of ED associated with endothelial dysfunction.

Besides therapeutic angiogenesis, other approaches are considered for preserving the morphology and function of the CC. Antihypertensive therapies represent an approach for vascular remodeling, interventions that may change the phenotype of “hypertensive" vessels toward decreased medial wall thickness (209). The changes are possibly associated with vascular smooth muscle cell apoptosis or rearrangement, changes in the extracellular matrix composition, or alterations in signaling pathways involved in vascular remodeling (209). The renin-angiotensin system may be particularly relevant for this concept, and angiotensin type 1 receptor antagonists have effectively been used to preserve erectile function experimentally in animal models of erectile dysfunction (210 - 214) as well as clinically in men with ED (215 - 217).
IV. REGENERATIVE MEDICINE AND GENE THERAPY FOR ED

1. INTRODUCTION

There has been a rather remarkable (re)evolution of therapies for the treatment of erectile dysfunction in the past 10-12 years. The goal of this section is to review potential therapies related to the application of stem cells, tissue engineering and gene therapy for the treatment of erectile dysfunction. While the first two provide the foundation for regenerative medicine, in one sense, all of these technologies serve as components of, or pathways to, regenerative medicine (Figure 5). Simply stated, regenerative medicine is the repair or replacement of damaged cells, tissues and organs. The goal is to restore native tissue and organ viability and function, in this instance, erectile capacity and sexual function. The regenerative nature of stem cell therapy and tissue engineering approaches are quite obvious, and clearly gene therapy techniques can be used to further improve the utility of both.

In this scenario, these technologies have rather recently generated great interest in the basic research and clinical communities. Table 1 summarizes the published literature. As illustrated, by far, the most widely studied of these technologies for the treatment of erectile dysfunction is gene transfer. Nonetheless, the purpose of this report is to provide an overview of the basic concepts and findings associated with each of these technologies. Clearly each topic could serve as subject matter for an entire chapter itself, and so the interested reader is referred to more detailed reviews of the subject matter in each instance below.

2. GENE THERAPY FOR ERECTILE DYSFUNCTION.

Gene therapy, or gene transfer, refers to the cellular incorporation of genes to mitigate or reverse a

Figure 5. Schematic depiction of potential future treatment strategies for erectile dysfunction. In this scenario, a diversity of regenerative and gene therapy technologies can be developed to treat a spectrum in the severity of erectile dysfunction, ranging from mild and moderate disease through complete end organ failure (i.e., lack of significant viable erectile tissue). Note that nanotechnologies are likely to play an important role as a drug and cell delivery vehicle for improvements to both regenerative and gene therapies.
disease process. Traditionally, gene therapy has been applied to the treatment of a life threatening disease relying on genomic integration with viral vectors in target cell populations (218). Despite early tragedy and disappointment, a recent editorial in the New England Journal of Medicine, notes that the tide may be turning (218). More recently, gene therapy has been pursued for the treatment of a wide range of disorders, including erectile dysfunction. In fact, the recent completion of the first Phase I gene transfer trial for erectile dysfunction (219) has started a new conversation concerning the potential application of gene transfer to diseases/disorders that have substantial impact on quality of life. As noted by Dr. Arthur Caplan (220), erectile dysfunction can be considered a serious medical problem as judged by a variety of relevant criteria. Moreover, since current treatment options are not effective in all patients, one can certainly make a strong case that gene therapy represents an ethical course of research for the treatment of erectile dysfunction (220).

The first preclinical publications on the potential applicability of gene therapy for the treatment of erectile dysfunction appeared in 1997 (221 - 223). Since then numerous research teams have confirmed the viability of this treatment modality, and examples of the numerous strategies employed to date are summarized in Table 2, and have been recently reviewed by several experts (224 - 226). One recent report has even noted that the preclinical studies of gene transfer for erectile dysfunction may even be useful for improved understanding of the pathophysiological basis of the disease process (227). The strategies thus far employed have interrogated numerous distinct molecular targets in several physiologically relevant erectile pathways, but again, as summarized in Table 1, the distinct strategies applied thus far can be grouped according to which cell type provides the primary mode of action. Not surprisingly, all of the gene transfer/therapy strategies used thus far affect either: 1) nerves, 2) smooth muscle cells, or 3) endothelial cells. However, because of the nonspecific mode of administration (i.e., intracavernous injection) as well as the lack of specificity of most of the vectors used, one cannot unequivocally rule out the possibility of involvement of more than one cell type in the observed response.

#### a) Endothelial Cells

The presence of erectile dysfunction (ED) correlates highly in men with hypercholesterolemia, cardiovascular disease, hypertension, and diabetes mellitus (228). A common thread among these conditions is the putative presence of endothelial dysfunction, defined as a pathological state of the vasculature with compromised endothelial responsiveness to vasodilator mediators, or conversely, an increase in sensitivity to vasoconstrictors. Because ED generally precedes or presents concurrently with cardiovascular risk factors, and furthermore, because cardiovascular disease has been clearly associated with endothelial dysfunction, it is logical to conclude that ED may result from endothelial dysfunction of the penile vasculature (229 - 232). As a result, several gene therapy strategies have been employed to manipulate this cell and enhance the effects generated to treat the disease condition, and many of these studies have been recently reviewed (233). In short, these strategies have centered around modulation of expression of NOS isoforms, SOD and most recently HO-1. In all cases the goal is the same, that is, to increase cGMP levels/NO bioavailability.

#### b) Vascular Function

While not strictly an index of endothelial cell health or dysfunction, an insufficient vascular supply is thought to be responsible, at least in part, for the etiology of men with erectile dysfunction. While it seems that in many cases, sufficient corporal smooth muscle relaxation (i.e., intracavernous injections) can overcome this deficit, there is nonetheless a rational basis for expecting that an increased blood flow will aid recovery of erectile function/capacity. In this regard, the concept here is to use angiogenesis to increase the vascularity of the penis and provide an increased blood flow component to the erectile process. While the number of patients whose erectile dysfunction is solely related to decreased vascularity may be small, a technique that could produce more subtle increases in vascularity might prove to be prophylactic. In fact, VEGF gene transfer techniques are currently being applied to the treatment of other ischemic cardiovascular diseases such as myocardial ischemia (234). The direct intracorporal injection of VEGF in a rat model of vascular
With respect to K channel gene transfer, it is based on K channel gene transfer (see below). The ultimate distinguishing feature among these approaches is the advent of human clinical trials. The preclinical success of gene transfer targeting smooth muscle has been nothing short of spectacular. In short, these initial studies provide proof of concept that increasing the magnitude of the stimulus for erection can be accomplished via manipulation of neuronal innervation density. Such a possibility has been previously suggested on both theoretical and practical grounds (223), and would present a major step forward (186, 249). In fact, Kato et al. (186, 250) used gene transfer with herpes simplex virus vector (HSV) expressing glial cell line-derived neurotrophic factors (GDNF or neurturin) in rats where the cavernous nerve was bilaterally injured using a ‘gutless’ (i.e., replication incompetent) Ad vector, as well as plasmids (247). In addition, this group has also evaluated the utility of pSilencer2.1-U6-PIN-shRNA gene therapy (PIN; protein inhibitor of nNOS), and concluded that it was more effective than the antisense PIN mRNA in ameliorating ED in the aged rat. Regardless, the implication is that PIN is indeed a physiological inhibitor of nNOS and nitrergic neurotransmission in the penis (248). In all cases the therapeutic strategy is the same, that is, to increase the bioavailability of NO following erectile stimulation.

In addition to overexpression of NOS in existing nerves, others have tried gene transfer with neurotrophic factors. The goal here is to increase the number and/or function of nerves, and thereby increase the stimulus for erection. Obviously, this approach is of specific interest when addressing neuropathic changes that accompany age, diabetes or radical prostate surgery, for example. Thus Lue and colleagues (180) examined the ability of brain derived neurotrophic factor (BDNF) gene therapy to restore the cavernous nerve-stimulated ICP response in a rat model of neurogenic impotence. In short, these initial studies provide proof of concept that increasing the magnitude of the stimulus for erection can be accomplished via manipulation of neuronal innervation density. Such a possibility has been previously suggested on both theoretical and practical grounds (223), and would present a major step forward (186, 249). In fact, Kato et al. (186, 250) used gene transfer with herpes simplex virus vector (HSV) expressing glial cell line-derived neurotrophic factors (GDNF or neurturin) in rats where the cavernous nerve was bilaterally injured using a clamp and dry ice. Four weeks after nerve injury, treated rats displayed significant recovery of erectile function compared to rats treated with control vector or untreated rats.

e) Clinical Trials

The ultimate goal of all of these approaches is to apply the findings to improve the treatment of ED in humans. In this regard, the first human clinical trial of gene transfer for the treatment of ED has been completed (219). In this seminal dose-escalation safety study, sponsored by Ion Channel Innovations, LLC (see www.ionchannelinnovations.com for
details) eleven patients with moderate to severe erectile dysfunction (ED) were given a single-dose corpus cavernosum injection of hMaxi-K, a “naked” DNA plasmid carrying the human cDNA encoding hSlo (for human slow-poke), the gene for the alpha, or pore-forming, subunit of the human smooth muscle Maxi-K channel (in a pVAX expression vector). More specifically, 3 patients each were given 500, 1000, and 5000 µg, and two patients were given 7500 µg, of hMaxi-K and followed for 6 months. The primary endpoint of this phase I study was safety. Importantly, no serious adverse events or dose-related adverse events attributed to gene transfer were observed for any patient at any dose during any study visit. Moreover, no clinically significant changes from baseline were seen in physical evaluations (general or genitourinary), hematology, chemistry, and hormone analyses. There were no cardiac events, as determined by repeated electrocardiograms, and no plasmid was detected in the semen of patients at any time after the injections. In addition, secondary efficacy endpoints were measured using the International Index of Erectile Function (IIEF) scale, with patient responses validated by partner responses. In this regard, one patient at each of the two highest doses of hMaxi-K (i.e., 5000 and 7500 µg doses) had apparently sustained improvements in erectile function (EF) as indicated by improved IIEF-EF domain scores over the length of the study. In fact, these patients reported EF category improvements that were highly clinically significant and maintained throughout the 24 weeks of study. While efficacy conclusions clearly cannot be drawn from the results of a phase I trial without a control group, these initial safety data are very encouraging. Moreover, the preliminary indications of potential effectiveness suggest that hMaxi-K gene transfer may be a viable approach to the treatment of ED. Clearly further clinical investigation is both required and justified. Nonetheless, these exciting data represent a major step toward one day making gene transfer a treatment option for ED.

3. STEM CELL THERAPY FOR ERECTILE DYSFUNCTION

Cellular therapy for the repair of damaged tissues and organs represents the entry point technology for regenerative medicine (see Figure 5). That is, in addition to technologies built around genetic modification of endogenous cells (to restore physiologically relevant aspects of cellular, tissue and organ function), another possibility is the (re-)implantation/introduction of cells into the corpus cavernosum, where the goal is to essentially “re-seed” or “repopulate” the penis with the requisite parenchymal cells for normal tissue/organ function. In theory, this could be accomplished by either systemic or intracorporal injection, but in light of the specialized anatomy and external location of the penis, direct injection is the currently preferred route of cellular delivery. Assuming there is sufficient viable tissue and vascularity remaining, (i.e., moderate erectile dysfunction; see Figure 1) to support the regenerative process then this approach provides a tractable therapeutic option.

Wessells and William (251) were the first to demonstrate the feasibility of utilizing autologous transplantation of endothelial cells into the corpus cavernosum of the rat for this purpose. Certainly, the use of autologous cells would be most beneficial, but in some cases, there may not be sufficient erectile tissue for this purpose. Thus, a considerable amount of effort has been devoted to identifying alternative cell sources (Table 2). More specifically, in addition to the injection of differentiated cell populations, one can also utilize stem or progenitor cells. Stem cells, by definition, retain both their clonogenic capacity (i.e., ability for self renewal) as well as their potential for multilineage differentiation (i.e., ability to differentiate into distinct cell types; Rookmaaker et al., 252). As recently pointed out (232, 233), stem cell therapy for ED is still a relatively young field of research, albeit a quite promising one. Not surprisingly then, there are only a handful of publications reporting original preclinical work with stem cell therapies. Nonetheless, the extant preclinical work summarized in Table 3 bodes well for the potential utility of cellular therapy for erectile dysfunction, and the interested reader is referred to these publications for additional details.

4. TISSUE ENGINEERING FOR ERECTILE DYSFUNCTION

At the other end of the regenerative medicine technology spectrum is tissue engineering. The basic concept is to use biocompatible, biodegradable scaffolds, either with or without cells, to repair rather extensively damaged tissues and organs. The concept of tissue engineering in urology has received considerable recent attention (253 - 256). Tissue engineering is required when the end organ damage is extensive, and thus, requires replacement for restoration and maintenance of function-rather than modulation. In a seemingly ever-aging population, regardless of the precisely etiology for the onset of erectile dysfunction, it is clear that if the duration of organic disease is sufficiently long, traditional pharmacotherapies will eventually fail. The latter provides the rationale for pursuing tissue engineering strategies for the treatment of erectile dysfunction (257).

In this scenario, the use of acellular scaffolds has shown value in preclinical studies for tunica patch repair (258) as well as cavernous nerve regeneration (259). In addition, a series of publications has shown the plausibility of using tissue engineering for phallic reconstruction and formation and reconstitution of

ICP denotes intracavernous pressure response; NS: nerve stimulation; Ach: acetylcholine; BDNF: brain-derived neurotrophic factor; CGRP: calcitonin gene-related peptide. HO-1; heme oxygenase-1. \(^a\)Duration of effect refers to the latest time point at which a physiologically significant increase in the ICP response was measured. \(^b\)The most recent data from our group indicates that the physiological effect on ICP lasts for up to 6 months in the aged rat model, and up to 4 months in an experimentally diabetic rat model. Also note that an increased ICP to NS refers to a statistically significant increase over that observed in an untreated age-matched control rat. In general, the responses observed in the gene therapy treated rats was similar to that observed in young animals.
corporal tissue both in vitro and in vivo (260 - 264). With respect to the former, engineered cartilage rods were made via the combination of autologous chondrocytes suspended in biodegradable polymers. These structures were implanted as engineered penile prostheses, and when retrieved possessed the histological and biomechanical characteristics of cartilage (260 - 262). With respect to the latter, taken together, these experiments demonstrate the feasibility of using autologous donor cells for corporal tissue reconstruction, and moreover, illustrate that human corporal smooth muscle and endothelial cells seeded on biodegradable scaffolds formed vascularized cavernosal tissue when implanted in vivo (262 - 264). In a rabbit model, this approach, that is, autologous penile corpora cavernosa replacement was sufficient to support mating activity by three months postoperatively (265). Development of methods to further enhance cellular content, and thus function, of these engineered constructs are currently ongoing (266).

5. COMBINATION THERAPY FOR ERECTILE DYSFUNCTION

As one views the horizon for novel treatments for erectile dysfunction, it is clear that all of the technologies discussed thus far can be used not only individually, but likely also in combination (again, refer to Figure 1 for details). For example, in applying the regenerative technologies, one can envision that recapitulating aspects of normal erectile developmental biology with sonic hedgehog might also be useful (267 – 268). Certainly, the regulatory hurdles will be greater for combination therapies, but nonetheless, it is important to evaluate the possibilities in preclinical studies. Furthermore, it corresponds to intuition that combination therapies would be more likely to succeed in the case of severe erectile dysfunction. Undoubtedly, this field of research will continue to evolve, and the enabling tools and technologies available to the investigator (i.e., nanotechnologies for sustained and controlled gene, growth factor or drug delivery) will only further increase in sophistication.

V. PHARMACOLOGIC TARGETS FOR EJACULATORY DISORDERS

1. INTRODUCTION

Ejaculatory dysfunction may be caused by any problem in this series of events, including premature ejaculation (PE), retarded ejaculation, anejaculation, retrograde ejaculation and painful ejaculation. However, PE is the most common type of ejaculatory dysfunction. As such, PE will be the main paradigm applied for this subsection.

Studies on the etiology and pathophysiology of PE critically depend on research animal models, which are very important to investigate the anatomy, physiology, cell biology, biochemistry and pharmacology of PE and to develop new therapies for PE. However, experimental animal models of PE have not been developed to investigate the etiology, pathophysiology and pharmacological mechanism of drug therapy on PE yet. The problem in researching the etiopathogenesis of PE and developing a therapy for PE is that it is very difficult to create a standard animal model of PE. Most of our current understanding of the neurobiology of the sexual and ejaculatory function has been derived from animal studies using rats or rabbits with normal sexual behavior (56). Spinal somatosensory evoked potentials and bulbocavernosus reflex in rabbits were used for evaluating the efficacy of the topical agent SS-cream (270 - 272). Olivier (273, 274) and Pattij (275) established an animal model of PE and delayed ejaculation research using male Wistar rats. Fast and slow ejaculatory rats were distinguished based on the number of ejaculations during 30-minute tests, each presenting almost 10% at both ends of the Gaussian distribution. Similar to the situation with humans, intravaginal ejaculatory latency time (IELT) distribution is positively skewed with regard to basal ejaculatory performance in a normal population of rats. However, standard guidelines applying animal models for PE research still needs to be developed.

In general, at present, various biological and psychological theories have been proposed to explain the cause of PE. Most of these theories are not evidence-based and are speculative at best. The psychological theory emphasizes the impact of early experience and sexual conditioning, anxiety, sexual technique, the frequency of sexual activity and other psychodynamic conditions. The biogenic theory relates to evolutionary theories, the sensitivity of the penis, central neurotransmitter levels and receptor sensitivity, a certain degree of arousability, the speed of ejaculation reflex and sex hormone levels.

2. PHARMACOLOGICAL TREATMENTS

Pharmacological modulation of the ejaculatory threshold provides a novel and refreshing approach to the treatment of PE and is distinct from the psychosexual and behavioral treatment model. Current and widely accepted pharmacological treatment options include anti-depressive agents, topical desensitizing agents, PDE5 inhibitors and alpha-receptor blockers.

a) 5-Hydroxytryptamine

Several studies using male rats have shown that serotonin (5-hydroxytryptamine [5-HT]) and various serotonin receptors are involved in the ejaculation process. Activation of 5-HT2c receptors can delay ejaculation, while activation of 5-HT1a receptors
speed-up ejaculation. PE has been attributed, in part, to decreased central serotonergic neurotransmission, 5-HT\(_{2C}\) receptor hypersensitivity, and/or 5-HT\(_{1A}\) receptor hypersensitivity (275-277). Thus, 5-HT\(_{2C}\) receptor agonists, such as selective serotonin reuptake inhibitors (SSRI) and serotonergic TCAs, should theoretically work for PE.

5-HT transporters blockade, similar to acute administration of SSRIs, has been demonstrated to increase 5-HT levels in the synaptic space and the space around neuronal cells (278). Increasing 5-HT levels activates 5-HT\(_{1A}\) autoreceptors, resulting in a lower 5-HT release into the synaptic cleft within minutes (278 - 281). A higher 5-HT concentration will increase activation of presynaptic 5-HT\(_{1B}\) autoreceptors that by itself will reduce the 5-HT release. In physiological conditions, the net effect of the acute SSRIs administration is only minor or no increase in the 5-HT neurotransmission and mild or no stimulation with all the postsynaptic 5-HT receptors (279-281). Based on these data, it is predicted that on-demand SSRI treatment does not acutely cause stimulation of the 5-HT post-synaptic receptors; therefore, there is hardly any of the 5-HT increase in the synapse and little or no synaptic stimulation of 5-HT receptors. If postsynaptic 5-HT receptors have little or no activation, clinically relevant ejaculation delay will not occur (283, 284). Therefore, the development of some novel SSRIs for acute administration in PE treatment is needed.

In contrast, chronic administration of currently available SSRIs induce delayed ejaculation by a different mechanism. The ongoing blockade of 5-HT results in a persistent increase of 5-HT levels in the synaptic spaces around cells. As opposed to acute administration, this leads to desensitization of the 5-HT\(_{1A}\) autoreceptors in a few weeks (285) and also possible desensitization of 5-HT\(_{1B}\) autoreceptors (285), which therefore causes less inhibition of 5-HT release into the synapse. The net effect of chronic administration is that more 5-HT is released into the synapse, enhancing 5-HT neurotransmission more strongly, and consequently stronger activation of the 5-HT receptor compared with acute SSRIs administration (283, 284, 286, 287). These data suggested that the daily treatment of SSRI will stimulate 5-HT post-synaptic receptors and therefore lead to clinically significant ejaculation delay after 1-2 weeks (286).

b) Noradrenaline

Clomipramine is a tricyclic antidepressant that inhibits the uptake of noradrenaline and 5-HT by adrenergic and 5-HT neurons (288).

Tramadol is a registered central analgesic agent, which has been used for many years, and its safety is widely accepted. The mode of action of tramadol is not fully understood. From animal experiments, there are at least two different mechanisms: one enantiomer exerts a major weak μ-opioid effect, while the other inhibits norepinephrine and serotonin reuptake, activating descending monoaminergic inhibitory pathways (289 – 293). Inhibiting reuptake of norepinephrine and serotonin may represent its effect of ejaculation delay (293). However, the action of 5-HT\(_{1A}\) and 5-HT\(_{2C}\) induced by tramadol requires further investigation.

c) Phosphodiesterase Type 5

Some experiments have shown a relationship between ejaculatory function and PDE5 function. Mancina and colleagues demonstrated the expression of PDE5 in human and rabbit vas deferens muscle (294). Kriegsfeld and colleagues reported the role of endothelial NOS on sexual function by observing abnormalities in ejaculatory function in endothelial NOS gene knockout mice. The effect was proposed to be associated with reduced sympathetic nervous system activity (295). Based on these findings, PDE5 inhibitors have been suggested in the management of patients with ED and concomitant PE (296, 297).

d) α1-Adrenoceptors

It is known that ejaculation is controlled by the sympathetic nervous system; therefore, a hypothesis was proposed that α-blockers might also be effective in the treatment of PE. Some animal studies have demonstrated that the stimulation of hypogastric nerve can reduce the pressure of the vas deferens and the seminal vesicle (298).

e) Hypoaesthesia

One of the proposed etiologies of PE is hypersensitivity of the penis. Thus, one of the goals of PE treatment is to reduce the sensory perception of the penis. The basic principle for the use of topical agents has traditionally been based on penile hypersensitivity in PE patients (299 - 301). The topical drugs for PE treatment that are currently available include the SS cream, lidocaine and prilocaine cream, and lidocaine spray (297).

The SS-cream (CJ Co Ltd, Seoul, Korea), developed at Yong-Dong Severance Hospital in Korea, is made with the extracts from nine natural products. A novel formulation, named ‘Renewal SS-cream’, is a new local agent composed of two main components of the original SS-cream. However, so far, only the results of animal studies have been published. The renewed SS-cream delays the latency of spinal somatosensory evoked potential more effectively than the original SS-Cream in rabbits (270 - 272, 297).

f) Oxytocin

Immunohistochemical studies have revealed the local synthesis of oxytocin and its synthesis-
associated protein, neurophysin I, in epithelial cells of the epididymis\(^{[132]}\). Therefore, the use of oxytocin as a potential therapeutic agent in the treatment of PE has been under investigation (302). Interventions at other points in this pathophysiologic pathway are also under investigation (303, 304). Dietary deficiencies, such as low magnesium intake, may prove to play a limited role (305).

VI. CENTRAL NON-HORMONAL AND HORMONAL TARGETS FOR FSD

Women with female sexual dysfunction secondary to low sexual interest, reduced sexual arousal or impaired or muted orgasm may be considered to have: 1) under-activity of the excitatory system regulating critical central nervous system structures involved in desire, arousal or orgasm, 2) over-activity of the inhibitory system, or 3) some combination of the two where, in the end, functional central inhibition is the more prominent action (10, 306 - 309). In women with low sexual interest, arousal and/or orgasm, reduced sexual activity is secondary, in general, to a combination of psychologic and physiologic factors (10, 306 - 310). As it concerns the physiologic, organic factors, basic science knowledge regarding the neurochemical contribution to inhibition and excitation is increasing. It is hoped that one day, in addition to time-honored psychologic strategies, novel pharmacologic treatments (307, 308, 310 - 317) can be available to help reverse either the underactive excitatory neurochemical system or the overactive inhibitory neurochemical system or both so that functional sexual excitation and, in the end, sexual satisfaction of the woman, improves.

An understanding of the neurochemicals involved in sexual inhibition and excitation is required when looking at future treatment targets. Sexual inhibition involves such neurochemicals as serotonin (318 - 322), endocannabinoids (322 - 325) and opiates (326 - 330). Conceptually, pharmacologic agents that inhibit the synthesis, release or receptor binding of brain inhibitor neurochemicals will increase sexual excitation. The most prominent and well-studied brain inhibitor neurochemical strongly linked to sexual inhibition is serotonin. Pharmacologic treatments that stimulate serotonin activity decrease sexual desire, while treatments that inhibit serotonin action increase sexual desire (318 - 322). Endocannabinoid and opiate activation, similar to serotonin release, act to decrease sexual desire and diminish orgasmic capacity (322 - 325). Antagonists to these neurochemicals will increase sexual activity.

Sexual excitation involves such neurochemicals as oxytocin (331 - 335), noradrenaline (336 - 338), dopamine (339 - 342), and melanocortins (343 - 345). Conceptually, pharmacologic agents that activate the synthesis, release or receptor binding of brain excitatory neurochemicals will increase sexual excitation. Oxytocin is a well-investigated sexual facilitator neurochemical that acts to stimulate sexual behavior, especially orgasm, when delivered centrally (331 – 335). Another brain neurochemical that facilitates sexual interest is noradrenaline, an alpha–1 adrenergic agonist. In appropriate levels centrally, unrelated to levels consistent with panic or apprehension, alpha –1 adrenergic agonist is associated with increased sexual behavior (336 – 338). An alpha–2 receptor blocker, such as yohimbine (346-347), prevents pre-synaptic endogenous noradrenaline inhibitory feedback, and thus results in increased noradrenaline levels. Agents such as yohimbine facilitate sexual interest, arousal and orgasmic capabilities (346-347). Dopamine agonists are the most well-known sexual neurochemical facilitators. Such agents are typically used for Parkinson’s disease where they have been recognized for years to be associated with increases in sexual interest. On the other hand, agents that are dopamine receptor antagonists have been shown to block sexual facilitation and result in lowered sexual interest, arousal and orgasm (339 - 342). Finally, other facilitator neurochemicals are melanocortin agonists that have been reported to stimulate sexual arousal and sexual interest in women with sexual dysfunction following intranasal and subcutaneous administration (343 - 345).

Sex steroid hormones are also involved in sexual desire, arousal and orgasm. Sex steroids such as testosterone (348 - 351), 17–beta estradiol (352 – 357) and progesterone (358) act at the molecular level to direct the synthesis of multiple proteins such as enzymes and receptors for the various facilitory neurochemical systems including oxytocin, noradrenaline, dopamine, and melanocortins. Sex steroid hormones bind to specific androgen, estrogen and progestin hormone receptor complexes in the cytoplasm that form transcriptional agents in the nucleus, and lead to the synthesis of different neurotransmitter proteins and transmitter receptor proteins. The overall effect of sex steroid hormones is to provide the protein biochemical machinery to enable a state in which sexual stimulation is likely to result in sexual desire, arousal and orgasm (348 – 358).

Non-hormonal centrally acting agents that have been investigated and may play a future role in the treatment of hypoactive sexual desire disorder in women include bremaelanotide (308, 311) and fibanserin (312-317). Bremelanotide is a melanocortin agonist that increases sexual interest by increasing dopamine release in the medial pre-optic area mPOA. Subsequent stimulation of downstream dopamine
ventral tegmental area outputs facilitates critical dopamine outputs in the mesolimbic area that form relevant and crucial neuronal circuits in the overall dopamine sexual excitatory system. Government regulatory agency approval of bremelanotide in the United States is currently delayed based on safety data. There is an increase in systolic blood pressure in some patients requiring additional clinical studies (308, 311).

Flibanserin is a serotonin antagonist that lowers central serotonin levels via two positive actions. The first is to diminish serotonin release (serotonin 1A agonism) and the second is to inhibit binding to the serotonin 2A receptor (serotonin 2A antagonism) involved in inhibitory cortical outflow. Furthermore, flibanserin increases dopamine and noradrenalin levels. In the end, this mixed serotonin 1A agonist and serotonin 2A antagonist both reduces inhibitory serotonergic function and increases excitatory dopamine and noradrennergic function. Flibanserin does not appear to be associated with addiction or dependence, as flibanserin does not have direct action on dopamine receptors or dopamine reuptake mechanisms. In addition flibanserin does not directly effect the opioid system so there is limited opportunity for excessive sexual desire with drug administration (312 – 317).

In summary, the current state of knowledge is that sexual activity may involve, in part, central sexual activation of various dopamine pathways in the medial pre-optic area and nucleus accumbens that focus attention to sexual-based motivation stimuli and sexual-based motor patterns (306, 307). Inhibition of sexual activity may involve, in part, central sexual activation of various inhibitory neurochemicals that feedback to multiple levels of the excitatory dopamine pathway. In general, the end result of neurochemical inhibition of sexual activity is stronger than that for sexual excitation (306, 307). The outcome of reduced excitation or excessive inhibition of central reflexes is low sexual interest, arousal and/or orgasm (306, 307). As our knowledge of the neurochemical interactions in the brain increases, novel non-hormonal and hormonal methods of central extracellular, intracellular, and molecular sorting are being realized in different regions, especially as they pertain to regulation of sexual reflexes. In women with distress from low sexual activity who seek medical/psychologic intervention, it is hoped that safe and effective non-hormonal and hormonal pharmacologic strategies, along with traditional sex therapy strategies, can one day be developed to reduce excessive central neurochemical inhibition and/or to increase central neurochemical excitation to result in improved patient satisfaction with sexual activity (306, 307).

**Current Status and Future Trends of Functional MRI for Female Sexual Dysfunction**

Female sexual arousal response is a neurovascular event that is elicited by various sexual stimulations, such as visual, auditory, olfactory or tactile input. Physiological measures for the assessment of sexual arousal in women include central components, as well as peripheral genital components. Recent innovative functional MRI (fMRI) studies are capable of measuring CNS correlates of sexual arousal. The principle use of fMRI is based on changing cerebral blood flow when neurons become active. The brain regions of neuronal activity show localized increase in blood flow, which changes the ratio of oxyhemoglobin/deoxyhemoglobin in cerebral tissue and result in MRI signal changes (359). The functional neuroanatomy of sexual arousal has been investigated using 1.5 or 3 Tesla fMRI with BOLD technique in women with or without sexual dysfunction (Table 3). Park et al (360) reported the first study by evaluating cerebral activation areas associated with female sexual arousal response. Karama et al (361) found that

there were many similar areas of brain activation in both male and female subjects. The differences between genders were in the activation areas of the thalamus and hypothalamus.

Hormone influences CNS arousal response in menopausal women. Murphy et al (362) suggested that aging is associated with a decrease of glucose metabolism in the brain; including frontal, temporal and parietal lobes. The activation pattern of regional cerebral blood flow attenuated in prefrontal cortical structures during a hypoestrogenic state (363). Jeong et al (364) reported that brain activation ratios of menopausal women were generally less than those of premenopausal women (Figure 6). Archer et al (365) reported that agonadal serum hormone levels result in decreased brain activation patterns in postmenopausal women during erotic stimulation. Administration of both estradiol and testosterone increases limbic system activation.

Depression is closely related with sexual dysfunction. Yang et al (366) reported that depressive women had lower activity in the brain areas of the hypothalamus, septal area, anterior cingulated gyrus and parahippocampal gyrus. Sexual desire disorder is the most commonly reported sexual complaint in women. Arnow et al (367) reported that women with no history of sexual dysfunction (NHSD) demonstrated a significantly greater activation in the bilateral entorhinal cortex than women with hypoactive sexual desire disorder (HSDD). In contrast, HSDD females showed a higher activation than NHSD in the medial frontal gyrus, right inferior frontal gyrus and bilateral putamen. Interestingly, peripheral sexual response was not significantly associated with brain activation patterns, which was presumed to have a weak relationship between the genital and subjective arousal responses in women.

The effect of centrally acting medication can be measured by a fMRI. One of the future potential roles of fMRI techniques is to evaluate the central effect of medications for the treatment of female sexual dysfunction as well as to define possible anatomic sites of its action in the brain. Van Wingen et al (368) investigated whether nasally applied testosterone rapidly increases amygdale reactivity in healthy, naturally cycling, middle-aged women. They found that a single nasal testosterone administration increases amygdale reactivity in middle-aged women to young adulthood level. Centrally acting medication such as bremelanotide, apomorphine will be a good candidate to elucidate the activation areas of the brain using fMRI (308, 369).

For the future perspectives of fMRI studies, high resolution fMRI will provide an ideal tool to investigate functional neuroanatomy of subcortical structures in erotic and emotional processing (370). The MRI-based diffusion tensor imaging (371), white matter fiber tractogram (372), and electroencephalogram (373) will be helpful to obtain additional information on neural connectivity and electrical potentials.

**Summary**

Since 1973, with the advent of surgical treatments for biologic forms of erectile dysfunction, such as, penile prosthesis insertion and microvascular arterial bypass surgery, there have been realized numerous advances in basic science and clinical research in biologic focused sexual medicine. Such investigations have led to an increasingly profound understanding of the underlying molecular biological factors and mechanisms governing both male and female sexual function. Ongoing scientific investigation in sexual medicine is mandatory to both increase and enhance our knowledge in all areas of male and female sexual function. Such knowledge will set the groundwork for the next line of treatments for the various male and female sexual dysfunctions.

The goal of this committee was to present current scientific, state of the art, evidence based knowledge of the major cellular and molecular targets of biologic systems responsible for sexual function. With such information as a background, the committee was charged with emphasizing the most innovative and exciting developments in the field of biologic-focused sexual medicine in such areas of pharmacotherapy, growth factor therapy, gene therapy, stem and cell-based therapies, regenerative medicine and others. It is hoped that current knowledge and future research will translate into future safe and effective biologic therapies for various sexual medicine disorders of desire, arousal, and orgasm. Disorders of sexual pain will be discussed in different committees. Future psychologic therapies will be discussed in other committees.

I. INTRODUCTION

Male sexual dysfunctions symptoms are highly prevalent and must be considered as the most frequently reported health complaints of men.[1-7]. Based on the literature the most prevalent and therefore most important male sexual disorders are:

Erectile dysfunction (ED)
Premature ejaculation (PE)
Delayed/absent ejaculation
Libido disorders/loss of desire

With the exception of lifelong PE which has shown a consistent prevalence rate of between 18 and 25% in several surveys across all age groups between 18 and 65 years, all male sexual dysfunctions/diseases are age dependent with profoundly increasing prevalence rates from the 5th decade on [1-12]. For all male sexual dysfunctions their significantly negative impact on life quality and satisfaction with sexual life as well as on a broad range of psychosocial domains and partnership issues is well documented [1-14]

Besides the above, well defined male sexual dysfunctions, which are reported in epidemiological studies and surveys, the following diseases/pathological conditions are also associated with a clear negative impact on sexual life and satisfaction and therefore were/are subject to medical treatment and development of new therapeutic strategies being investigated in clinical trials:

Peyronie’s disease
Late Onset Hypogonadism (LOH)

Peyronie’s disease is a fibrotic disorder of the cavernous bodies of the penis originating in the tunica albuginea and the septum penis resulting in penile deformities and penile shrinking. The etiology of this disease is not well understood. It may be associated with contractions of the palmar (M.Dypuytren) and plantar (M.Ledderhose) tendons and afflicts between 3% and 8% of the entire male population [15]. It is quite often associated with erectile dysfunction and results in a considerable subset of patients in the inability for vaginal penetration either to the extent of penile deformity and/or the severity of associated ED.

Late Onset Hypogonadism is the decrease of testosterone levels below 3 – 3.5 ng/ml, depending on the definition used, associated with clinical symptoms of hypogonadism. LOH may be prevalent in up to 40% of males above the age of 45 [16]. Sexual symptoms of LOH may be libido-, erectile and ejaculatory dysfunctions depending on the T-levels measured.

Because there is a substantial body of evidence that all the above male sexual dysfunctions show a clear impact not only on the sexuality but also on the psyche and general well-being of the males, afflicted by these disorders, there is a great medical need for the development of new efficacious and safe treatment options either as medications or other conservative options or even as surgical procedures.

Since the previous 2 International Consultations on Sexual Medicine a substantial number of new validated questionnaires were developed and used to investigate the change in patient reported outcomes (PRO’s) after therapy for certain male sexual dysfunctions. Until now validated questionnaires were developed, used and published for investigating the outcome of clinical trials in ED, PE and LOH. Two further new questionnaires are developed and currently undergoing validation process in Peyronie’s disease and LOH.
The current chapter on “Standards for Clinical Trials in Male Sexual Dysfunctions” critically reviews the published literature in this field with special focus on the study designs and study endpoints used. Recommendations are also provided for the future regarding the development and assessment of new therapeutic options in this field.

II. DESIGN OF CLINICAL TRIALS IN MALE SEXUAL DYSFUNCTIONS.

1. GENERAL CONSIDERATIONS

a) Impact of the Sexual Partner

The evaluation of therapy for Male Sexual Dysfunctions (MSD) distinguishes itself from clinical trials in other medical conditions in so far that in general the interaction of 2 human beings is involved – the male afflicted by the sexual dysfunction and his sexual partner either hetero- or homosexual. This is in contrast to many other diseases/dysfunctions requiring the development of new therapy where the impact on the sufferer is the key index. In the design of studies in MSD it is therefore essential that the influence of the sexual partner is considered and should not be underestimated both in terms of the efficacy and the acceptance of the medication/treatment under consideration. There is no doubt that the willingness of the respective sexual partner to accept the participation of the patient in such a clinical trial can play an important role regarding the outcome, personal perception of the treatment and discontinuation rates. Unwilling partners who, for whatever the reason, are negative towards a new treatment aimed at improving the sexual function/performance of the patient can exert a negative or even discouraging influence on the partner and thereby his perception of the efficacy and tolerance of the treatment in question.

Moreover large epidemiological studies have provided evidence that a considerable number of women are suffering from sexual dysfunctions too which of course may have an impact on both their willingness to engage in sexual activities and the level of the sexual life as such in a partnership[3-6].

All of the above has to be considered regarding the design, selection of primary and secondary endpoints and the overall assessment of the study drug/treatment under consideration.

Therefore it is strongly recommended that at least all phase III trials in male sexual dysfunction are also considering study endpoints for the sexual partner in the format of validated patient reported outcomes (PROs) / questionnaires/assessment tools). In addition, the males participating in clinical trials for sexual dysfunction should in the trial protocol at least be strongly encouraged that they communicate the trial design at home with their regular partner. Ideally, the trial should include a requirement for informed partner consent. However, it is recognized that under these conditions recruitment for such trials becomes much more difficult considerably expanding the recruitment phase and trial duration.

As a minimum it is recommended that all participants should at least verbally inform their partners. Preferably a signed partner consent form should be mandated, to ensure the accuracy of data recording.

Recommendation 1 (Grade B)

All clinical trials in male sexual dysfunction should consider the involvement of the sexual partner at least by verbal communication thru the study participant.

All clinical trials which consider active involvement of the sexual partner, i.e. collection of partner reported outcomes a signed partner consent should be mandated to ensure maximally possible accuracy of data recording.

b) Study Duration

In contrast to many other dysfunctions/diseases such as hypertension, diabetes or CAD sexual dysfunctions become only interpretable when assessed over a few weeks; sexual activity occurs on average once to three times a week and can be intermittent. Clinical trials in male sexual dysfunctions have to consider this very special situation which is unique in the clinical research setting and must therefore allow a reasonable time frame for investigating the changes in the sexual dysfunction under investigation and yet if possible record data from each sexual encounter.

It is recommended that phase IIb and phase III in male sexual dysfunction should include at least a 3 month treatment period to give the couple the opportunity for reasonably numerous sexual attempts to ensure that the data recorded is representative of their normal (pre-dysfunction) at home sexual activity.

The treatment phase must be preceded by a treatment-free run in period of at least 4 weeks, or even better 6-8 weeks treatment free run-in period to achieve a consistent baseline.

Because many couples who are confronted with moderate to severe male sexual dysfunctions for a longer time have often given up any sexual activities for longer periods of time, even for years, it is important that in such relationships the protocols should not force couples to adopt an unnatural sexual frequency pattern.
Recommendation 2: (Grade A)

All clinical at home phase IIb/III trials in MSD should consider

a, at least a 4 , preferable 6-8 weeks medication free run-in period to give those patients/couples, who have given up sexual activities for a longer time, an adequate time period to re-familiarize with their sexual life under natural basic conditions enabling them to collect correct baseline data regarding the severity of the dysfunction under consideration.

b, at least a 3 months medicated treatment phase following the medication free run in period to provide a reasonable time period for collecting efficacy and safety data of the investigational drug.

c) Study populations

As sexual performance patterns and sexual perceptions may differ markedly between nations, cultures and religions it is recommended by the committee that once a certain treatment/medication is considered for world-wide approval/launch the respective clinical trials should consider at least the major populations.

The same recommendation applies for different sexual orientations. In clinical trials for male sexual dysfunctions in theory one phase III clinical trial should be conducted in a homosexual population which accounts for about 7 % of male sexual orientations.

Recommendation 3 (Grade C)

Clinical trials in MSD should consider

a, possible differences regarding sexual habits among different cultures and countries, i.e. that at least the world-wide most representative cultures should be considered in a clinical research program of any investigational drug.

b, not only heterosexual but also homosexual populations

d) Study designs for clinical trials in male sexual dysfunctions

The only acceptable study design for a new drug for MSD, as for other diseases is in randomized, double-blind, placebo-controlled format.

In general after a certain drug has been identified in the preclinical setting to have the potential for the treatment of a certain (sexual) dysfunction this drug has to undergo a well established clinical phase I-III/IV research program according to the requests/rules of the regulatory authorities, which may vary with respect to study endpoints, numbers of patients and populations being investigated. To expedite eventual regulatory approval all pharmaceutical companies are in regular contact with the authorities to obtain up to date guidance. To help with this process, the FDA has created a Guidance for Industry in 2006 [17]

Recommendation 4 (Grade A)

All clinical trials in MSD regarding a new investigational drug/treatment must follow where ever feasible a Randomized, double-blind, placebo-controlled study design

All clinical trials in MSD regarding the investigation of any treatment either conservative or invasive should consider at least a randomization of the study population under investigation to avoid any undesirable bias

III. RATIONALE AND DESIGN OF PHASE I TO IV CLINICAL TRIALS IN SEXUAL MEDICINE

Drug development in male sexual dysfunction requires a carefully phased approach. In this process, safety, tolerability and pharmacokinetics of a novel compound are studied early in development (Phase I, conducted in healthy volunteers), preliminary efficacy and safety at a range of doses are studied next in the Phase II. Commonly phase II stage subdivides in Phase Ila and Phase Ilib trials. Phase Ila represents a proof of concept stage to investigate in small patient populations, suffering from the sexual dysfunction under consideration,
whether the drug shows significant efficacy against placebo. Afterwards one or two Phase IIb dose finding studies are conducted in an at home setting in larger patient groups with the typical patient/sexual dysfunction profile at which the drug is aimed for approval. Ideally in Phase IIb trials those doses are identified which show both a statistically significant efficacy against placebo and on the other hand a tolerable safety profile. Clinical efficacy and safety are confirmed fairly late in the Phase III stage in which the most common special study populations (for example diabetic or hypertensive patients etc.) are investigated with the doses identified at the Phase IIb program, just prior to marketing approval. Studies in special populations, observational safety studies, and studies for novel clinical uses may be conducted either during this process (where appropriate) or after initial marketing of a product (Phase IV).

1. PHASE I

In Phase I, a new drug or treatment is tested in a small group of people for the first time to evaluate its safety, to determine a safe initial dosage range for subsequent efficacy studies, and to identify commonly occurring side effects. Since these studies are often the first in humans, particular care is spent in the design to ensure patient and/or volunteer safety. The most important decisions in the protocol design are: rationale for the study, objectives of the study, design of the study to meet the objectives, selection of dose and dosing frequency, recognition of all potential risks, monitoring for those risks, and maintaining adequate precautions to manage those risks.

The earliest studies of a new molecular entity are usually single and multiple-dose safety, tolerability and pharmacokinetic (PK) investigations. These tend to be conducted in healthy young volunteers, followed by the same studies in older (age-matched) volunteers. In some cases the studies can be in patient volunteers. The starting dose is selected using the results of pre-clinical (animal or in vivo) toxicology, safety pharmacology and toxicokinetic studies. One might also use the results of non-clinical in vitro studies (such as receptor binding studies) and other non-clinical evidence to select a starting dose. This dose is usually many times lower than the toxic dose and the No-Observed-Adverse-Effect Level dose (NOAEL) in animals. It is common to "escalate" the dose in single-dose Phase I trials. One may escalate the dose in the same cohort of patients or one may select a new cohort for each dose escalation step. Dose is usually escalated in multiple of two (e.g. 1x, 2x, 4x 8x 16x) until a "maximally tolerated dose" (MTD) is reached.

Phase I dose-rising studies are often conducted totally in-hospital or in a clinical research centre because the clinical adverse events associated with the compound are yet to be fully delineated and because a major objective of these studies is to identify (or to safely "prompt") these side effects. Safety assessments are monitored at frequent and regular intervals and these may include clinical adverse events, vital signs, ECGs, clinical serum and urine chemistries, and other special safety assessments (e.g. injection or other application site monitoring, visual effects monitoring, pain assessments, sedation scores, etc.)

Phase I studies also routinely test the pharmacokinetics of a compound; that is, the concentrations of the compound and its metabolites in the plasma. This requires blood sampling at regular intervals to determine the maximum plasma concentration ($C_{max}$), time to maximum concentration ($T_{max}$), the average concentration ($C_{avg}$), area-under-the-concentration time curve (AUC), and elimination half-life ($T_{1/2}$). These parameters, are determined both after single doses and after multiple doses, in younger and in older patients, after eating and while fasting, after various dose strengths, and after various dosing frequencies. In these early studies, it is not uncommon to seek out the metabolic pathways for the compound in order to gain insight into future problems with specific drug interactions or the need to lower the dose in special populations (e.g., those with renal or hepatic impairment or the elderly). However, such analyses in sub-populations are often carried out later in the drug development program.

The importance of understanding the pharmacokinetics of the compound and the body's handling of the compound cannot be overemphasized in the study of drugs intended to treat sexual dysfunction.

In Phase I, it may also be possible to conduct some preliminary efficacy assessments, but only if these do not interfere with the primary reasons for doing the study: to assess safety, tolerability and PK. These may be carried out in patient volunteers. There is a cautionary note in that whatever "efficacy" measurements are made, the accrual of safety data should not be compromised. In ED, where preliminary efficacy may be assessed through a visual sexual stimulation test (VSS) using Rigiscan device, such efficacy procedures may confound the more critical safety assessments. The same could be true from the use of the SAM device in the assessment of ejaculation latency. One should avoid the tendency to try to answer too many questions in one Phase I or Phase II study. In other research areas, such as the study of medication for benign prostatic hyperplasia (BPH), a simple urine flowmetry examination may not confound safety assessment.
2. PHASE II.

In Phase II trials, the study drug or treatment is given to a larger group of people (anywhere from several dozen to several hundred persons) in order to characterize its preliminary efficacy and to provide additional safety data.

The key objective of the Phase II program is to explore a wide range of doses so as to define accurately the lowest effective dose, the dose(s) to be carried into larger Phase III trials, the maximally tolerated dose and the dose(s) showing obtrusive side effects. In essence this is the definition of therapeutic ratio or benefit: risk ratio.

This determination is key in sexual dysfunction, where both PE and ED are considered “lifestyle” indications and where there will be limited acceptability for a poor therapeutic ratio. For development of drugs for the treatment of sexual dysfunction, Phase II is a key phase, in part because the Phase III programs are usually very large and costly and dose-ranging in Phase III is unwieldy. Also, toxicities and preliminary efficacy that are identified in Phase II tend to predict those that will be seen in Phase III. Therefore, the Phase II estimates can be used to predict Phase III outcomes, to plan Phase III trials designs, and to focus attention on the most important clinical safety and clinical pharmacology concerns. The information from phase II is invariably used to determine the powering (patient numbers) for the pivotal phase III studies.

In Phase II, actual patients with the clinical condition (as opposed to healthy volunteers or “subjects”) almost invariably serve as the study population. One would particularly like to determine clinical benefit and safety in selected high-risk or treatment-resistant groups in Phase II. Early evidence of efficacy and safety in these “more difficult to treat” groups often bodes well for efficacy and safety in the broader Phase III population and may expedite a decision to move the program forward.

In Phase II, it may also be appropriate to explore particular safety issues in a small number of highly monitored patients; these issues might include: drug interactions, use in selected populations, selected organ-system risks (e.g. eye, liver, cardiovascular, neurological), local toxicities, or other drug-specific matters.

The endpoints in Phase II efficacy trials are usually similar to those in Phase III but may include such “pharmacodynamic” parameters as Rigiscan-monitored percent rigidity, or duration of time for maintaining a certain degree of rigidity. Such endpoints are often referred to as “surrogates” i.e. indirect indices of clinical benefit. Also, shortened versions of classical endpoints (modified sexual history diaries, patient-reported outcomes measure, and quality-of-life questionnaires) or shorter treatment periods, may be used to lessen the overall time, effort and financial burden of the individual Phase II program. Since these trials generally do not serve as the “pivotal” evidence for safety and effectiveness, novel endpoints may be explored at the discretion of the investigator or pharmaceutical company, preferably in consultation with the regulatory authorities.

Trial design in Phase II is not unlike Phase III, except perhaps for the use of shorter treatment intervals and greater use of crossover designs. It is possible to conduct smaller Phase II trials (Phase IIa) or much larger Phase II trials (Phase IIb) which resemble Phase 3 trials in their scope. Phase II studies may be designed according to the two-stage designs of Simon [18,19]. These are based upon deciding between “acceptable” and “unacceptable” response proportions. If the response proportion is high, i.e. “acceptable”, then the treatment will be considered for further study. If the response proportion is low then the treatment will not be considered for further study. Often these studies recruit in the region of 25-50 patients with about 15-25 in the first stage and the remainder in the second stage. If the proportion of patients in the first stage responding to the therapy is sufficiently low as to make it highly unlikely that the proportion of patients responding is at the acceptable level then the study is terminated early. This means that potentially poor treatments are stopped early. If the proportion of patients in the first stage responding to the therapy is sufficiently high then the second stage subjects are recruited and a decision made at the end of the study. As Phase II studies often have a small number of patients, it is generally best to use exact statistical methods to analyze them: e.g. StatXact or LogXact [20]. However, several web-based power calculation services are now routinely available and these have aided in satisfactory clinical trial design and data analysis.

It is possible to design Phase II trials taking into account both toxicity and treatment response; for example, using the methodology of Bryant and Day [21]. When using the methodology, the sample sized will be larger because one must take into consideration two variables: safety and efficacy. Such designs also have a mechanism for stopping the study should toxicity prove to be high or treatment response be less than adequate.

3. PHASE III

Phase III trials provide the bulk of the “substantial evidence” towards regulatory approval of a compound and correspondingly are often referred to as pivotal.

In sexual dysfunction, at least two such trials are usually conducted. These must be adequate and well-controlled. All Phase III trials in sexual dysfunction should be randomized, double-blinded and placebo-
controlled. In general, they tend to use parallel, fixed-dose arms, but are not limited to such designs. In fact, crossover designs or mixed crossover-parallel designs (where crossover treatment periods are built into a parallel randomization) are possible. However, if a crossover design is employed, one must take into consideration the possible bias of carryover effects or sequence effects in the design and analysis of the trial. Most regulatory authorities prefer parallel arm to crossover design studies at phase III.

The Phase III trial duration must be long enough to predict efficacy over a reasonable duration of use, but not so long as to cause excessive dropout in the placebo arm. The treatment period in most ED trials has been traditionally 12 weeks in duration and this would seem to be a realistic period of assessment of ejaculatory function in PE studies. There must be some form of a baseline period to allow for screening and baseline (prerandomization) assessments of efficacy. During the baseline period, a certain number of attempts at sexual intercourse should be made and in order for a given patient to be eligible for continued participation, a certain percentage of these should be failures. These baseline periods tend to be treatment-free, but some studies have used a single-blind placebo to estimate treatment compliance. The controlled treatment period is usually followed by an open-label extension study for the purpose of collecting longer-term safety data.

The population in Phase III must be as broad as reasonable safety permits, such that anyone who might receive the drug after marketing was at least eligible to receive treatment in Phase III. It may not be possible to conduct distinct subgroup analyses for each of these patient types, but that should not prevent this “open enrolment” policy. One might exclude those patients at the highest risk of adverse events, such as someone who has recently suffered significant major illness, e.g. a stroke, a myocardial infarction, or life-threatening arrhythmias. One might exclude patients with substantially reduced drug clearance such as those with significant renal or hepatic diseases.

Of the greatest importance in Phase III trials is the choice of a reliable, validated and sensitive primary efficacy endpoint (or endpoints) and the proper analysis of these. In ED, a tri-partite primary endpoint has been used with successful regulatory and clinical outcome: the Erectile function (EF) domain of the International Index of Erectile function (IIEF) and Questions #2 and #3 of the Sexual Encounter Profile (SEP) diary [22,23]. The later two questions refer to the per-attempt, diary-documented success in inserting the penis into the vagina and in maintaining the erection until satisfactory completion of sexual intercourse. We have found the use of these three endpoints to yield easy-to-interpret results and to provide reliable, reproducible clinical data. Also, we have found that using all three of these endpoints is sensitive to small drug treatment effects but does not exaggerate such effects.

In PE, likewise co-primary endpoints are used and data are presented as a composite of single event records particularly IELT and domains from validated patient reported outcomes (PROs)

Additional information relevant to Phase III outcomes for ED and PE may be found in the Patient Population and Outcomes Assessments sections below.

4. PHASE IV

Phase IV studies are those conducted following marketing approval or conducted as a condition of approval. They may be requested specifically by a regulatory agency, or may be conducted voluntarily. There are many reasons to conduct a Phase IV study.

a) Pharmaco-Vigilence Database

In addition all regulatory authorities require that a pharmaco-vigilence database is set up to record all clinical side effects post approval. Some of these reasons include the following:

• To assess better safety and efficacy in a specific subgroup.
• To assess better a particular safety concern that does not preclude approval.
• To monitor for a potential risk.
• To assess the efficacy and safety of a novel clinical use of an already approved product.
• To compare the efficacy and/or safety of two approved products.
• To interpret better the impact on overall quality-of-life.
• To assess longer-term safety in controlled trials.
• To assess patient or physician understanding of product labelling, or compliance with labelled instructions.

Other factors that may warrant a Phase IV study include health-related economic issues, such as drug costs, overall drug benefit for overall cost, or comparative costs. Such studies relating to healthcare economics are mandated in the EU.

In sexual dysfunction, conducting of post approval Phase IV studies is not unusual. However, because the acceptability of drug risk is fairly low in perceived lifestyle indications, although in the medical domain they are generally recognized diseases, some regulatory agencies may request that specific potential drug safety issues (for example, selected
relevant drug interactions) be studied prior to marketing approval. In all situations, phase IV studies intended for marketing claims must be designed as carefully and must be analyzed as rigorously as Phase III studies.

b) Drug Interaction and Special Population Studies

In developing a novel drug for erectile dysfunction, it is of utmost importance that the interaction potential of that novel compound with other clinically relevant compounds undergoes investigations. We are now fully aware that the sexual dysfunction population is a largely varied group, with many middle-aged and older males who have co-morbid medical conditions and who take concomitant medications. We are also now aware that compounds for sexual dysfunction are pharmacologically potent medications which can have adverse effects if taken with other substances. While not all concomitantly administered medications can (or should) be investigated, the most relevant potential interactions ought to be assessed.

For example, if it is known that a given drug has a potential effect upon the metabolism or excretion of the investigational sexual dysfunction drug, this may be assessed by a controlled drug-drug interaction study. An example of this would be a drug that inhibits a cytochrome P450 liver iso-enzyme that is critical to the metabolism of the particular ED or PE drug (e.g. the inhibitory effect of ketoconazole on the 3A4 iso-enzyme may affect the metabolism of the PDE5 inhibitors). Or, if the investigational drug itself affects the CYP450 iso-enzymes then particular drug-drug interaction trials may be appropriate. These types of studies are called "pharmacokinetic drug interaction" studies. They seek to determine the effect of a given drug upon the bodily exposure of the other drug, and vice versa. Blood concentrations of parent drug and the major metabolite(s) are the endpoints of interest. Safety endpoints such as vital signs and electrocardiograms may also be assessed concurrently in these studies.

Another type of critical drug interaction study is the "pharmacodynamic study". When two drugs have an interaction potential not related to pharmacokinetic interaction, but when their combined effects are still clinically relevant (for example, lowering of the blood pressure or increase in the heart rate), then a pharmacodynamic trial may be appropriate. Some relevant situations include the interaction between PDE5 inhibitors and nitrate-containing medications, or the interaction between a PDEI for ED and selected anti-hypertensive medications, alpha-adrenoceptor antagonists, or with alcohol. The endpoints of greatest interest in these trials are by definition "pharmacodynamic" endpoints and these can include vital signs, effects on cognition or sedation, or effects on other bodily signs or symptoms.

Finally, given the importance of the pharmacokinetics of the compound and the knowledge that sexual dysfunction (particularly ED) patients are often aged, and often have co-morbid conditions that may limit renal or hepatic function, it is crucial to understand the safety of the compound in special populations such as the aged, the renal impaired, or those with hepatic insufficiency. Other special population studies may also be appropriate and careful consideration is required in each particular circumstance.

Recommendation 5 (Grade A/B)

1. General: The requirements for all phases of clinical development of novel drugs in erectile dysfunction are well established and in the public domain and on web-sites for regulatory authorities. These should be adhered to, to ensure adequate benefit-risk ratio is identified.

2. trials at each phase have a different purpose and each phase helps investigators and/or the pharmaceutical industry to answer a different set of questions.

3. The earliest studies of a new molecular entity are usually single and multiple-dose safety, tolerability and pharmacokinetic investigations.

4. The critical objective of the Phase II program is to explore a wide range of doses so as to capture the lowest effective dose, the dose to be carried into larger Phase III trials, the maximally tolerated dose and the toxic dose(s). Surrogate endpoints are often used at this stage.

5. It is recommended that several endpoints are used as primary indices and these are derived from validated questionnaires.

6. Phase III trials provide the bulk of the "substantial evidence" towards regulatory approval of a compound. Endpoints must be relevant to the disease condition in the patient and usually involve PROs.

7. Phase IV studies are those conducted following marketing approval. They may be requested specifically by a regulatory agency, or may be conducted voluntarily. There are many reasons to conduct a Phase IV. Studies in specific populations can be required as part of the phase IV program.

8. Pharmacokinetic and pharmacodynamic drug-drug interaction studies and studies in special populations are critical to the overall understanding of the safety and efficacy of a given drug for sexual dysfunction. While each particular drug may require different studies, and careful consideration is necessary in each situation, it is assumed that almost all drug development programs in sexual dysfunction will require at least some of these types of investigations.
In PE the track for global drug approval (registration) has not yet been established. However, the early stage (phases I/II) should be similar to that from ED.

Likewise it is recommended that phase III in PE should be similar to ED in that 2 double-blind placebo-controlled studies are conducted with an open-label extension giving an exposure of at least 1 year to at least 100 patients.

**IV. CLINICAL TRIALS ON ERECTILE DYSFUNCTION**

1. **SPECIAL CONSIDERATIONS FOR CLINICAL TRIALS IN ERECTILE DYSFUNCTION**

   **a) Study populations - Key-inclusion Criteria**

   In general the overwhelming majority of all clinical trials conducted in this indication have required the following criteria for enrollment:

   1st: Chronic erectile dysfunction for at least 3 months (in many trials 6 months)
   
   2nd: Stable partner in a heterosexual relationship for at least (3)/6 months
   
   3rd: Willingness to participate in the trial and comply with the key requests of the trial:

   To maintain regular sexual activities over the whole course of the trial with a mean frequency of sexual activities of at least once per week
   
   To give up any other erectile function enhancing treatment including hormonal (testosterone) replacement therapy with study entrance
   
   To complete the patient’s diaries where applicable
   
   To present at the scheduled visits and return all study drug material (drug accountability)

   **b) Key Efficacy Endpoints - ED Severity**

   The presence of chronic erectile dysfunction is ensured during the treatment free run in phase mostly by means of the following assessment tools:

   **1) **SEXUAL ENCOUNTER PROFILE (SEP) **QUESTIONS 2 AND 3**
   
   **2) INTERNATIONAL INDEX FOR ERECTILE FUNCTION - ERECTILE FUNCTION DOMAIN (IIEF-EF) [22,23]**

   The Sexual Encounter Profile (SEP) is a 5 item questionnaire which is completed after each sexual intercourse attempt and contains the following questions:

   1. Were you able to achieve at least some erection (some enlargement of the penis)?
   
   2. Were you able to insert your penis into your partner’s vagina?
   
   3. Did your erection last long enough for you to have successful intercourse?
   
   4. Were you satisfied with the hardness of your erection?
   
   5. Were you satisfied overall with this sexual experience?

   Many clinical trials for male erectile dysfunction used the SEP 2/3 data as the main entrance criteria requesting that in at least 50 % of the requested sexual intercourse attempts (usually at least 1 attempt per week, i.e. at least 4 attempts within 4 weeks, were key for considering of randomization) either question 2 and/or 3 were answered with no.

   The International Index of Erectile Function (IIEF) is a 15 items comprising validated questionnaire which was developed with the financial support of the pharmaceutical industry (here Pfizer Incorp. New York, US) for the sildenafil clinical research development program [22,23]. Later on the IIEF-EF domain, comprising questions 1-5 and 15 served as the basic standard tool for categorization of the severity of the erectile dysfunction as was subjectively reported/felt by the patients included in clinical trials.

   The IIEF-EF domain was used until now in all clinical trials for a variety of new ED medications which were considered for market development.

   **Per definition the data of the IIEF-EF reflect the patients’ memory recall of their sexual experience during the past 4 weeks.**

   The maximum score which can be reached in the IIEF-EF domain is 30 and the categorization of the severity of ED according to the IIEF-EF domain is as follows:

   **Severe ED:** Score 1-10
   
   **Moderate ED:** Score 11-17
   
   **Mild ED:** Score 18-25
   
   **No ED/normal function:** Score 26-30

   Per definition do all patients with an IIEF-EF domain score < 26 suffer from any kind of erectile dysfunction and were therefore generally allowed to be involved in the majority of clinical ED trials.

   Some trials in the past restricted the inclusion criteria to a certain IIEF-EF score below and above which patients were not allowed to be recruited and some ED trials randomized patients according to the IIEF-EF severity at baseline, i.e. to assign patients with mild, moderate and severe ED per random to a certain treatment arm.
In many ED trials the final IIEF-EF domain score and/or its change from baseline was used as primary or secondary endpoint.

Another quite often used endpoint in clinical trials is the number/percentage of patients reaching a normal IIEF-EF score at study end indicating normal erectile function.

It has been proven in several clinical studies that the ED severity as assessed by the IIEF-EF score does not at all correspond with the underlying ED – etiology, i.e that the IIEF-EF ED categorization does not allow any conclusions regarding the assignment of the ED cause in terms of organic – mixed – psychogenic ED.

Thus the IIEF cannot substitute any diagnostic work-up aimed at identifying the underlying ED etiology.

c) Further study endpoints used as primary or secondary endpoints were:

Global Assessment Question (GAQ):

Has the treatment you have been taking over the past four weeks improved your erections?

O yes   O no

(Please compare to your erections before your participation in this study)

Patient Global Confidence Question:

Over the past 4 weeks, to what extent did your level of sexual functioning affect your self-confidence?

O (1) significantly lowered my self-confidence
O (2) moderately lowered my self-confidence
O (3) did not affect my self-confidence
O (4) moderately raised my self-confidence
O (5) significantly raised my self-confidence

Both the GAQ and the Global Confidence Question represent relatively weak efficacy end points and are not recommended to be used as primary efficacy endpoints

d) Further Validated Questionnaires Used as Efficacy Endpoints in ED Trials:

1) EDITS: Erectile Dysfunction Inventory of Treatment Satisfaction:

The EDITS was developed with the financial support from Pfizer Inc. New York, US (manufacturer of Sildenafil – Viagra®) and underwent the common study drug

</table>

Table 1: Results of oral drug phase II/III trials for Erectile Dysfunction (ED): Range in key efficacy endpoints in non selective broad- spectrum ED populations.

Number of study patients reported in the table refer to the whole study populations (active + placebo).

Integrated analyses of sildenafil trials reported “successful sexual intercourse attempts” not distinguishing between successful penetration (SEP2) and maintenance of erection up to completion of sexual intercourse (SEP 3)
validation process to assess satisfaction with medical treatments for erectile dysfunction and comprises a patient (11 items) and a partner (5 items) part. Test-retest reliability for the patient EDITS was 0.98 and for the partner EDITS 0.83. [35]. EDITS was used in several clinical trials with PDE 5 inhibitors. All items are scored from 0 (no satisfaction or dissatisfaction) to 4 (high satisfaction) and inally the mean satisfaction score was calculated and multiplied by 25 so that EDITS scores could range from a low of 0 (extremely low treatment satisfaction) to a high of 100 (extremely high satisfaction).

2) PAIRS: PSYCHOLOGICAL AND INTERPERSONAL RELATIONSHIP SCALES:

Pairs was developed and validated with the financial support by Eli Lilly and Company, Indianapolis, US (manufacturer of Tadalafil - Cialis®) to measure sexual self-confidence, spontaneity, and time concerns associated with ED and its treatment [36]. Later on a 15-item short version of Pairs was introduced [37]. Because the items contained in Pairs were obviously linked to the pharmacokinetic profile of Tadalafil with its longer half-life time this tool was exclusively used in clinical trials with Tadalafil and not accepted by the other PDE 5 inhibitor companies.

3) SEAR: SELF-ESTEEM AND RELATIONSHIP QUESTIONNAIRE:

Sear was developed and validated with the financial support of Pfizer Incorp., New York, US (Manufacturer of Sildenafil – Viagra®), to evaluate treatment responsiveness to sildenafil in ED patients. There are two domains: Sexual relationship (8 items) and conidence (6 items), the latter comprising two domains with sexual relationship (4 items) and overall relationship (2 items) subscales [38].

4) TSS: THE TREATMENT SATISFACTION SCALE:

This scale was developed and validated with the financial support by Bayer Healthcare, Germany (manufacturer of Vardenail – Levitra®) and comprises six scales: “satisfaction with medication”, “ease with erection”, “satisfaction with erectile function”, “pleasure from sexual activity”, “satisfaction with orgasm” and either “sexual conidence” for patients and “conidence in completion” for partners [39]. The TSS was used in clinical vardenail trials.

5) EQS: ERECTION QUALITY SCALE:

The EQS was developed and validated to investigate the erection quality and was supported by an unrestricted fund from Bayer Pharmaceutical Corp. and GlaxoSmithKline (manufacturer of Vardenail-Levitra®) [40]. With its 15 questions only related to erection it is comprehensive and was therefore rarely used in clinical trials.

6) EHS: ERECTION HARDNESS SCORE:

The EHS is a single-item, patient reported outcome...
(PRO) for scoring erection hardness and was financially supported by Pfizer Incorp., New York, US (manufacturer of Sildenafil – Viagra®) [41,]:

EHS: How would you rate the hardness of your erection?

0 Penis does not enlarge
1 Penis is larger but not hard
2 Penis is hard but not hard enough for penetration
3 Penis is hard enough for penetration but not completely hard
4 Penis is completely hard and fully rigid

7) QEQ: Quality of Erection Questionnaire:

The QEQ has been developed and validated with the financial support from Pfizer Incorp., New York, US (manufacturer of Sildenafil – Viagra®). It comprises 6 questions related to erection quality and duration with the sum of responses to all items being transformed onto a 0 – 100 scale with 100 as the highest possible score [42]

8) Proposals for PROs Used in Clinical Trials with in ED:

The need for a reliable patient reported outcome is obvious and now mandated by the regulatory authorities. In ED, historically the IIEF-EF domain score has been used and was considered as the standard efficacy PRO tool to assess the efficacy of any new drug under consideration for approval to treat ED and all the other validated PRO’s served as additional secondary efficacy endpoints to demonstrate further details on the features of a certain drug.

There is no question that the IIEF has shortcomings and may therefore deserve changes and improvements. It should be remembered in the design of new PROs that of paramount importance for patient and partner is the capability to induce a hard erection for a sufficiently long time to allow satisfactory sexual activities. Therefore the ED PROs should predominantly focus on:

A. completion of sexual intercourse/activities
B. rigidity/hardness of erection
C. self-confidence to engage in sexual activities.
D. impact of the new drug on patient’s personality/ quality of life
E. impact of the new drug on relation-/partnership-issues

The major problem with many of the PRO’s, focusing on all these items, is that all were funded by always only one pharmaceutical company and may have therefore considerable biases directed towards the product of that pharmaceutical company.

These shortcomings can only be overcome by the development of a new completely neutral PRO-tool aimed at capturing all the important items, mentioned above, and developed by a neutral committee of experts with an unrestricted fund of all drug producers in this field. Only when (or if) this happens will we have a neutral PRO tool for ED-trials capturing all the important items.

Recommendation 6 (Grade A)

For clinical trials with a new investigational drug in ED (Grade A)

a, Study populations - Key inclusion/exclusion criteria:

Only patients with a well-established, permanent chronic ED for at least 3, preferably 6 months, living in a stable partnership at least 3, preferably 6 months should be considered.

Patients must be willing to comply with the key requests of the trial i.e. to maintain regular sexual activities over the whole course of the trial with a mean frequency of sexual activities of at least once per week, must give up any other erectile function enhancing treatment, including hormonal (testosterone) replacement therapy with study entrance.

Patients with concomitant risk factors/diseases which may raise safety concerns because of the pharmacodynamic or pharmacokinetic profile of the study drug under consideration must be excluded.

b. Assignment of ED etiology

Assignment of the underlying ED etiology in terms of psychogenic, organic or mixed psychogenic-organic etiology is only justified and therefore recommended where specific etiology-oriented diagnostic investigations such as hormone parameters and intracavernosal injection test combined with penile duplex/color doppler are part of the study protocol.

Otherwise assignment of ED etiology must be considered arbitrary and unreliable

c. Assignment of ED severity

As long as there is no other more sensitive validated tool available ED-severity should be categorized according to the IIEF-EF Score.

d. Study endpoints (primary/secondary)

As long as no other more sensitive and more specific new validated questionnaires are available both the IIEF-EF score and SEP data are recommended for primary efficacy endpoints.
Because IIEF-EF is missing a key efficacy parameter in ED trials, i.e. erection hardness, it is strongly recommended to use in addition a validated erection hardness scale/score.

Regarding SEP data the committee recommends to use as study endpoints SEP 3 (ability to complete sexual intercourse) and SEP 4 (satisfaction with erection hardness) and not SEP 2.

Regarding assessment of other efficacy parameters such as effects on psyche, self-confidence, partnership and life quality the use of validated questionnaires is recommended which contain a patient and partner version like EDITS, TSS and SEAR.

e. Safety data

Established and recommended objective safety data are lab-exams, ECG recordings and blood pressure monitoring which have to be determined on a regular basis in phase II/III pivotal trials. It is highly recommended that at least in the early clinical research stage blood pressure and ECG recordings are conducted in conjunction with the study drug intake for 2-3 hours to investigate the direct impact of the study drug on these vital parameters.

It is recommended that adverse event (AE) data collection in conjunction with the study drug use is managed by means of an at home documentation considering a time frame of 24 h after study drug intake and using a Likert-like intensity/severity scale.

2. SPECIAL CONSIDERATIONS FOR COMPARATOR ED DRUG TRIALS

The arrival of three effective but similar PDE5 inhibitors in the marketplace has prompted the pharmaceutical industry to conduct comparator studies to determine patient or partner preference. Such preference studies are controversial particularly when designed by pharmaceutical companies.

The 2007 European Association of Urology Guidelines [43] stress the importance of patient education emphasizing the fact that all available PDE5 Inhibitors have similar effectiveness, claiming that ‘the patient will choose the final drug after his own personal experience’. The acknowledgement that the ED patient and his partner play an important role in therapeutic decisions has fuelled interest in the concept of patient preference and the need to determine the drug that most patients and partner prefer. From a clinical viewpoint, it seems logical that comparisons of existing PDE-inhibitors will be made as such evaluations might allow patients and physicians to choose a compound giving an optimal profile for their particular needs.

a) Methodological Aspects

Several preference studies have been conducted in the last few years, either by independent investigators or sponsored by the respective drug company eager to show any advantages of the own product. Unfortunately, the majority of these studies have shown serious design and methodological flaws limiting their clinical value and reliability. J Mulhall emphasized that patient preference studies differ from the classical efficacy and safety studies regarding study design and study endpoints [44,45].

The major limitations of published preference studies are biased drug instructions, compromising the blinding process or even conditioning patients’/couples’ preference, comparison of non-equivalent doses, inadequate wash-out intervals between treatment periods, lack of standardized preference assessments, differences in patient demographics, and lack of robust statistics [46].

The absence of a well-designed and validated questionnaire to evaluate adequately all aspects of patients’ and partners’ preference is a major issue. An extreme example is that in some studies only a single question reading ‘Which treatment did you prefer?’ is used as an index.

Recommendation 7 (Grade A)

Comparator trials in ED should consider the following rules:

a. randomized, double-blind, crossover study-design with adequate wash-out phases in between
b. no pre-selection of patients to avoid any bias suitable to favor one study drug
c. equivalent maximum doses of each study drug
d. equivalent treatment periods for each study drug
e. adequate and equivalent wash-out phases

3. SPECIAL CONSIDERATIONS FOR ED TRIALS WITH TOPICAL, TRANSURETHRAL AND INJECTABLE VASOACTIVE DRUGS

In ED trials with topical agents, transurethral or injectable vasoactive drugs the same criteria regarding study designs and endpoints should be employed as for oral drugs. The only exception is that in self-injection (intra-cavernosal) trials a placebo arm may be not considered appropriate by some ethical review committees due to the somewhat invasive nature of the procedure.

For topical agents only with prostaglandin E1 (alprostadil) have placebo-controlled trials with reasonable numbers of patients been published.
Equally only a limited number of adequately controlled trials on transurethral and intracavernosal applications of alprostadil as MUSE® or alprostadil alfadex or sterile powder have been published [48,50-52]

In addition to oral drug-trials trials with locally administered ED drugs should consider:

- Ease of application
- Acceptance rates
- Prolonged erections/priapism
- Local complications such as burning, fibrosis, infection
- Long-term use

4. SPECIAL CONSIDERATIONS FOR ED TRIALS WITH VACUUM-DEVICES

Reliable date on long-term use and acceptance is relatively limited and frequently concern the Osbon ErecAid device [53] Trials with vacuum devices should follow the same recommendations as described for the other ED treatments regarding the endpoints and questionnaires. In addition because of the special mode of application trials with vacuum devices should consider

- Ease of application
- General acceptance of application mode by both the patient and the partner
- Local complications
- Long-term use discontinuation rate
- Mechanical failure rates

5. SPECIAL CONSIDERATIONS FOR ED TRIALS WITH PENILE IMPLANTS

There is general agreement that penile implants represent the last step/resort in the treatment cascade of erectile dysfunction [54-55] Because penile prosthetic surgery is the most invasive treatment option for ED prospective trials have to follow special rules regarding potential study populations. In addition because from the operational point of view there are generally speaking 3 different device options: semi-rigid, 2 piece inflatable and 3 piece inflatable implants the general question raises whether it is reasonable to conduct prospective trials in this field only with a certain type of implant (inflatable, semi-rigid) or to consider all types of implant in the same trial and to leave the choice to the participating patient.

Considering the numbers of penile implants being inserted per year with only about 30,000-40,000 per year world-wide [54] it is understandable that prospective trials in this field are difficult and cumbersome to conduct. These problems regarding prospective trials in penile prosthetic surgery have become obvious in one of the very few prospective trials which have been published in this field with a reasonable number of patients[56]: In this prospective multicenter trial with the inflatable Mentor alpha one prosthesis only 54 % (234/434) of the patients were willing to fill a patient questionnaire after a mean follow-up of 22 months. The overwhelming majority of penile implants today are 3 piece inflatable prostheses amounting to more than 80 % of all inserted implants. In an review of the most experienced institute the long-term survival rate of inflatable penile implants comprising altogether 14 different inflatables (n=2,384) 10-years revision free survival rates were 68,5 % and 15-years revision free survival rates were 59,7 % [57].

These figures make clear that regarding potential prospective trials in penile prosthetic surgery should ideally comprise a time frame of between 10-15 years similar to prospective trials in prospective prostate cancer trials.

With these data in mind the challenges of prospective trials in this field are obvious.

In general prospective trials in penile prosthetic surgery must therefore consider 2 different parts:

- **Mid-term trials** ideally with a mean follow-up of at least 2 years evaluating the following topics:
  - Short-term mechanical failure rates (cylinders, pump, and reservoir)
  - Surgical failure rates (infection, mal-insertion such as Concorde phenomenon, bulging etc.)
  - Patients' and partners’ acceptance rates
  - Patients and partners’ satisfaction rates regarding the implant function and sexual life as such
  - Ease of device operation
  - Penile length and penile shape
  - Effects of penile implant surgery on partnership, self-esteem etc.
  - Regular use rates of the penile implant
  - Additional use of other ED treatments such as PDE 5 inhibitors, MUSE, others

- **Long-term trials**
  - With the primary outcome revision free survival after 5, 10 and even 15 years in addition to the above mentioned topics.
  - **Prospective trials in penile prosthetic surgery** should only consider experienced surgeons/institutes with a reasonable number of procedures per year.
  - In the previously mentioned multicenter trial the request was > 20 implants per year which seems a reasonable number in this field.
Unfortunately there is no validated questionnaire available in the public domain which considers all the special items linked to penile implants.

6. SEXUAL FUNCTION (REHABILITATION) ASSESSMENT AFTER PELVIC SURGERY

After the introduction by Walsh and Donker 1982 Nerve-Sparing Radical Prostatectomy (NSRP) has become world-wide the procedure of choice to preserve erectile function postoperatively provided location and volume of PCA is not speaking against that procedure. Although the majority of all radical prostatectomies either performed as open or as laparoscopic/Robotic procedure is eager to preserve the cavernosal nerves incidence of post operative ED is still high and recovery of erectile function does not occur in the majority of cases without medical support even after bilateral nerve sparing prostatectomy (BNSP)

In the current era of early PCA detection, where increasingly many young, sexually active men are undergoing this surgical procedure, the importance of preservation of erectile function becomes even more crucial. To improve postoperative outcome of curative prostate cancer treatment the concept of penile rehabilitation was first introduced by Montorsi 1997 [58]. The rationale of penile rehabilitation is to prevent cavernous tissue and function damage, which inevitably occurs after cavernosal nerve injury.

Following the idea of Montorsi’s research group Mulhall further developed this concept, showing in a non randomized study with 132 patients not responding after prostatectomy to on demand sildenafil, that a pharmacologic penile rehabilitation protocol (sildenafil and alprostadil) resulted in higher rates of spontaneous functional erections [59].

Recently, PDE-5-inhibitors have been studied for their use in penile rehabilitation, either on demand, given at night or daily. [60-63] Unfortunately there is considerable heterogeneity among these studies and the scientific evidence available today that penile rehabilitation therapy works is still limited. Table 3 summarized the most relevant clinical trials dealing with penile rehabilitation published today.

Some of these studies provided limited evidence that early penile rehabilitation strategies with PDE 5 inhibitors may be superior to wait and see strategy [60,62,63].

Recently Montorsi et all [64] published a multinational prospective randomized, double blind, double–dummy study in a huge population of 628 patients after NSRP, conducted only in so-called centers of excellence, with normal preoperative erectile function (IIEF-EF score ≥ 26). Erectile function and sexual intercourse completion rates improved significantly in both treatment arms compared to placebo during the initial double-blind period. But the results clearly show that nightly dosing with vardenafil did not have any effect beyond that of on demand use. Following a washout phase for 2 months with placebo, IIEF-EF scores ≥ 22 were achieved in 28.9%, 24.1%, and 29.1% of patients who were prior to this 2 months wash-out phase on placebo, vardenafil nightly, and vardenafil on demand, respectively, showing no statistically significant difference among the 3 different treatment arms . The advantage of the vardenafil treatment arms over placebo was not persistent in the open-label phase. Although this is currently the most comprehensive prospective study dealing with penile rehabilitation therapy after BNSP unfortunately due to a mayor study design flaw this study could not answer the question whether daily PDE 5 inhibitor therapy, dosed adequately according to the pharmacokinetic profile of the study drug, may be superior to an on demand regimen. Regarding the short half life of vardenafil with about 4 hours daily vardenafil should have been dosed three times per day to guarantee a steady drug exposure and not once as it was the case in this trial.

a) Methodological Problems in Trials for Penile Rehabilitation Therapy After Curative Treatment (Surgery, Brachytherapy, External Radiation) for Prostate Cancer

At present all the published data except one on this subject did only focus on restoration of erectile function and completely ignored the high frequency of other sexual dysfunctions which occur especially after prostatectomy. Just recently at the annual congress of the European Association of Urology 2009 in Stockholm a multidimensional scale for the assessment of sexuality after radical prostatectomy was introduced showing that [65]:

- 75.4% of 53 consecutive patients after RRP used ED treatments 82% i.c. injections and only 10 % PDE 5 inhibitors

- 53% reported lower sexual desire and 79% a decrease of sexual activities

- 41.5% reported loss of orgasm (!!) , another 38% decreased orgasmic intensity

- 21% reported loss of urine during orgasm

- 59% reported lower sexual satisfaction of the partners

- 82% reported loss of masculinity

- 55% reported loss of self-esteem

These data make clear that prostatectomy exerts a profound negative impact on all sexual functions even on self-esteem and masculinity. Until now in all the published studies only erectile dysfunction was
considered disregarding that prostate removal shows a much broader spectrum of negative consequences on sexual functions and psychological features.

Considering these new data and our personal experiences, prospective trials for sexual rehabilitation therapy must consider the following domains:

**Erectile function**

**Ejaculatory/orgasmic function/intensity**

**Incontinence problems during sexual activities**

**Penile length/shape problems**

**Sexual satisfaction**

**Impact on psyche and life quality**

**Impact on partnership and partner’s satisfaction**

**Recommendation 8 (Grade B)**

Sexual (Penile) Rehabilitation Trials After Pelvic Surgery/Radiation Therapy Should

- be conducted timely after the procedure, i.e. 2-4 weeks afterwards
- be conducted in homogenous, well defined study populations (BNSP, UNSP or NNSP, cystectomy, brachytherapy other)
- last for a reasonable period of time (6-12-24 months – at least 12 months study duration is recommended).
- be followed by a 2 months wash-out phase (placebo or no treatment) to assess IIEF-EF and SEP data afterwards
- consider the pharmacokinetic profile of the study drug regarding the frequency of dosing if daily dosing trials are considered: short acting drugs must be dosed 2-3x/day, long-acting once a day.
- consider age and relevant preexisting co-morbidities which may interfere with the study outcome
- be conducted only in those couples/patients who were regularly sexually active before the intervention in question and wished to continue.
- should consider in one arm combination therapy regimens such as PDE 5 inhibitor with injection- or intraurethral therapy

7. GENE THERAPY TRIALS IN ERECTILE DYSFUNCTION

The bar to conduct clinical gene transfer trials for ED has been set quite high because of the well publicized deaths of 18 years old Jessie Gelsinger in 1999, two children in Paris who developed leukemia after treatment to modify stem cells with a retroviral vector for leukemia and a 36 year old woman, Jolee Mohr, who was transferred with adeno-associated viral vector for chronic painful rheumatoid arthritis.[67-69] Most of the approximately 800 gene transfer trials have been conducted in people with diseases in which there are few other alternatives or are potentially fatal such as cancers, end stage ischemic disease, or for a genetic, immutable disease. The stigma related to those aforementioned deaths has made the conducting of a clinical transfer trial for the indication of ED dificult. Particularly as some assume that ED is not a significant enough problem to warrant the risk or that it is no longer considered a problem as the problem is considered “managed by the PDE5 inhibitors”

In the United States all gene transfer trials submissions are reviewed by the Center for Biologics Evaluation and Research (CBER) of the Food and Drug Administration (FDA). CBER has recognized the following:

1) ED is a significant problem that both adversely effects the quality of life of the patient and his sexual partner,
2) That the pursuit of therapy may unmask an underlying life-threatening illness, and
3) that there is room for improvement above currently available therapies.

In addition to FDA each application is also reviewed in an advisory capacity by the Recombinant DNA Advisory Committee (RAC) of the National Institutes of Health (NIH). The NIH established the RAC on October 7, 1974 in response to public concerns regarding the safety of manipulating genetic material through the use of recombinant DNA techniques.

Important considerations regarding gene therapy trials in ED or other dysfunctions in Sexual Medicine include the following:

- The plasmid should be manufactured under good manufacturing process conditions (GMP) by a licensed production company. That process insures that the product is what it is supposed to be in terms of
  1. gene structure
  2. plasmid size
  3. gene restriction mapping
  4. plasmid stability,
  5. host strain purity,
  6. no toxic contaminants,
  7. guaranteed sterility.

The GMP process is a lengthy multistep process.

- The final product must be tested and shown to have a physiological effect before transfer into humans is allowed.
- It must use a vector that does not have a high incidence of allergy in the population (for example use of a kanamycin resistance gene rather than a penicillin resistance gene in the manufacturing process).

IND Approval

Extensive pre-clinical Information is vital for IND approval. Some of the major points include

- Proof of efficacy that demonstrate activity of the transferred gene
- Duration of action in the organ or tissue of interest
- Biodistribution of the gene after transfer

For this point 42 organs and fluids of the animal model are evaluated for untoward effects after transfer.

- Duration of activity of the stored product.

Institutional Review Board (IRB) Approval

Once IND approval is granted no study in humans can be conducted without (IRB) approval. That is true whether studies are done in academic institutions or in private practice offices or centers designed for trial. However, the IRB may be either based at an institution or independent. In the case of ICI’s ED trial the institutional IRB would not approve the trial because of concerns of conflict of interest, but a private IRB, comprised of many of the same reviewers did approve the trial. To allow total neutrality in both accruing participants or analyzing data the sponsor or developer of the product should not have any direct role in the trial. [70]

Informed consent

The issue of proper informed consent has received the most intense scrutiny in the lay press, in scientific journals, and by biomedical ethicists.[71,72] This component of the process is particularly important for a trial using gene transfer done for a non-fatal disease. In addition to the specific additional recommendations for Informed Consents for gene therapy trials (compared to ordinary drug trials), added layers of protection for the participant must be included.

In addition to independent IRB approval the protocol
must also be approved by a separate Institutional Biosafety Committee (IBC). The charge of the IBC includes:

1. Review of ALL research proposals involving recombinant DNA.
2. Conducting periodic review to ensure compliance
3. Proscribing emergency plans covering accidental spills and personnel contamination by recombinant agents, as developed and recommended by the Biosafety Office.
4. Reporting significant problems or violations of the NIH Guidelines

Other specific issues related to gene transfer include:

- The FDA has great concern that the gene should not be transmitted by sperm thus placing progeny at some unspecified risk. Thus all men and their partners in separate informed consents in the trial agreed that condoms would be used during the duration of the trial.
- Semen specimens are requested at the visits during the trial
- Men could only be admitted to the trial with moderate to severe ED who had failed, or were unwilling to continue using other modes of therapy
- Participants were willing to have an autopsy should they succumb during the trial
- Initially the participants agreed to 15 year follow-up after transfer. That was later modified to 18 months after plasmid transfer as opposed to viral vector transfer.

Phase 2 and 3 trials will include the added element of a placebo group, multiple dosing of the gene and use of transfer into specific subgroups as for drug trials. Safety data and any (including lack of) efficacy accrued in phase 2 trials should be reviewed with the participant.

Efficacy and duration of effectiveness after transfer as a byproduct of the phase 1 trial are similar to those employed in the drug trials for ED listed in this chapter.

At present only one gene transfer phase 1 trial for ED has been successfully conducted and published using gene transfer of potassium channels to treat smooth muscle diseases(73,74)

**Recommendation 9 (Grade A)**

For clinical trials with a gene transfer in ED

**a. Study populations - Key inclusion/exclusion criteria:**

Only patients with a well-established, permanent chronic ED for at least 6 months, living in a stable partnership at least 6 months should be considered.

Participants must be willing to comply with the key requests of the trial i.e. to maintain regular sexual activities over the whole course of the trial with a mean frequency of sexual activities of at least once per week, must give up any other erectile function enhancing treatment, with study entrance.

Participants who are capable of ejaculation must be willing to use condoms during coitus (until it is proven that the gene does not transfer to semen)

Participants must be willing to be followed for 18 months post-trial for plasmid transfer and 15 years if viral vectors are used.

Participants must be willing to give permission for autopsy in the event of death post transfer during follow up period.

Participants and partner should be explicitly told that they should not expect cure from transfer by an independent counselor while obtain informed consent.

Participants with concomitant risk factors/diseases which may raise safety concerns because of the profile of the study gene under consideration must be excluded

**b. Assignment of ED severity**

As long as there is no other more sensitive validated tool available ED-severity should be categorized according to the IIEF-EF Score. For Phase I and Phase II trials participants should be in the moderate to severe range. For Phase III after long-term safety has been demonstrated the participants can be extended to mild to severe ED

**c. Study endpoints**

For Phase I safety is the primary study outcome. Sequential increase in dose should be used and before proceeding to the next highest dose an independent Data Safety Monitoring Board must review the collected data and agree that the next cohort can commence.

For Phase II and Phase III trials both safety and efficacy should be followed. The primary study outcome will be the change from baseline or last observation carried forward of IIEF-EF and SEP at 12 weeks after transfer.

As long as no other more sensitive and more specific new validated questionnaires are available both the IIEF-EF score and SEP data are recommended for primary efficacy endpoints.

Because IIEF-EF is missing a key efficacy parameter in ED trials, i.e. erection hardness, it is strongly recommended to use in addition a validated erection hardness scale/score.
Regarding SEP data the committee recommends using as study endpoints SEP 3 (ability to complete sexual intercourse) and SEP 4 (satisfaction with erection hardness) and not SEP 2.

d. Safety data

Established and recommended objective safety data are lab-exams, semen evaluations for gene, exam of penis at regular intervals, ECG recordings and blood pressure monitoring. It is highly recommended that at least in the phase I and II blood pressure and ECG recordings are conducted in conjunction with the transfer for 2-3 hours.

V. PATIENT REPORTED OUTCOME (PRO)

1. PRO VALIDATION PROCESS SHOWN ON OCCASION OF IPE DEVELOPMENT

The following represents the background on the need for PROs and the validation procedure. This is described in detail for the IPE, one of the more recently developed PROs.(75) This does not indicate that the committee has any preference for the IPE over any other validated PRO but the only is illustrative of the validation exercise.

Although IELT is an objective measure of ejaculatory function it does not address the impact of therapy on the patients’ well-being and confidence in their sexual performance, which are important markers of treatment benefit. This can be measured by the use of patient-reported outcome (PRO) questionnaires. A PRO is a measurement of any aspect of a patient’s health status that comes directly from the patient, without the interpretation of the patient’s responses by a physician or anyone else. In clinical trials, a PRO instrument can be used to measure the impact of an intervention on one or more aspects of patients’ health status, hereafter referred to as PRO concepts, ranging from the purely symptomatic (response of a headache) to more complex concepts (e.g., ability to carry out activities of daily living), to extremely complex concepts such as quality of life, which is widely understood to be a multidomain concept with physical, psychological, and social components. Data generated by a PRO instrument can provide evidence of a treatment benefit from the patient perspective. For this data to be meaningful, however, there should be evidence that the PRO instrument effectively measures the particular concept that is studied. Generally, findings measured by PRO instruments may be used to support claims in approved product labeling if the claims are derived from adequate and well-controlled investigations that use PRO instruments that reliably and validly measure the specific concepts at issue. The glossary defines many of the terms used in this guidance. In particular, the term instrument refers to the actual questions or items contained in a questionnaire or interview schedule along with all the additional information and documentation that supports the use of these items in producing a PRO measure (e.g., interviewer training and instructions, scoring and interpretation manual). The term conceptual framework refers to how items are grouped according to sub-concepts or domains (e.g., the item walking without help may be grouped with another item, walking with difficulty, within the domain of ambulation, and ambulation may be further grouped into the concept of physical ability).

In the context of studies in sexual dysfunction, a PRO is a measurement of any aspect of a patient’s health status that comes directly from the patient, without the interpretation of the patient’s responses by a physician or anyone else, and therefore uniquely provides evidence of treatment benefit from the patient perspective. Guidance from the regulatory authorities indicates that both objective and PRO methods are required to document improvements in sexual function [17]. For data to be interpreted and evaluated by the regulatory authorities, the PROs used must be both validated and relevant to patients.

The 10-item IPE questionnaire (Table 4) is divided into three domains, i.e. ejaculatory control (four questions), sexual satisfaction (four questions) and distress (two questions), each answered on a 6-point scale. The maximum possible scores for control and satisfaction are 20 points (most control/satisfaction) and the maximum score for distress is 10 points (least distressed).

The stages of the validation exercise for the IPE are summarized in Table 5. Ultimately any instrument must be capable of detecting change and defining or identifying minimally clinically important differences (MCIDs, Table 6).
Table 4: IPE Individual Questions.

All questions relate to the past 4 weeks with graded responses:

- How often did you have control?
- How much confidence did you have?
- How often was intercourse satisfactory?
- How satisfied were you with your sense of control?
- How satisfied were you with the length of intercourse?
- How satisfied are you with your sex life?
- How satisfied have you been with your sexual relationship with your partner?
- How much pleasure has sexual intercourse given you?
- How distressed were you by how long you lasted before ejaculation?
- How distressed have you been about your control over ejaculation?

Table 5: Stages in IPE PRO validation.

Develop initial questionnaire

- Interviews with Althof & Rosen: 17 item questionnaire
- Assess measurement properties
- Four domains identified via factor analysis
- One domain found dropped
- Good reliability (internal consistency and test-retest reliability) and validity (convergent and known-groups)

Modify questionnaire

- Qualitative interviews with PE patients: question refinement; no new concerns raised
- FDA requested modifications to some questions: cognitive debrief with PE patients; small refinements
- Current version: 10 items, 3 domains (control, satisfaction & distress)

Reliability and validity retested and found to be good

- Internal consistency (Cronbach’s α >0.7)
- Test-retest reliability (ICC >0.7)
- Correlation with IELT >0.6 for all domains
- Discriminates between PE and normal men

Table 6: Final requirements for validation.

Ability to Detect Change

- Change versus changes in global rating of change
- Change versus changes in premature ejaculation profile (PEP)
- Change versus changes in IELT

Minimum clinically important difference (MCID)

- Anchor based
- Small improvement in global rating
- One category improvement in PEP
- Distribution based
- 0.5x SD

Recommendation 10. (Grade A)

PROs have been developed for several urological conditions such as stress incontinence, OAB, BPH and ED. Almost all regulatory authorities require the use of validated PROs in phase III pivotal studies and the validation exercise is described on their websites.

It is recommended in phase III that either a validated PRO is used or if not available that the validation procedure explained on regulatory authority websites is adhered to rigorously.

VI. CLINICAL TRIALS IN PREMATURE EJACULATION (PE)

1. DEFINITION OF PE

Premature ejaculation represents one of the most common male sexual disorders with prevalence rates between 18 and 25% depending on the definition used.

Until recently 5 different definitions for PE were in use:

International Classification of Diseases 10th Edition (ICD-10) [76]
Diagnostic and Statistical Manual of Mental Disorders 4th Edition (DSM-IV) [77]
American Urological Association (AUA) Guidelines [78]
European Association of Urology (EAU) guidelines [79]
2nd International Consultation on Sexual Dysfunctions/World Health Organization (ICSD/WHO) 2004 [80]

The major shortcoming of all these definitions was that they were all authority based rather than...
evidence based and were not supported from controlled clinical and/or epidemiological studies, a fact which raised criticism in the literature [81]

To address this obvious lack of a generally acknowledged definition of PE which establishes the basis for both diagnosis and treatment of PE and clinical trials for PE, the International Society for Sexual Medicine (ISSM) convened an ad-hoc steering committee on PE 2007. The members were the world-wide leading experts in PE, identified through peer reviewed publications in this field, and were responsible for constructing a new evidence based definition of PE. Based on an extensive literature review of the last decades, the committee formulated the following new definition for lifelong PE [82];

Lifelong PE is defined as a male sexual dysfunction characterized by

- Ejaculation which always or nearly always occurs prior to or within about one minute of vaginal penetration; and
- Inability to delay ejaculation on all or nearly all vaginal penetrations; and
- Negative personal consequences, such as distress, bother, frustration and/or the avoidance of sexual intimacy

The restriction of the Intravaginal Ejaculation Latency Time (IELT) to about one minute is supported by several epidemiological studies using stop-watch measured IELT’s in men with lifelong PE and those with normal PE, serving as controls[9,83]: According to these studies about 90 % of patients with lifelong PE ejaculated within 1 min. after vaginal penetration with 80 % of them showing an IELT within 30 sec. whereas the median IELT of an unselected normal population, comprising 500 heterosexual couples, was 5.4 min [81]. In the US observational study with a total of 1.587 subjects, among them 207 subjects with PE according to the DSM-IV criteria, the median IELT in men with PE was 1.8 min. as compared to a median IELT of 7.3 min. in non-PE men [9]. In this study 26 % of PE men showed an IELT< 1min., 52 % < 2 min.,35 % between 2-5 min. and 13 % between 5-25 min. In the non-PE population in 6 % of all men the measured IELT was < 2 min.

With these data in mind the defined IELT of about 1 min. in the new ISSM PE definition sets a strict criterion for defining PE.

In addition to the IELT as an objective indicator, the following parameters were identified as being particularly significant for the diagnosis of PE:

Lack of control over ejaculation/inability to delay ejaculation

PE-related negative consequences such as distress, bother, frustration.

These assessment measures which turned out to be sensitive for the definition of PE were elaborated in two different validated PRO-based questionnaires. One of these questionnaires (Index of Premature Ejaculation) was developed with the financial support of Pfizer Incorp.;US [75] and the other one (Premature Ejaculation Profile (PEP) with the financial support of Johnson & Johnson,US and was used in the Dapoxetine clinical research program [84].

There is an increasing evidence in the literature that lifelong PE has an underlying neurobiological and/or genetic and thus a more organic than psychogenic etiology [85,86].

In contrast to lifelong PE acquired PE can have a variety of contributory risk factors such as Erectile Dysfunction (ED), prostatitis or thyroid disorders [87].

Regarding these differences between lifelong and acquired PE the ad hoc committee on PE 2007 decided that at that time there are insufficient published objective data to support an evidence based definition on acquired PE.

In an 2nd attempt to reach a consensus for an evidence based definition on acquired PE in a joint meeting of the ISSM and the European Academy of Andrology (EAA), which was held once more under the auspices of the ISSM Standards Committee at 2nd July 2008 in Hamburg the committee came to the following position statement:

- Acquired PE is a sub-type of premature ejaculation characterized by

  - a substantial decrease in time-to-ejaculation compared to a man’s previous sexual experience,
  - the inability to delay ejaculation on all or nearly all vaginal penetrations, and
  - negative personal consequences, such as distress, bother, frustration and/or the avoidance of sexual intimacy 1

1 The third construct required for PE definition, i.e, temporal range of IELT. Further clinical research is required to obtain IELT and PRO-data for acquired PE.

2. CLINICAL TRIALS FOR PE STUDY DESIGNS AND OUTCOME MEASURES

Based on the published literature regarding PE it is generally acknowledged that PE causes considerable psychological burden both for the patients and the partners and their relationship [88]. In this regard there is general agreement both in the medical domain and within the regulatory authorities that PE has to be considered a pathological condition/ dysfunction rather than a lifestyle issue and that it is worth to consider new treatments for alleviation of this dysfunction.
Considering all the different clinical trials conducted in men with PE and which has been published in peer reviewed journals only a few of them met more or less the new criteria for the definition of PE, i.e. IELT of about one minute, PROs such as lack of control over ejaculation/inability to delay ejaculation and distress/bother related to PE, and were conducted as randomized, placebo-controlled, double-blind trials [89].

3. DAPOXETINE CLINICAL TRIAL PROGRAM

Dapoxetine is a new serotonin transporter inhibitor with a short T MAX and a short T ½ which has been developed for on demand use in premature ejaculation. The drug is meanwhile approved and launched across several European countries.

a) PROs Used in Clinical trial Program

1) Premature Ejaculation Program (PEP)

2) Clinical Global Impression of Change (CGI-C):

Compared to the start of the study, would you describe your premature ejaculation problem as:
- 3 much worse
- 2 worse
- 0 no change
- 1 slightly better
- 2 better
- 3 much better

The world-wide Dapoxetine clinical trials program used world-wide the same study design:

US-trials [90,91]

Men ≥ 18 years and living in a stable monogamous heterosexual relationship for ≥ 6 months with PE according to the DSM-IV criteria for ≥ 6 months (in the US trials IELT was neither reported nor assessed)

European/Canada/South America/South Africa 22 countries trial [92]

Men ≥ 18 years and living in a stable monogamous heterosexual relationship for ≥ 6 months PE according to the DSM-IVTR criteria for ≥ 6 months

Moderate PE-related distress or interpersonal difficulty

Measured IELT of ≤ 2 min. in ≥ 75 % of valuable events (at least 4 requested) during a 4 –wk screening/baseline run in phase.

No relevant ED as assessed by an IIEF-EF score of ≥ 21

Study endpoints used in the Dapoxetine program:

US-trials

Changes in the Premature Ejaculation Profile (PEP) [84] Assessment of treatment/drug-related adverse events

European/Canada/South America/South Africa 22 countries trial [92]

Stopwatch measured IELT

PRO measures including the Premature Ejaculation Profile (PEP, 84) and the Clinical Global Impression of Change (CGI)

In this regard a composite PRO definition of clinically relevant benefit was applied based on the percentage of patients achieving an increase of greater than or equal to two categories in control and a decrease of greater than or equal to one category in distress at week 12 and week 24. In addition other secondary endpoints were the percentages of men with a decrease of greater than or equal to one category in distress or an increase of greater than or equal to one category in satisfaction.

Table 7: The Premature Ejaculation Profile [84]
Fig. 2: Study design of the European/Canada/South America/South Africa 22 countries trial [92]

Fig. 3: Dapoxetine clinical trials: mean IELT by study and treatment at endpoint [90-94]

Fig. 4: Dapoxetine clinical trials (pooled data) Drug-related adverse events [90-94]
b) Outcome of Dapoxetine Trials

The relevant efficacy and safety data of the Dapoxetine trials are summarized in fig. 2-5 and may lay the reference basis for other drugs under consideration for PE treatment. Regarding patients with lifelong or acquired PE the pooled data did not show any statistical significance in terms of efficacy and safety.

4. TOPICAL EUTECTIC MIXTURE FOR PREMATURE EJACULATION (TEMPE - PSD502) CLINICAL PROGRAM

PSD502 is a topical agent designed specifically for treating PE and consists of a metered-dose aerosol formulation of lidocaine and prilocaine dissolved in a non-chlorofluorocarbon propellant, which also acts as a solvent, forming a eutectic-like mixture [95,98]. Uniquely the desensitizing agents in this non-aqueous formulation can penetrate the poorly keratinized modified mucosa of the glans penis, but not the fully keratinized skin of the penile shaft, enabling a localized desensitizing effect [95,97]. The efficacy of PSD502 in PE has been tested in two previously published clinical trials [96,98]. In both of these studies, patients were selected according to the subjective Diagnostic and Statistical Manual of Mental Disorders, fourth edition (DSM-IV) definition of PE which does not include a time element [96,98].

In the phase III multicentre, multinational study in all, 300 men with PE, were randomized from 31 centres in the UK (37), Czech Republic (121), Hungary (21) and Poland (121). Men aged >18 years, in stable heterosexual, monogamous relationships, and with lifelong PE diagnosed according to both the Diagnostic and Statistical Manual of Mental Disorders, fourth edition (text revision) criteria and the ISSM definition, consented (together with their partners) to enter the baseline period of the study. Patients who documented an IELT of ≤1 min with two or more of the first three sexual encounters during the 4-week baseline period were randomized, in a 2:1 ratio, to receive double-blind treatment with PSD502 (three actuations of spray each containing 7.5 mg lidocaine and 2.5 mg prilocaine applied 5 min before intercourse) or placebo for 3 months. Patients completed Index of Premature ejaculation (IPE-75) questionnaire at entry and at monthly clinic visits, and recorded stopwatch-timed IELT during each sexual encounter. Patients rated the quality of their orgasms on a 5-point scale at baseline and at the end of the treatment period, and rated the study medication on a 4-point scale. The flow of patients through the screening, baseline and double-blind phases of the study is shown in fig. 5. At entry to baseline, the PSD502 groups had similar overall demographics and PE history. All patients except three (in the PSD502 group) were Caucasian and the mean age was 35 years in both groups (SD 9.6 and 11.2, PSD502 and placebo). Overall, 95% of patients in both groups had lifelong PE and a similar proportion of men in both groups were uncircumcised (94% and 93% in the PSD502 and placebo groups respectively). A similar proportion of patients in each group had used previous treatments for PE, the most common being SSRIs or other oral antidepressants, which had been previously used by ≈25% of patients in both groups.

The Index of Premature Ejaculation (IPE-75) Individual questions (all questions relate to the past 4 weeks with graded responses):

- How often did you have control?
- How much confidence did you have?
- How often was intercourse satisfactory?
- How satisfied were you with your sense of control?
- How satisfied were you with the length of intercourse?
- How satisfied are you with your sex life?
- How satisfied have you been with your sexual relationship with your partner?
- How much pleasure has sexual intercourse given you?
- How distressed were you by how long you lasted before ejaculation?
- How distressed have you been about your control over ejaculation?

The geometric mean (range) IELT over the 3-month treatment period increased from a baseline of 0.6 min in both groups to 3.8 (0.3-57.8) and 1.1 (0-15.0) min in the PSD502 and placebo groups, respectively. Adjusting for treatment-group imbalances, this represents a 6.3-fold and 1.7-fold increase in adjusted geometric means. There were significantly greater increases in the scores for the IPE domains of ejaculatory control and sexual satisfaction in the PSD502 group than in the placebo group, with a mean 7.0 (SEM 0.59)-point difference between treatments in change from baseline to the IPE domain for ejaculatory control and a 5.9 (SEM 0.57)-point difference in change from baseline in the IPE domain for sexual satisfaction (both P < 0.001). This was supported by improvements in all secondary endpoints. At the end of the treatment period 66% of patients rated PSD502 as ‘good’ or ‘excellent’.

PSD502 was well tolerated and no systemic adverse events were reported. Localized treatment-related adverse events were reported by 2.6% and 3.1% of patients and partners, respectively.
5. CONCLUSIONS ON CLINICAL TRIALS IN PE

a) Observational Trials in PE:

The purpose of observational trials is to provide reliable and representative data of a certain health condition/disorder in certain nations/cultures.

Regarding the new developments in the field of PE observational studies should make use of the new ISSM PE definition [82] and the new validated PRO measures developed for investigation of PE [75,84]. Observational trials in PE usually provide prevalence data with a representative cross-section analysis of the population/cohort in question.

Because there is a substantial body of evidence that PE exerts also a great negative impact on the partnership and on partners’ sexual life experience and satisfaction it is explicitly recommended by the committee that partner data of PE patients are also collected in these studies by means of validated PROs. Wherever possible observational studies in PE should follow a prospective trial design [98,99,100].

b) Interventional (Drug) Studies in PE

In the future drug trials should follow a standardized trial design which follows the rules of all trials: prospective, randomized, placebo-controlled and double blind.

Similar to ED trials PE trials should allow the enrolled couples adequate time periods both for the run-in phases, in which the baseline data regarding the severity of PE are generated, and for the treatment phases in which the change from baseline data is investigated.

The non medicated run-in phases should last between 4 and 6 weeks and the treatment phases at least 3 months.

---

Fig. 5 Study-Design of the TEMPE - PSD502 study

Figure 6: Geometric Mean IELT at baseline and over the 3 month treatment period: ITT population [98]

Figure 7: Change from baseline to month 3 in adjusted mean IPE scores [98]
Measured IELT must be considered as a standard regarding primary study endpoints in PE trials and PRO’s with validated measures, containing questions addressing control over ejaculation and distress/bother related to PE, as standard for secondary endpoints. In this regard the PEP seems currently to be the most appropriate and widely used one PRO measure for PE.

Data collection is managed both by home diaries, recording each single sexual event (IELT recording) and at the scheduled visits, where the different PROs are recorded as well as treatment related adverse events.

For all new PE drug trials at least one flexible dose study design should be considered in the phase III program. Such a flexible dose study design, starting with the minimally effective dose as identified during the phase II program, will provide more realistic data for the broad spectrum market use especially as for the frequency and severity of drug-related AE’s and usually mirrors the later labeling recommendations. A flexible dose study design finally also generates more reliable data on how many patients are satisfied with lower doses.

Unfortunately in the Dapoxetine clinical program flexible dose study designs were not considered.

Finally for all new drug trials designs in PE it is recommendable to consider one treatment arm either in the phase IIB or phase III trials with the standard dose of this drug which has been approved for PE and is considered as the current standard medication in this indication.

Recommendations 11 (Grade A)

Clinical Trials in Premature Ejaculation Should Consider the Following Items:

a. Key inclusion and endpoint parameter is the measured IELT

b. Although the new ISSM definition for lifelong PE sets an IELT cut off point of 1 minute the committee recommends also consideration of patients with IELT cut-off points of 2 and between 2-5 min. provided there is evidence by history taking and/or PRO’s that the patients/couples show psychological distress

c. PE patients should be randomized according to the respective IELT cut-off values considered in the trial

d. PE trials should enroll reasonable numbers of both patients with lifelong and acquired PE to ensure collection of reliable data for both patient populations

e. One trial in a population with ante portal ejaculation is encouraged

f. At least one trial in an investigational drug development program should consider a well-defined population suffering from a combination of ED and PE

g. Validated PRO’s specifically developed for PE trials such as IPE or PEP should be used as study endpoints in addition to IELT

h. Evaluation of validated partner reported outcomes (available in PEP) is encouraged.

VII. PEYRONIE’S DISEASE (PD)

1. INTRODUCTION

Peyronie’s disease (PD) is an acquired fibrotic disorder of the tunica albuginea and the septum penis which affects between 3% and 8.9% of all men >18 years depending on the populations investigated [15,101-103]. Although the etiology of Peyronie’s disease is not well understood many facts speak for a multifactorial etiology of this disease with genetic factors (in between 10 and 30% Peyronie’s disease is associated with the autosomal dominant passed fibrosis of the palms: Dupuytren’s contracture, Paget’s disease of the bones and in some per cent with fibrosis of the plants: Ledderhose’s contracture), microtrauma (in some patients Peyronie’s disease manifests after latent or obvious penile fracture) and an increase in the concentration of Transforming Growth Factor (TGF) – β1 in cell cultures of the fibrotic plaques [15]. The course of Peyronie’s disease is usually progressive in many cases commencing with a painful nodule/plaque frequently at the dorsal(upper) surface of the tunica albuginea of the cavernous bodies spreading into the septum penis, sometimes at the lateral and rarely at the ventral (lower) surface of the tunica albuginea. Quite often the course of Peyronie’s disease is characterized by phases more than by a stable progression whereby nodules and deformities can change their location and direction.[101,102]

Pain with erectile state of the penis is a characteristic feature of early Peyronie’s disease and usually disappears in nearly all patients with or without treatment within 3-18 months. But pain is not present in all cases and may be absent in up to more than 80% [103,104].

The cumulative manifestation ages for Peyronie’s disease are between 45 and 65 years.

2. THE DIFFERENT PHASES OF PEYRONIE’S DISEASE

Usually 3 phases of Peyronie’s disease can be distinguished:

Acute inflammatory phase often associated with painful erections and manifestation of a “soft” nodule/plaque and onset of penile curvature
Fibrotic/calcifying phase with hard plaques characterized by ultrasonography as clearly hyper-echoic lesions without or with (calcified plaques) echoes.[Fig.7-10,103] At this phase of Peyronie's disease patients may develop considerable deformities of the penis either as notching and circumferential hourglass defects with or without penile curvature or as rapidly increasing penile curvatures up to more than 90 degrees making sexual intercourse impossible. In the majority of the patients the direction of the penile deviation is dorsal (upward) often associated with a lateral component either to the left or to the right side. Rarely Peyronie's disease plaques manifest at the ventral(lower)surface of the cavernous bodies causing a downward (ventrally) directed curvature[105] Regardless of the direction and the extent of the penile deviation at this stage of the disease the patients are complaining of a marked shrinking of the penis, often associated with a considerable narrowing of the cavernous bodies distal to the curvature. Many patients are complaining of a considerable, "join-like" instability of the distal part of the penis causing them to say that the distal part of the penis is not able to get firm.

During both the first and the second phase of the disease new nodules /plaques and changes in the degree and direction of penile curvature is not uncommon.

Terminal (stable) stage of the disease: This is characterized by the fact that no changes within the last 12 months occurred, i.e that this stage has to be considered as the final stage of Peyronie's disease with a high likelihood that no new nodules/ deviations will occur. At this stage of the disease severe deviations may remain either with calcified plaques or not and may require surgical corrections once sexual intercourse is severely impaired. This final stage of the disease is also characterized by a considerable shrinkage of the penis which may account for loss of penis' length of up to 4-6 cm in the erect stage.

Especially in the first inflammatory and also in the fibrotic, not yet calcified phase spontaneous regression ("healing") may occur without treatment. The spontaneous/natural healing rate of Peyronie's disease is observed in between 10 and 15 % of all cases.

Fig. 7: Hypo-echoic not well confined plaque in the dorsal tunica albuginea in acute Peyronie's disease

Fig.8: Three hyper-echoic plaques in the septum penis with moderate acoustic echoes 6 months after onset of the disease

Fig. 9 : Proximal and distal plaques in the septum penis in the same patient 9 months after onset of disease

Fig. 10: End stage of Peyronie's disease with calcified plaque on the dorsal tunica albuginea and 90 degree deviation
According to a mono-center prospective observational study of Peyronie’s disease course in 246 men after 1 year without treatment the situation was as follows: 12 % improved, 40 % remained stable and 48 % worsened [106]

3. PEYRONIE’S DISEASE AND ED

Peyronie’s disease is frequently combined with Erectile Dysfunction (ED) with incidence-rates in the literature ranking between 36 % and 100% (101-108). In many of these patients the etiology of ED is vasculogenic, i.e. either arteriogenic or veno-occlusive or both, proven by intracavernosal injection test combined with penile duplex/color Doppler sonography [107,108].

4. THERAPEUTIC STRATEGIES IN PEYRONIE’S DISEASE

Typical nonsurgical treatments for Peyronie’s disease are oral drug therapies including para-aminobenzoate (Potaba), vitamin E, colchicine, tamoxifen, propol, acetyl-L-carnitine and propionyl-L-carnitine and intralesionally injected drugs such as verapamil, interferon-alpha2a, collagenase, cortisone, hyaluronidase and superoxide dismutase [107].

In a survey analyzing the US urologist practice patterns in the management of Peyronie’s disease with a response rate of 24 % the following treatments/strategies were applied [108]:

Vitamin E 70 %, wait and see 32 %, potaba 20 %, colchicine 12 %, verapamil injections 7 %, verapamil gel 10%. Surgery was performed by 57 % of the respondents.

Other in the literature reported treatments for Peyronie’s disease are extracorporeal shock wave and radiation therapy. Some of the above mentioned treatment options were investigated in mono-or multicenter trials with the majority of them exhibiting considerable flaws in the study designs especially due to the fact that Peyronie’s disease predominantly represents a disease in phases rather than with a stable course and there is no validated PRO measure capturing all the different features of Peyronie’s disease. In addition until now there is no general agreement on objective measures which should be used in clinical trials.

5. GENERAL CONSIDERATION FOR TRIALS IN PEYRONIE’S DISEASE:

The real difficulties regarding trials in Peyronie’s disease are the facts that the course of this disease is usually subdivided in phases and that there is a variety of features which are characteristic for this disease but not necessarily all being present in the same patient.

Regarding the different stages of Peyronie’s disease clinical trials have clearly to define the study population according to the disease’s phase.

Regarding the different features of Peyronie’s disease clinical trials should capture all these different features of Peyronie’s disease by means of appropriate subjective PROs and objective measures.

Until now there is no validated PRO measure available for Peyronie’s disease although one has been developed and is currently undergoing validation process for the ongoing Xiaflex (combination of collagenases which has to be injected into the plaque-developed by Auxilium Pharmaceuticals,US) phase II/III program [109].

a) Domains/Items to be Considered for PRO’s in Peyronie’s Disease

According to the different phases and characteristics of Peyronie’s disease a valid and reliable PRO measure capturing the most important changes after treatment must consider the following items:

Penile shape (deviation, notch, hourglass deformity)
Penile size (length and circumference)
Penile stability during erection (in many Peyronie’s patients penile instability occurs because of pseudo-joint formation at the site of angulations)
Penile pain
Sexual intercourse possible related to degree of deviation
Sexual intercourse possible related to erectile function
Erectile function (hardness/rigidity of erection)
Ejaculatory/orgasmic function/feelings
Impact of Peyronie’s disease on patients’ psyche and mood
Distress/bother related to Peyronie’s disease
Satisfaction with treatment modalities (oral injections, surgery etc.)
Satisfaction with treatment outcome
Body image/physical appearance
Life quality
Clinical Global Impression of Change

Especially changes in patients’ psyche/mood should be given a broad space in PRO because it is proven that many Peyronie patients may develop depressive symptoms [110,111].

Because Peyronie’s disease frequently has a
negative impact on the sexual performance and sexual relationship a PRO measure for partners must also be considered for trials in Peyronie’s disease.

b) Objective Measures to be Considered for Clinical Trials in Peyronie’s Disease:

Measurement of the stretched penis length

Documentation of the degree of penile curvature in the erect stage by intracavernosal injection test (alternatively self-documentation by means of auto-photography may be considered but it does not provide as reliable data as with in office testing)

Measurement of the penis circumference

Sonographic measurement of the plaque’s/plaques’ sizes

(this diagnostic tool provides only reliable data with clear echoic/calcified plaques but not with soft plaques during the early stage of Peyronie’s disease!!)

Because Peyronie’s disease shows a variety of clinical features it is mandatory that clinical trials are considering these different features, ie. that they should enroll reasonable numbers of patients showing certain main characteristics of Peyronie’s disease:

Measurable echoic but not calcified plaques

Measurable echoic and calcified plaques with acoustic shadow

Peyronie’s disease without penile curvature but only nodules/plaques

Peyronie’s disease with penile curvature between 10 and 60 degree

Peyronie’s disease with penile curvature between 60 and 100 degree

Peyronie’s disease with only notching and/or hourglass deformity.

Patients with/without ED

Only by stratification of the patient groups according to these main features of Peyronie’s disease reliable statements on the efficacy of a certain drug/treatment for the different characteristic manifestations of this disease may be possible.

Recommendation 12 (Grade B)

Considering the different phases, the potential for spontaneous healing, the completely different features of Peyronie’s Disease and the long-term course of this disease clinical trials should consider:

a. at least a 3 arm study design with a placebo, active and wait and see group the latter serving as control group.

b. study duration of at least 12 months, better 18 months

c. randomization according to the following parameters:

  - pain yes/no, plaque yes/no – clearly visible by sonography yes/not only notching-hour-glass deformity yes/not
  - penile bending yes/no – up to 60 and between 60 and 90 degrees penile shrinking/shortening yes/not combined with ED yes/not

d. PRO’s should consider the following domains:

  - Penile pain, penile shape, penile size (length and circumference) penile stability during erection sexual intercourse possible related to degree of deviation or related to ED
  - Erectile function (hardness/rigidity of erection)
  - Ejaculatory/orgasmic function/feelings
  - Impact of Peyronie’s disease on patients’ psyche and mood
  - Distress/bother related to Peyronie’s disease
  - Satisfaction with treatment modalities (oral injections, surgery etc.)
  - Satisfaction with treatment outcome
  - Body image/physical appearance
  - Life quality
  - Impact on psyche and mood

VIII. CLINICAL TRIALS IN TESTOSTERONE REPLACEMENT THERAPY FOR HYPOGONADISM

1. INTRODUCTION

Androgen deficiency in the elderly men and its substitution by testosterone replacement therapy, where clinical symptoms are evident, has become a topic of increasing interest and awareness. It is proven that from the age of 40 a continuous decline of total T and even more of free T occurs combined with a constant increase of sex hormone binding globulin (SHBG) (112,113). Many of these men develop clinical symptoms affecting general and sexual health.

The prevalence of so-called Late Onset Hypogonadism (LOH) clearly depends on the cut-off value used for normal T-serum levels: Based on the respective cut-off T-levels the incidence of hypogonadism in a population comprising 2.807 men
aged 25-85 and suffering from erectile dysfunction was as follows (114):

- T < 2.00 ng/ml: 7%
- T < 3.00 ng/ml: 23%
- T < 3.46 ng/ml: 34%
- T < 4.00 ng/ml: 48%

In a randomized selection of 130 out of 2650 GP practices where during a period of 2 weeks in all men > 45 years T-levels were measured between 8.00 and 12.00 am regardless of the complaints they were presenting 836/2162 (39%) have had T-levels < 3.0 ng/ml which meets the laboratory criteria of hypogonadism (115).

Hypogonadal T-levels are often associated with clinical symptoms / diseases such as fatigue, decline of vitality, loss of muscle strength and mass, osteoporosis and anemia or sexual dysfunctions such as erectile dysfunction, loss of libido and/or ejaculatory/ orgasmic dysfunctions which often improve with T-replacement therapy. Moreover several long-term observational studies have clearly shown that hypogonadism is linked to a higher cardiovascular and mortality risk (116-118). Although a variety of treatment options (T-gels, plasters, injections, pellets) are approved and available for treating hypogonadal men only limited data are available regarding the long-term safety of T-replacement therapy. The main obstacle for T-replacement therapy is the concern of imminent prostate cancer danger induced by exogenous T-substitution. Nearly all of the published studies regarding T-replacement therapy in hypogonadism have enrolled relatively small numbers of patients (mainly dozens and not hundreds or even thousands) with a limited follow-up. Thus no definite statements can be made with respect to PCA risk with T-replacement therapy. In a recent Medline supported review on this topic 197 publications relating to T-replacement therapy were identified but only 44 met inclusion criteria: 11 placebo-controlled, randomized studies; 29 non-placebo-controlled studies of men with no prostate cancer history; and 4 studies of hypogonadal men with history of prostate cancer (119).

In the 11 placebo-controlled, randomized studies, prostate cancer was detected in 7 of the 542 men treated with testosterone as monotherapy (1.3%) and 5 (1.5%) of the 333 men who received placebo. Prostate cancer incidences across studies varied from 0% for both the testosterone and the placebo groups in seven studies to 9.5% for the testosterone group and 21% for the placebo group in one study. Prostate cancer in testosterone-treated men was detected at as early as 3 months and in placebo-treated men at as early as 6 months. Gleason grades were reported for four testosterone-treated patients (two of grade 5, one of grade 6 and one of grade 7) and four placebo-treated subjects (all grade 6) (119).

Recommendations on the criteria for diagnosis, treatment and monitoring of late-onset hypogonadism were published recently (120):

According to these recommendations the definition of LOH is a clinical and biochemical syndrome associated with advancing age and characterized by symptoms and a deficiency in serum T-levels below the young healthy adult male reference range.

Symptoms which the committee identified to be often related to LOH are loss of libido, erectile dysfunction, decreased muscle mass and strength, increased body fat, decreased bone mineral density and osteoporosis, decreased vitality and depressed mood. But none of these symptoms are specific to low androgen levels.

Questionnaires such as the Aging Male Symptom Score (AMS), the Androgen Deficiency in Aging Men (ADAM) are not recommended for use as screening tools for hypogonadism because of their low specificity.

Regarding T-lab values total testosterone assessment should preferably be conducted in the morning between 7.00 and 11.00 am. A value of < 3.5 ng/ml (12 nmol/l) are in line with the diagnosis of LOH. T-levels above this value do not require T-substitution.

Regarding the assessment of treatment outcome (improvement of the clinical symptoms such as sexual dysfunctions) an interval of 3-6 months after initiation of T-replacement therapy is recommended. Considering prostate cancer risk under T-replacement therapy the committee concluded that there is currently no adequately powered and optimally designed long-term prostate disease data available to determine whether there is any prostate cancer risk from T-replacement therapy.

Prostate and blood (hematocrit, PSA) monitoring are recommended in 3-6 months intervals in the first year and at least annually thereafter.

Contraindications for T-replacement therapy considered by the committee are men with prostate and breast cancer, men with hematocrit > 52%, untreated obstructive sleep apnea and untreated severe congestive heart failure.

In a recently published study with 40 men and PSA values of between 2.5 and 4.0 ng/ml receiving a single intramuscular injection of 400 mg T-cypionate those men (18/40 - 45 %) with an increase of PSA of 0.9 ng/ml 4 weeks after T-injection showed prostate
cancer in the subsequent prostate biopsies whereas men with only a mild PSA increase of 0.3 ng/ml were cancer free (121)

Finally, debate has surfaced regarding the need for prostate biopsy in hypogonadal men prior to starting T replacement therapy. A study by Morgentaler et al (122) evaluated a total of 345 consecutive hypogonadal men with a PSA level of 4.0 ng/ml or less with digital rectal examination and prostate biopsy before initiating a program of testosterone replacement therapy. All men had low serum levels of total or free testosterone, defined as less than 300 and 1.5 ng/dl, respectively. Cancer was identified in 15.1%. The cancer detection rate was 5.6%, 17.5%, 26.4%, and 36.4% for a PSA level of 1.0 or less, 1.1 to 2.0, 2.1 to 3.0, and 3.1 to 4.0 ng/ml, respectively (P < 0.05). Cancer was detected in 26 (30.2%) of 86 men with a PSA level of 2.0 to 4.0 ng/ml. Cancer was detected in 21% of men with a testosterone level of 250 ng/dl or less compared with 12% of men with a testosterone level greater than 250 ng/dl (P = 0.04). Men with free testosterone levels of 1.0 ng/dl or less had a cancer rate of 20% compared with 12% for men with greater values (P = 0.04). The odds ratio of cancer detection for men in the lowest tertile compared with the highest tertile = 0.04). The odds ratio of cancer detection for men in the lowest tertile compared with the highest tertile was 2.15 (95% confidence interval 1.01 to 4.55) for total testosterone and 2.26 (95% confidence interval 1.07 to 4.78) for free testosterone. These data are controversial, but nonetheless might suggest the need for a preemptive prostate biopsy in certain men before starting T replacement.

The endocrine society guidelines (123) are presented for completion and suggest the follow up post inception of T replacement therapy: We recommend urological consultation if there is:

An increase in serum or plasma PSA concentration greater than 1.4 ng/ml within any 12-month period of testosterone treatment.

A PSA velocity of more than 0.4 ng/ml yr using the PSA level after 6 months of testosterone administration as the reference. PSA velocity should be used only if there are longitudinal PSA data for more than 2 yr.

Detection of a prostatic abnormality on digital rectal examination.

An American Urological Association (AUA) prostate symptom score of more than 19.

We recommend evaluation for symptoms and signs of formulation-specific adverse events at each visit

We recommend determining hematocrit at baseline, at 3 months, and then annually. If hematocrit is greater than 54%, stop therapy until hematocrit decreases to a safe level, evaluate the patient for hypoxia and sleep apnea, and reintiate therapy at a reduced dose.

These recommendations must be tempered against accepted urologic practice norms.

2. FINAL COMMENTS ON CLINICAL TRIALS FOR HYPOGONADISM

Regarding the current literature T-replacement therapy trials may be subdivided in:

a) Therapeutic T-replacement trials in men with clinical symptoms and proven hypogonadal T-levels (T< 3.5ng/ml or 12 nmol/l): in these men improvement of clinical symptoms may be expected in a time frame of 3 - 6 months or even later if muscle mass and strength, body composition and bone mineral density is considered provided that T-replacement is able to elevate the T serum levels within the normal range.

b) Preventive long-term T-replacement trials in asymptomatic men to evaluate the cardiovascular and mortality risk.

Regarding the increasing evidence in the past two years that hypogonadism is linked to a higher risk of major cardiovascular events and increased mortality, a long-term trial of T-replacement therapy in hypogonadal, asymptomatic men at risk (diabetics, coronary artery disease, metabolic syndrome) would make sense and would be desirable from the scientific point of view. Primary outcome of such a long-term trial with an untreated or placebo-treated control group would be major cardiovascular events (stroke, myocardial infarction) and mortality.
Recommendation 13 (Grade B)

1. The diagnosis of late–onset hypogonadism (LOH) is based on clinical symptoms combined with a morning total serum testosterone of less than < 350 ng/100 ml (12 nmol/l).

2. Currently, there are no accepted PRO instruments for either screening of hypogonadism or for follow up post starting T replacement therapy.

3. The risk of prostate cancer after starting and during long-term T-replacement is unknown, but thought to be low by expert opinion.

4. A serum PSA and hematocrit should be drawn within 3-6 months post starting T replacement therapy and thereafter in 6-12 months intervals depending on individual findings and risks.

5. The time course to determine T related benefits varies amongst the endpoints. While sexual function is thought to improve within 6 months post starting T replacement therapy, bone mineral density, muscle mass etc may require longer periods of time to see demonstrable effects.

6. An increase in serum or plasma PSA concentration greater than 1.4 ng/ml within any 12-month period of testosterone treatment, or a PSA velocity of more than 0.4 ng/ml/yr using the PSA level after 6 months of testosterone administration as the reference, should prompt a urologic evaluation and possible prostate biopsy.

7. If the hematocrit is greater than 54%, stop therapy until hematocrit decreases to a safe level, evaluate the patient for hypoxia and sleep apnea, and reinitiate therapy at a reduced dose.

606
Penile erection is initiated after central processing and integration of, e.g., tactile, visual, olfactory, and imaginative stimuli. Signals to the peripheral tissues involved are generated, and the final response is mediated by coordinated spinal activity in the autonomic pathways to the penis and in the somatic pathways to the perineal striated muscles. The central regulation of penile erection involves many transmitters and transmitter systems, the details of which are still incompletely known. Some of the anatomical areas of the brain that relate to sexual function have been defined, including the medial amygdala, medial preoptic area, paraventricular nucleus, the periaqueductal gray, and ventral tegmentum [1-3]. In rats, electrical stimulation of, e.g., the medial preoptic area [4], the paraventricular nucleus [5], or the hippocampal formation [6] can elicit an erectile response.

Spinally, there seems to be a network consisting of primary afferents from the genitals, spinal interneurons, and sympathetic, parasympathetic and somatic nuclei. This network appears capable of integrating information from the periphery and eliciting reflexive erections, and also to be the recipient of supraspinal information[7]. The degree of preservation of sensory function in the T11-L2 dermatomes could be used to determine the potential for psychogenic erectile responses in men with spinal cord injury[8].

The central mechanisms controlling erection include supraspinal as well as spinal pathways. The current knowledge about these mechanisms is largely based on experimental data from animals—mainly, rats.

Central dopaminergic neurons project to the medial preoptic area and the paraventricular nucleus [17]. Furthermore, dopaminergic neurons have been identified that travel from the caudal hypothalamus to innervate the autonomic and somatic nuclei in the lumbosacral spinal cord [18, 19]. Thus, dopamine can be expected to participate in the regulation of both the autonomic and somatic components of the penile reflexes.

Both the two major families of dopamine receptors, D1- (D1, D5) and D2-(D2, D3, D4) like receptors [20], have been associated with central erectile functions; however, the D2-like receptor subtype seems to have the predominating effect. The non-selective dopamine receptor agonist, apomorphine, when administered systemically to male rats, was found to induce penile erection [21], simultaneously producing yawning and seminal emission. Similarly, low-dose systemic administration of other dopamine agonists initiates erection [1]. The effects of these agonists can be attenuated by centrally-, but not peripherally-acting, dopamine receptor antagonists.

Injection of apomorphine into the medial preoptic area demonstrated that low levels of dopaminergic stimulation, via D1 receptors in particular, facilitated erections[22]. In contrast, dopaminergic antagonists injected into the medial preoptic area decreased the number of penile reflexes [23, 24]. In the paraventricular nucleus, similar experiments have established that D2- rather than D1- like receptors primarily facilitate erections [1].
The erection following paraventricular D2–like receptor stimulation apparently involves oxytocinergic neurotransmission. Dopaminergic neurons impinge on oxytocinergic cell bodies in the paraventricular nucleus [25, 26], and apomorphine-induced penile erection is prevented dose-dependently by oxytocin receptor antagonists [27], or by electrolytic lesions of the paraventricular nucleus that deplete the oxytocin content [28-30]. Conversely, injection of oxytocin into the paraventricular nucleus induced erections that were not attenuated by dopamine receptor blockade, suggesting that dopaminergic neurons activate oxytocinergic neurons in the paraventricular nucleus, and that released oxytocin then accounts for the erectile response. Melis et al. (2006) showed that penile erections in male rats induced by selective dopamine D4 agonists were reduced by selective dopamine D4 antagonists, voltage-dependent Ca2+-channel blockers, neuronal nitric oxide synthase inhibitors and oxytocin receptor antagonists given in the lateral ventricles, not in the paraventricular nucleus. Martino et al. [31] investigated central oxytocinergic and dopaminergic mechanisms regulating penile erection in conscious rats and concluded that pro-erectile activity mediated via D2-like (D4?) receptors may be dependent on supraspinal and spinal oxytocin receptors, and that oxytocin-mediated erection (supraspinal and spinal) requires basal D2-like (D4) receptor activation. The same group aimed to identify dopamine D4 receptor signal transduction pathways in vivo [32]. They showed that the selective dopamine D4 agonist PD168077 induced c-Fos expression and extracellular signal regulated kinase (ERK) phosphorylation in the paraventricular nucleus. The selective dopamine D4 receptor antagonist A-381393 blocked both c-Fos expression and ERK1/2 phosphorylation produced by PD168077. In addition, PD168077-induced ERK1/2 phosphorylation was prevented by SL327, an inhibitor of ERK1/2 phosphorylation. Interestingly, treatment with A-381393 alone significantly reduced the amount of Fos immunoreactivity as compared to basal expression observed in vehicle-treated controls. Dopamine D4 receptor and c-Fos coexpression in the paraventricular nucleus was observed using double immunohistochemical labeling, suggesting that PD168077-induced signaling may result from direct dopamine D4 receptor activation. The authors concluded that these results demonstrate functional dopamine D4 receptor expression and natural coupling in the paraventricular nucleus linked to signal transduction pathways that include immediate early gene and MAP kinase activation. Further, the ability of the selective dopamine D4 antagonist A-381393 alone to reduced c-Fos expression below control levels were interpreted to indicate the presence of a tonic dopamine D4 receptor activation under basal conditions in vivo.

Brioni et al. [33] reported that the dopamine D4 receptor plays a role in the regulation of penile function using a selective dopamine D4 receptor agonist, ABT-724, with no effect on dopamine D1, D2, D3, or D5 receptors. ABT-724 dose-dependently facilitated penile erection when given s.c. to conscious rats, an effect that was blocked by haloperidol and clozapine (acting centrally and peripherally) but not by domperidone (acting only peripherally). A proerectile effect was observed after intracerebroventricular (i.c.v.) but not intrathecal administration, suggesting a supraspinal site of action. The drug seemed to be without emetic effects in a ferret model of emesis [34], and it was suggested that ABT-724 could be useful for the treatment of erectile dysfunction (ED).

The same group identified a structurally distinct D(4)-selective agonist with superior oral bioavailability to ABT-724 for the potential treatment of erectile dysfunction. Optimization with the (N-oxy-2-pyridinyl)piperidine template led to the discovery of ABT-670, which exhibited excellent oral bioavailability in rat, dog, and monkey (68%, 85%, and 91%, respectively) with comparable efficacy, safety, and tolerability to ABT-724 [35].

Injection of apomorphine into the lumbosacral subarachnoid space was reported to impair ex copula (i.e., outside the context of copulation) penile reflexes, slow the rate of copulation, and decrease the number of intromissions preceding ejaculation [36, 37], suggesting an inhibitory effect on spinal erectile mechanisms. This is in contrast to recent findings showing that intrathecal injection of apomorphine in rats evokes erection in both normal animals and animals where the spinal cord has been transected [38, 39]. Most likely, stimulation of the dopaminergic system can produce erection both at supraspinal and spinal sites.

As mentioned above, systemically administered apomorphine enhances seminal emission. Pehek et al. [37] found that apomorphine injected into the paraventricular nucleus, but not in the MPoA, enhanced seminal emission. Recording of intracavernosal pressure in the non-anesthetized rat after systemic administration of apomorphine showed that the pressure response consisted of both smooth and striated muscle components [40]. This implies that systemically given apomorphine has effects not only on the sacral parasympathetic output, but also on somatic pathways.

IV. OXYTOCIN

Oxytocinergic spinal projections from the supraoptic and paraventricular nuclei of the hypothalamus are likely to influence the sacral autonomic outflow more than the somatic outflow [41, 42]. The finding that immunoreactive oxytocin-containing spinal neurons associate with sacral preganglionic neurons supports the idea that oxytocin has an important role in the autonomic spinal circuitry that mediates penile erection [43, 44].
Oxytocin is a potent inducer of penile erection when injected into the lateral cerebral ventricle, the paraventricular nucleus, or the hippocampus of laboratory animals; intrathecal oxytocin can also initiate an erection. These erections can be blocked by the administration of oxytocin antagonists given (i.c.v.) or (i.t.), or by electrolytic lesion of the paraventricular nucleus. Additionally, non-contact erections can be reduced by a selective oxytocin receptor antagonist administered into the lateral ventricles, which supports the view that oxytocin mediates this response [45].

Succu et al. (2007) analyzed the effect of pro-erectile dose of the selective dopamine D4-agonist PD-168077 and apomorphine, a mixed dopamine receptor agonist, injected into the paraventricular nucleus on the concentration of extra-cellular dopamine and its main metabolite DOPAC in the nucleus accumbens in male rats [46]. Both drugs induced penile erection episodes that were reduced to various extents by D2/D3 and D4 antagonists. The pro-erectile effect and the concomitant increase in dopamine and DOPAC concentration in the nucleus accumbens dialysate were almost completely abolished by the potent oxytocin receptor antagonist d(CH(2))[5]Tyr(Me)[2]-Orn[8]-vasotocin, given into the lateral ventricles. The authors concluded that stimulation of dopamine receptors (mainly of the D2 to D4 subtype) in the paraventricular nucleus induces the release of oxytocin in brain areas that influence the activity of mesolimbic dopaminergic neurons mediating the appetitive and reinforcing effects of sexual activity.

Oxytocin increases NO production in the paraventricular nucleus [13, 47], and NO synthase (NOS) inhibitors prevent penile erection and yawning in rats induced by oxytocin, and also by dopamine, excitatory amino acids, the 5-HT(2C) receptor agonist, m-chlorophenylpiperazine (m-CCP; 5-HT(2C) agonist, trazodone metabolite), and ACTH/α-MSH. Yawning is a phylogenetically old, stereotyped event that occurs alone or associated with stretching and/or penile erection in humans and animals under different conditions [48]. It has been suggested that NO acts as an intracellular rather than an intercellular modulator inside the paraventricular oxytocinergic neurons in which NO is formed to facilitate the expression of this phylogenetically old event by guanylate cyclase-independent mechanisms [48, 49]. It is likely that this involves the parvocellular neuron population within the nucleus [49].

Plasma oxytocin concentrations are known to be elevated following sexual stimulation in humans [1]; however, the relevance of the oxytocinergic pathway has never been established. This makes it of interest to explore the therapeutic potential of this system.

V. ACTH AND RELATED PEPTIDES

Administered i.c.v., the adrenocorticotropic (ACTH) and α-melanocyte stimulating hormones (α-MSH) are able to induce penile erection—along with grooming, stretching, and yawning [1, 2, 50]. These effects are most probably mediated via stimulation of melanocortin (MC) receptors, of which five different subtypes have been cloned and characterized [51, 52]. Alpha-MSH/ACTH seem to act in the hypothalamic periventricular region, and grooming, stretching and yawning, but not penile erection, was reported to be mediated by MC(3) receptors [50, 53]. It is unclear, however, what MC receptor subtype(s) can be linked to the erectile responses. For example, the MC(3) receptor is found in high density in the hypothalamus and limbic systems [30], regions known to be important for erectile functions. The site and mechanism of action responsible of αMSH/ACTH seem to be different from those involving dopamine or oxytocin [15].

Martin et al. [54] concluded that current evidence indicates that the MC(3) receptor subtype contributes to the proerectile effects observed with melanocortin pan-receptor agonists. However, the putative receptor subtypes, pathways and mechanisms implicated in mediating the proerectile effects of melanocortins remain to be fully elucidated.

Melanotan II, a synthetic analogue of α-MSH, when given subcutaneously, was shown to have pro-erectile effects in men with psychogenic impotence [55]. Still, the therapeutic potential of α-MSH analogues remains to be established [56–58].

VI. NITRIC OXIDE

Several investigators have shown that within the CNS, NO can modulate sexual behavior and penile erection [59–63]. NO may act in several discrete brain regions, e.g., in the medial preoptic area [62, 63] and the paraventricular nucleus [5, 53]. NO production increases in the paraventricular nucleus of male rats during non-contact penile erections and copulation, confirming that nitric oxide is a physiological mediator of penile erection at the level of the paraventricular nucleus [61].

As mentioned previously, injection of NOS inhibitors i.c.v. or in the paraventricular nucleus prevents penile erectile responses induced by dopamine agonists, oxytocin, and NMDA in rats. NO may also mediate the actions of ACTH/α-MSH and 5-HT(2C) agonists, which elicit erections when injected into the intraventricular system, according to mechanisms unrelated to oxytocinergic neurotransmission [60]. The inhibitory effect of NOS inhibitors was not observed when these compounds were injected concomitantly with L-arginine, the substrate for NO [60].

Zheng et al. examined the role of nitric oxide (NO) within the central nervous system component of the behavioral responses including erection in diabetic rats [64]. Four weeks after streptozotocin (STZ) and
vehicle injections, NMDA-induced erection, yawning, and stretch responses through the paraventricular nucleus were significantly blunted in diabetic compared with control rats. Examination of nNOS protein by Western blot analysis indicated a reduced amount of nNOS protein in the paraventricular nucleus of rats with diabetes compared with control rats. Furthermore, restoring nNOS within the paraventricular nucleus by gene transfer using adenoviral transfection significantly restored the erectile and yawning responses to NMDA in diabetic rats. The authors concluded that a blunted NO mechanism within the paraventricular nucleus may contribute to NMDA-induced erectile dysfunction observed in diabetes mellitus.

VII. EXCITATORY AMINO ACIDS

Microinjections of L-glutamate into the medial preoptic area elicits an increase in intracavernous pressure [4], and behavioral studies have shown that N-methyl-D-aspartate (NMDA) increases the number of penile erections when injected into the paraventricular nucleus [65-67]. Furthermore, NMDA, amino-3-hydroxy-5-methyl-isoxazole-4-propionic acid (AMPA), or trans-1-amino-1,3-cyclo-pentadecarboxylic acid (ACPD) increases intracavernosal pressures when injected into the paraventricular nucleus [68]. The effect of NMDA was prevented by intracebroventricular administration of an oxytocin antagonist [65]. The NO synthase signal transduction pathway is considered to mediate the effect of NMDA. Injection of the amino acid leads to an increased concentration of NO metabolites in the paraventricular nucleus [69], and the administration of NOS inhibitors into the paraventricular nucleus and intracebroventricularly, blocked the NMDA effect [65, 70].

VIII. SEROTONIN

Neurons containing serotonin (5-hydroxytryptamine, 5-HT) can be found in the medullary raphe nuclei and ventral medulla reticular formation, including the rostral nucleus paragigantocellularis, and bulbospinal neurons containing 5-HT project to the lumbar spinal cord in the rat and cat [1]. Some serotonergic fibers occur in close apposition with sacral preganglionic neurons and motoneurons, and synapses were demonstrated at the ultrastructural level [44]. These morphological findings support the involvement of 5-HT in both the supraspinal and spinal pharmacology of erection, with participation in both the sympathetic and parasympathetic outflow mechanisms.

In animals, 5-HT seems to exert a general inhibitory effect on male sexual behavior [71], although the amine may be inhibitory or facilitatory depending upon its action at different sites and at different 5-HT receptors within the central nervous system [72, 73]. This may explain conflicting reports of 5-HT agonists either enhancing or depressing sexual function. Yonezawa et al. [74] found that p-chloroamphetamine (PCA), an indirect serotonin (5-HT) agonist, elicited both penile erection and ejaculation simultaneously in anesthetized rats. It was suggested that these effects were mainly produced by the release of 5-HT as limited to the lower spinal cord and/or peripheral sites. The use of selective 5-HT receptor agonists and antagonists can reveal different components of male copulatory behavior [9].

Kimura et al. investigated the effects of the novel 5-HT2C receptor agonist YM348 on intracavernous pressure (ICP) in anesthetized rats [75]. YM348 induced penile erection and ICP increases, and was significantly inhibited by the selective 5-HT2C receptor antagonist SB242084. YM348 decreased the latency of but did not affect the quality of ICP (duration, peak pressure and area under the curve) even at the highest dose. The authors concluded that activation of the 5-HT2C receptor increased ICP and, as a result, induced penile erection.

5-HT2C receptors seem to mediate erectile responses [76], and stimulation of 5-HT2C receptors increased circulating oxytocin [77]. NOS inhibitors given i.c.v. prevents 5-HT2C-receptor-mediated erectile responses [60]. These findings suggest that both oxytocin and NO are involved in 5-HT2C-receptor mediated erections.

IX. NORADRENALINE

The information on noradrenergic mechanisms involved in the central neuromediation of penile erection is sparse; however, the current data suggest that increased noradrenergic activity stimulates, whereas decreased noradrenergic activity inhibits sexual function [7, 71, 78].

X. GAMMA-AMINO BUTYRIC ACID

Cumulative data resulting from investigations on the role of gamma-aminobutyric acid (GABA) in penile erection indicate that this neurotransmitter may function as an inhibitory modulator in the autonomic and somatic reflex pathways involved in penile erection [79]. Activation of GABA(A) receptors in the paraventricular nucleus reduced apomorphine-, N-methyl-D-aspartic acid- (NMDA-), and oxytocin-induced penile erection and yawning in male rats [79]. Dorfman et al. examined age-related changes of the GABA(B) receptor in the lumbar spinal cord of Sprague-Dawley rats of different ages using quantitative autoradiography [80]. GABA(B) receptor affinity showed significant age-dependent and regional increases. However, the GABA(B) receptor decrease in aged rats did not seem not to be related to the inhibitory function in penile erection.
XI. CANNABINOIDs

Administration of endogenous and exogenous cannabinoids was shown to be associated with changes in penile erection and modulation of male sexual behavior [81, 82]. The cannabinoid CB1 receptor antagonist SR 141716A was shown to potentiate the penile erection responses to apomorphine in rats [83]. Also, it was shown that cannabinoid CB1 receptors present in the paraventricular nucleus may influence erectile function and sexual activity possibly by modulating paraventricular oxytocinergic neurons mediating erectile function [84]. It was also demonstrated that SR 141716 induced penile erection by a mechanism involving excitatory amino acid neurotransmission causing activation of neuronal NO synthase in paraventricular oxytocinergic neurons [85].

XII. OPIOID PEPTIDES

Available information supports the hypothesis that opioid μ receptor stimulation centrally prevents penile erection by inhibiting mechanisms that converge upon central oxytocinergic neurotransmission [1]. In rats, morphine injected into the paraventricular nucleus prevents non-contact penile erections (i.e., when penile erection is induced in the male by the presence of an inaccessible receptive female), and impaired copulation. These morphine effects are apparently mediated by prevention of the increased nitric oxide production that occurs in the paraventricular nucleus during sexual activity [86]). Morphine also prevents apomorphine- oxytocin-, NMDA- and non-contact-induced penile erection and yawning by inhibiting NO synthase activity in the paraventricular nucleus [87-89].

XIII. PROLACTIN

Long-term hyperprolactinemia can depress sexual behavior, reduce sexual potency in men, and depress genital reflexes in rats [73, 90]. Acute and chronic central prolactin treatment in rats, however, may have stimulatory and inhibitory effects on male sexual behavior, respectively [91]. Correspondingly, striatal dopaminergic activity was shown to be increased and decreased by acute and five-day central prolactin treatment [91], supporting the view that the effects of prolactin are associated with changes in striatal dopaminergic activity. Prolactin has been shown to inhibit the dopaminergic incertohypothalamic pathway to the medial preoptic area [92].

In humans, it is still unclear whether the negative effects of hyperprolactinemia on erectile function are mediated centrally by way of reduction in sexual interest and sex drive [93], or through a direct effect of prolactin on corpus cavernosum smooth muscle contractility. In dogs, a direct effect on the corpus cavernosum was suggested [94]. In any case, the effect seems independent of circulating testosterone levels and gonadal axis function [95].

Paick et al. evaluated 261 men for anthropometry, hormone levels, metabolic profiles and lifestyle factors [96]. Erectile function was evaluated using the self-administered International Index of Erectile Function. Patients were classified into two groups based on the six-item erectile-function domain, as those with sexual activity and those without. The authors found a significant difference in mean prolactin level between patients with and without sexual activity. A higher prolactin level was associated with a greater likelihood of sexual inactivity. Thus, prolactin levels might play a role in sexual activity in men with ED.

XIV. SEXUAL HORMONES

Androgens, particularly testosterone, are necessary (though not sufficient) for sexual desire in men. They are essential in the maintenance of libido and have an important role in regulating erectile capacity [97-101]. In men with normal gonadal function, however, there is no correlation between circulating testosterone levels and measures of sexual interest, activity, or erectile function [102]. Following castration in the male (which may reduce plasma testosterone levels by 90% [103]), or other causes leading to a reduction in androgen levels, there is generally a decline in libido, and sometimes in erectile and ejaculatory functions. Testosterone administration restores sexual interest and associated sexual activity in hypogonadal or castrated adult men [104-106]. The testosterone dose-response relationships for sexual function and visuospatial cognition differ in older and young men, higher testosterone doses needed in the elderly for normal sexual functioning [100]. El-Sakka et al. (2006) assessed the pattern of age related testosterone depletion in patients with erectile dysfunction. They found a significant decrease in testosterone level throughout the 4-year follow up in patients with erectile dysfunction. Patients with decreasing testosterone were older than patients with a steady testosterone level.

When castration has been performed in humans, the resultant sexual function may range from a complete loss of libido to continued normal sexual activity. Thus, the role of androgens in erectile function is complex, and androgen deprivation may not always cause erectile impotence, either in man [107], or in rats [108].

Suzuki et al. studied the effects of castration and testosterone (T) replacement on ICP elicited with electrical stimulation of the medial preoptic area and cavernous nerve in male rats [109]. They measured the ICP during electrical stimulation of the medial preoptic area and cavernous nerve in castrated male rats with and without testosterone replace-
ment. The erectile response was expressed as the ICP/blood pressure (BP) ratio. The ICP/BP ratios during cavernous nerve stimulation of the animals at 2, 4, and 8 weeks after castration were significantly lower than those of the intact animals. However, the erectile responses were not eliminated. In contrast to these peripherally evoked responses, erectile responses elicited by electrical stimulation of the medial preoptic area were eliminated following castration. After testosterone replacement, both erectile responses were restored. The authors therefore concluded that testosterone plays important roles in both the central and peripheral neural pathways for the maintenance and restoration of erectile capacity.

In hypogonadal individuals, it is known that exogenous testosterone administration stimulates both sleep-related erections and erectile responses to visual erotic stimulation [110-112]. Serum testosterone levels, however, have to fall to well below the lower end of the normal laboratory range before nocturnal penile tumescence is impaired [113]. In healthy men, testosterone enhances sexual desire and the rigidity of nocturnal penile tumescence, and leads to more rigid spontaneous erections with longer duration [112, 114]. It is therefore possible that testosterone acts on the motor neurons that supply the striated muscles of the penis. Other reports suggested that the site of androgen action within the penile tissue might be on the pro-erectile postganglionic parasympathetic neurones [115]. Castration studies in rats revealed that testosterone deprivation might alter the dorsal nerve ultrastructure, as the diameter of both myelinated and unmyelinated axons appeared smaller as assessed by transmission electron microscopy [116]. Spontaneous nocturnal erections are androgen-dependent [101, 117]; they are impaired in states of androgen deficiency and restored with androgen replacement. Erections in response to visual erotic stimuli, on the other hand, are partly independent of androgens [117, 118]. They persist in hypogonadal men and are not altered by androgen replacement [110, 119]. Thus, there may be one androgen-dependent system in the brain subserving sexual arousability and sexual desire, and one androgen-independent system involving response to moving visual stimuli [101]. Yassin et al treated hypogonadal men with erectile dysfunction with intramuscular long-acting testosterone undecanoate [120]. In all patients, serum testosterone levels were restored to normal within 6-8 weeks. They found that restoring testosterone levels to normal in men with proven subnormal testosterone levels improves libido in most subjects, and erectile function in more than 50% of these men. It may take 12-24 weeks before the effects of testosterone become manifest. Further, in normal individuals, it has been shown that there is a relationship between bioavailable testosterone and the frequency, duration, and degree of nocturnal penile tumescence [114, 121]. Other studies performed in eugonadal men have shown that high testosterone may promote sexual arousal with no significant changes in sexual activity [122]. Several studies, however, suggest that testosterone replacement therapy in relatively modest deficiency states may improve erections in a minority of patients [118, 119, 123, 124].

Data from the Massachusetts Male Aging Study revealed the association between erectile dysfunction and total testosterone, bioavailable testosterone, sex hormone-binding globulin and luteinising hormone. The authors concluded that no association among total testosterone, bioavailable testosterone, sex hormone-binding globulin and erectile dysfunction was found. Testosterone levels were associated with a decrease in risk of erectile dysfunction only in men with increased luteinising hormone levels.

Sexual hormones can induce structural changes in the nervous system, including alterations in cell size and number, neural connectivity, and neural sprouting [125-128]. These changes, which may result in sex differences (sexual dimorphism), are obvious in most mammalian species during the prenatal or early postnatal periods. There is evidence, however, that brain regions containing sexual hormone-accumulating neurons in adult animals possess a considerable plasticity in response to sexual steroids, and that androgens have the potential to stimulate the growth of neuronal processes and remodel neural circuits also in the adult brain [129-131]. Naturally-occurring, socially-induced changes in androgen levels were not shown to induce morphological changes of the motoneurons of the spinal nucleus of the bulbocavernosus muscle [132].

The MPOA of rats and the spinal nucleus of the bulbocavernosus [1] are sexually dimorphic model systems that have been well investigated. In humans, the localization and morphology of neurons innervating the small, striated pelvic muscles correspond to that of Onuf’s nucleus X [133, 134]. This nucleus, similar to its rat homologue (the spinal nucleus of the bulbocavernosus), contains fewer motoneurons in the female than the male [135].

**XV. PERSPECTIVES**

Ongoing and future studies assessing the efficacy and tolerability of centrally acting agents for male sexual dysfunction will reveal the most promising targets. Based on current literature, clinical trials have shown benefits for some of the mediators which have been discussed above. Today, none of the available agents can be regarded as a major player in the practical treatment of ED. However, in the light of the relatively high rate of patients that do not respond to or do not tolerate phosphodiesterase-5-inhibitors, additional central pathways modulating sexual responses may be beneficial in the future.
XVI. CONCLUSION

The central regulation of the erectile process is still only partly known. Central transmitter systems, which seem to be dependent on androgens as well as NO, may be the targets of future drugs aimed at the treatment of ED. Increased knowledge of the central (and peripheral) changes associated with ED may lead to an increased understanding of these pathogenetic mechanisms and therefore new treatments and possibly even prevention of the disorder.

B. REGULATION OF SMOOTH MUSCLE FUNCTION

N Kim and S Ückert

I. INTRODUCTION

The penile corpora cavernosa are highly specialized vascular structures that are morphologically adapted to their function of becoming engorged during sexual arousal. In addition, the network of resistance arterioles that carry blood to the corpora cavernosa plays an equally important role in determining the state of penile engorgement. In the non-aroused, flaccid state, the arterial and trabecular smooth muscle remain constricted, and the hemodynamic environment of the corpora cavernosa is similar to the venous circulation in terms of pressure, flow, and oxygen tension. There is low resistance to the drainage of blood from the cavernosal bodies, and this contributes to the maintenance of penile flaccidity.

The onset and maintenance of penile tumescence is initiated by central psychogenic and/or peripheral reflexogenic sensory stimuli, as described in greater detail in the previous sections. Both central and peripheral pathways stimulate sacral parasympathetic efferent nerve fibers, which ultimately cause the relaxation of the vascular smooth muscle in the resistance arterial bed and the trabeculae of the corpora cavernosa. These events result in a higher rate of blood flow into the penis, and greatly increase the compliance of the cavernosal bodies, enabling expansion and accommodation of the increased blood volume within the cavernosal lacunae. The increased blood flow also potentiates local vasodilation through endothelial shear stress-induced responses. During this early filling phase, the hemodynamic environment within the erectile tissues transitions into an arterial system, with respect to blood flow and oxygen tension. However, blood pressure remains low.

The rapid volume expansion of the erectile tissue leads to engagement of the veno-occlusive mechanism, reducing the outflow of blood. The restriction of blood drainage is accomplished by elongation and compression of the subtunical venules that are located between the corpora cavernosa and the tunica albuginea. Veno-occlusion enables the trapping of blood within the cavernosal sinusoids and causes the intracavernosal pressure to rise to systemic arterial levels. As the pressure gradient between the systemic arterial circulation and the intracavernosal vascular compartment is dissipated, blood flow decreases. Altogether, these events act in concert to achieve and maintain full tumescence and rigidity.

Thus, changes in smooth muscle tone are crucial for regulating erectile function. In that regard, continuing research to elucidate the myriad of mechanisms that regulates vascular smooth muscle cell (VSMC) contractility is essential in understanding erectile physiology. The basic paradigm of smooth muscle, endothelium and nerve interactions to influence vascular reactivity is universally acknowledged, but warrants more detailed consideration within the context of genital tissues. The next several sections describe the basic mechanisms that regulate VSMC contractility, including additional consideration of non-contractile responses in VSMCs. While much of the information specific to genital tissue vascular physiology is derived from studies on penile corpus cavernousum, findings from cardiovascular research will also be presented to gain further insight into VSMC function.

II. TISSUE STRUCTURE AND CELLULAR ORGANIZATION

The overall structure of the genital tissues and the manner in which the cellular constituents are organized have significant implications on understanding the mechanisms that regulate smooth muscle tone and genital organ function. The erectile tissues of the penis have trabeculated structures that are uniquely suited to their function of becoming engorged during sexual arousal. In penile corpus cavernosum, the trabecular smooth muscle constitutes approximately 40-50% of tissue cross-sectional area, as assessed by histomorphometric analysis [1,2]. Most of the remaining cavernosal tissue area is occupied by extracellular matrix, which provides a fibroelastic framework and consists predominantly of collagen types I, III, and IV, and elastin [3-6]. Collagen types V and XI are also synthesized by the cavernosal smooth muscle at detectable levels. Although smaller in number, endothelial cells and neurons play critical roles in maintaining and regulating VSMC tone.

This complex architecture is maintained by the active and dynamic expression of numerous growth factors. Well-established as a regulator of limb morphogenesis, sonic hedgehog (Shh) has also been identified in the penis [7,8]. Studies indicate that inhibition of Shh in the adult leads to rapid atrophy and disorganization of the corpus cavernosum [7,8], suggesting that Shh is a critical protein in the development and maintenance of penile cavernosal tissue structure. Regulation of the growth and patterning of multiple cell types by Shh has been demonstrated in the central nervous system, vasculature, and penile tissue [8-15]. Thus, it is likely that Shh maintains the integrity of smooth muscle, nerve and endothelium in the penis. Of note, Shh levels
are regulated by cavernosal nerve activity and administration of exogenous Shh can reduce apoptosis in cavernosal tissue of animals subjected to cavernosal nerve injury [9,16,17]. Participants of the Shh signaling pathway such as patched (transmembrane receptor for Shh), the homeotic gene Hoxa-10, and the bone morphogenic protein BMP-4 have all been shown to participate in post-natal penile tissue differentiation and structure maintenance. In addition, Shh has been shown to stimulate the expression of vascular endothelial growth factor (VEGF) and nitric oxide synthase (NOS) in the penis [8]. Numerous other growth factors are expressed in the penis and are also likely to play important roles in maintaining cavernosal tissue structure and function. However, most studies have examined the use of exogenous growth factors to promote tissue growth, rather than investigating the roles of endogenously produced growth factors.

1. NERVES

The autonomic nerve fibers that extend from the pelvic plexus into the vascular tissues of the genital organs maintain the “basal” unaroused state and could be considered the initiators of sexual arousal in the periphery. While nerve tracing and immunohistochemical studies in penile cavernosal tissue have identified the presence of neurons containing numerous neurotransmitters, only a select few have been studied and many remain inadequately characterized.

In penile corpus cavernosum, unmyelinated nerve varicosities with no associated Schwann cells are observed to be localized to perivascular spaces and distributed in the parenchyma [18-21]. Histochemical studies demonstrate that adrenergic, cholinergic, and non-adrenergic, non-cholinergic (NANC) nerve endings appear in close proximity to VSMCs to regulate smooth muscle tone in the trabeculae and the blood vessels. In some instances, nerve endings have been identified near the endothelial layer [19]. Studies using immunostaining and confocal microscopy indicate that various peptide neurotransmitters are co-localized in the same nerve endings [21]. Among those identified are vasoactive intestinal polypeptide (VIP), pituitary adenylate cyclase-activating polypeptide (PACAP) and helospectin. Interestingly, more recent studies utilizing similar approaches have also demonstrated the co-localization of neuronal nitric oxide synthase (nNOS) and VIP with vesicular acetylcholine transporter (VAcHT), a marker for cholinergic neurons [22]. Each of these neurotransmitters has been shown to cause relaxation of isolated penile cavernosal tissue strips. In contrast, tyrosine hydroxylase, a marker for adrenergic nerves, was not associated with any of the other neurotransmitters examined. Thus, these data suggest that there may be a single class of parasympathetic nerves containing acetylcholine and the various NANC neurotransmitters. Alternatively, there may be a heterogeneous population of parasympathetic nerve fibers that contain various combinations of neurotransmitters that cause smooth muscle relaxation.

While the anatomical evidence is compelling, functional studies have revealed nerve interactions that cannot be discerned from histochemical studies alone. Neurotransmitter release and contractile experiments suggest that acetylcholine inhibits adrenergic nerve activity and stimulates NANC nerves through pre-junctional muscarinic receptors [19,23]. In addition, pre-junctional alpha-2 adrenergic receptors on adrenergic nerves inhibit neurotransmission and provide a self-regulating negative feedback loop for secreted norepinephrine.

It is important to note that not all NANC neurotransmitters initiate relaxation of smooth muscle. For example, neuropeptide Y has been shown to contract smooth muscle in the corpus cavernosum and in the circumflex veins of the penis [24]. In addition, with the exception of nitric oxide, the roles of NANC neurotransmitters as modulators of penile erection remain unclear due to inconsistent experimental findings and the lack of specific and effective antagonists.

2. ENDOTHELIUM

The endothelium consists of a monolayer of cells that forms a single, continuous surface lining the vascular compartment throughout the body. The total mass of the endothelium has been estimated to be 500 grams in the average adult human; the majority of which is contained in the pulmonary vasculature [25]. Much like skin, the endothelium may be considered a single organ with multiple functions and differential responses that are dependent upon both the systemic and local environments. Among other functions, a healthy endothelium serves to provide an anti-thrombotic, anti-inflammatory, and anti-atherogenic surface while also regulating vascular tone and permeability. The importance of endothelial regulation can be better appreciated by considering pathological states that share in common dysfunctional endothelium. Endothelium-dependent relaxation of blood vessels has been shown to be compromised in animal models of atherosclerosis, hypertension, diabetes, aging, smoking, and renal failure [25-28]. Thus, diseased or damaged endothelium has been proposed to be a major contributor to vascular insufficiency of genital tissues in men and women.

The endothelium produces many vasoactive compounds that can influence the contractile, trophic or synthetic function of vascular smooth muscle cells. Among the factors that cause relaxation are nitric oxide (NO), carbon monoxide (CO), endothelium-derived hyperpolarizing factor (EDHF), prostacyclin (PGI2), and endothelin (through ETB receptors).
Among the factors that cause contraction are endoperoxides, thromboxane A2, superoxide anions, and endothelin (through ETA receptors). One of the more novel mechanisms of regulating endothelial signaling involves changes in the number of caveolae on the surface of endothelial cells. Caveolae are invaginated microdomains of plasma membrane that are rich in endothelial nitric oxide synthase and the family of transmembrane structural proteins known as caveolins, as well as cholesterol, sphingolipids, and glycosylphosphatidylinositol-linked proteins. In addition, caveolae contain numerous other signaling proteins such as receptors with seven-transmembrane domains, G-proteins, adenylyl cyclase, phospholipase C, protein kinase C, calcium pumps, and calcium channels. Thus, these specialized signaling regions have been termed transductosomes [29].

Most cells possess the ability to respond to physical deformation through mechanotransduction pathways. By virtue of their location on the inner surface of blood vessels, endothelial cells possess the ability to sense shear stress across their apical surface. While the actual mechanisms of shear-induced signaling remain unknown, it has been hypothesized that shear causes changes in membrane fluidity by decreasing the density of phospholipid molecules within the cell membrane [30]. Independent of a specific membrane receptor protein, G-proteins may become activated due to their increased mobility within the more fluid phospholipid bilayer as shear stress is increased [30]. Such a change would be caused by a rapid increase in blood flow, as occurs during penile erection (Figure 1). Activation of G-proteins by shear stress may lead to receptor-independent activation of phospholipase C, triggering a rise in intracellular calcium and subsequent activation of endothelial NOS (eNOS). Alternatively, shear stress-induced G-protein activation could stimulate phosphatidylinositol 3-kinase (PI3K), which in turn phosphorylates Akt (also known as protein kinase B). Phosphorylated Akt is then able to phosphorylate eNOS, increasing its enzymatic activity in the absence of calcium. An interesting mechanism that has recently been defined is the activation PI3K through sphingosine 1-phosphate (S1P). S1P receptors have been demonstrated in penile corpus cavernosum and this may be an important pathway mediating prolonged calcium-independent activation of eNOS [31,32]. Increased shear stress can stimulate the production and secretion of numerous vasoactive factors from the endothelium, but it remains unclear as to how the cell differentially processes flow-induced shear stress to produce specific factors.

Figure 1. Activation of endothelium by shear stress. A) Receptor-independent activation of G-protein; B) Shear-induced NO synthesis by calcium-dependent mechanism; C) Shear-induced NO synthesis by calcium-independent mechanism; D) Receptor-mediated NO synthesis by calcium-independent mechanism.
3. VASCULAR SMOOTH MUSCLE

As a major constituent and primary effector of the vascular structures in the genitals, the vascular smooth muscle cell (VSMC) is highly adaptable and multi-functional. The two primary functions of VSMCs are contraction and synthesis/maintenance of extracellular matrix. In cell culture experiments, VSMCs have been characterized as having either "contractile" or "synthetic" functional phenotypes. However, these two categories are considered to be extremes that are manifested under in vitro conditions and it is likely that a range of intermediary phenotypes exist in any given tissue in vivo. Increasingly, protein and gene expression studies are illustrating the ability of VSMCs to alter their cellular phenotypes in response to changes in their environment [33,34]. In addition, studies by developmental biologists indicate that VSMCs in different vascular beds may arise from varying cellular lineages (multiple sources of progenitor cells) and can be recruited from different locations in the developing embryo [35]. Further, comparative studies of VSMCs have led investigators to speculate that lineage-specific differences in growth and transcriptional responses may persist beyond the early developmental period and into the adult organism [35]. It remains unclear as to what extent the observed heterogeneity of VSMCs is due to adaptation in altered cellular environments versus differences in lineage. The apparent mosaic nature of smooth muscle throughout the body may account for some of the diversity in responses found in different vascular tissues in health and disease. Nevertheless, most VSMCs in peripheral blood vessels are derived from the mesoderm and exhibit a set of common characteristics. This chapter describes the general mechanisms of signal transduction in smooth muscle cells that regulate contractility with particular regard to genital tissues. Additional consideration of non-contractile responses in VSMCs is also included. However, regulation of extracellular matrix by smooth muscle has been omitted, since it is addressed elsewhere. While much of the information specific to genital tissue vascular physiology is derived from studies on penile corpus cavernosum, findings from cardiovascular research will also be presented to gain insight into VSMC function in male genital tissues.

4. COORDINATED REGULATION OF VSMCs

The majority of VSMCs in blood vessels and in cavernosal tissues are not adjacent to or in direct contact with an endothelial cell or nerve terminus. However, the thickness of any arteriole or trabecular bundle is limited to several cell layers. Given this arrangement, intercellular communication for the purpose of regulating smooth muscle tone in a coordinated fashion can be accomplished by two general mechanisms: 1) extracellular diffusion of vasoactive and trophic factors released by endothelium, nerves and smooth muscle (paracrine and autocrine regulation), and 2) intracellular diffusion of second messengers from stimulated cells into adjacent cells by means of gap junctions. These mechanisms are not mutually exclusive and it is likely that they act in complementary fashion to propagate regulatory signals.

Extracellular diffusion of regulatory substances requires sufficient concentrations to be secreted near a population of effector cells. The magnitude of response would be determined by the number of cells that were directly stimulated by the secreted substance. In contrast, intracellular propagation of signals along multiple cells through gap junctions does not require every responding cell to be activated by the initial stimulus. A single cell may be stimulated by a secreted substance and generate second messengers that can diffuse into neighboring cells. In this mechanism, the magnitude of response would be directly proportional to the number of cells activated by the spread of intracellular messengers, rather than the number of cells directly stimulated by the secreted substance.

The structure and function of gap junctions in the vasculature have been studied for the past several decades. VSMCs and endothelial cells are known to form functional syncytia by virtue of junctional plaques in their plasma membranes [36,37]. These plaques contain hundreds to thousands of gap junction complexes. The diameters of plaques between VSMCs range from 0.2 to 0.5 μm, whereas those between endothelial cells have been observed to be up to twice as large [36]. The area of each junctional plaque may be important in determining the rate of signal propagation. Each gap junction channel is formed by the docking of two hemi-channels; each hemi-channel being contributed by an opposing cell. Hemi-channels are hexameric structures formed from connexins, a large family of proteins derived from multiple genes [38]. VSMCs have been shown to express connexin 40 (Cx40) and connexin 43 (Cx43), whereas endothelial cells express Cx37 in addition to Cx40 and Cx43 [36]. Connexin proteins apparently have relatively short half-lives with estimated cycling times of 1 – 5 hours [37]. This suggests that junctional plaques are highly dynamic structures that may have the ability to attenuate or potentiate smooth muscle responses.

While the role of most connexins have not been studied in genital tissues, the expression of Cx43 has been confirmed in smooth muscle and endothelial cells derived from human penile corpus cavernosum [36,37]. Further, functional and pharmacological studies, as well as theoretical modeling, suggest that gap junctions play an important role in signal propagation by virtue of their permeability to a wide array of intracellular molecules, including ions, inositol phosphates, cyclic monophosphates, nucleotide triphosphates, nucleotides, amino acids, glucose
and its metabolites, small RNAs, and small peptides [39-42]. Although it is likely that connexins are not uniformly permeable and do exert a level of specificity, the selectivity and relative permeability of different gap junctions to intracellular signaling molecules remains largely unknown and is the focus of more recent research efforts. It has been postulated that junctional permeability may change in response to elevated concentrations of specific ions or second messengers [40], but direct demonstration of this phenomenon is lacking.

In studies using non-genital tissues, junctional plaques between endothelial and smooth muscle cells have also been observed [43,44]. However, the presence of these “myoendothelial” gap junctions has not been studied in genital tissues and their significance remains unclear. Thus, gap junctions enable smooth muscle and endothelial cells to form a continuous network of functional units. These cellular networks can rapidly coordinate the response to various stimuli that may not be homogeneously distributed throughout the tissue.

### III. MECHANISM OF SMOOTH MUSCLE CONTRACTION

Multiple overlapping pathways regulate vascular smooth muscle tone. However, before any of these mechanisms can be discussed, it is essential to understand the basic mechanism by which smooth muscle cells generate force, which is ultimately determined by the interaction between myosin cross-bridges and actin filaments [45-47]. Numerous dense bodies consisting of α-actinin are distributed throughout the smooth muscle cell, either in the cytoplasm or associated with the plasma membrane. Analogous to the Z-disk structures in striated muscle, dense bodies provide points of anchorage for actin filaments and are themselves stabilized by a network of intermediate filaments that are composed of desmin and vimentin. Unlike striated muscle, the molecular contractile units of interdigitating actin (thin) and myosin (thick) filaments are not regularly aligned with one another and can be oriented in multiple directions.

Smooth muscle myosin is a large hexameric protein, consisting of 2 heavy chains and 4 light chains. The heavy chains are identical and have both globular and linear domains. The linear domains contain the C-termini and form coiled-coil structures that result in the “tail” of the myosin molecule, while the globular domains contain the N-termini and possess actin binding sites and ATPase catalytic activity. These globular heads of the myosin molecule form the cross-bridges of the contractile apparatus. The 4 light chains in myosin consist of 2 essential light chains that have a molecular weight of 17 kD each (ELC17) and 2 regulatory light chains that have a molecular weight of 20 kD each (MLC20). One essential and one regulatory light chain is associated with each globular head in myosin. In smooth muscle, myosin molecules self-associate into a side-polar arrangement in which the globular heads protrude in a linear array on 2 opposing sides of the thick filament [48]. On any given side, the globular heads are oriented in the same direction, but antiparallel to those on the opposite side. This is in contrast to skeletal muscle myosin, which has a bipolar helical arrangement in which the globular heads protrude in a helical pattern around the thick filament and are oriented in opposite directions on either side of the M-line within the sarcomere. Actin filaments are composed of two long strands of globular actin that intertwine into a double helical arrangement. While troponins are absent in smooth muscle, other regulatory proteins such as caldesmon and calponin are known to be associated with actin. The potential roles of these proteins will be discussed following a brief presentation of the cross-bridge cycle.

1. FORCE GENERATION IN VSMC – CENTRAL ROLE OF CALCIUM

The contractile response of the smooth muscle cell is tightly associated with the intracellular concentration of free calcium (Ca⁡²⁺). However, intracellular Ca⁡²⁺ regulates the contractile apparatus in an indirect manner through the regulatory protein calmodulin, which has the capacity to bind four calcium ions. Calcium-bound calmodulin undergoes a conformational change and thereby increases its affinity for myosin light chain kinase (MLCK) and activates it. Calmodulin-activated MLCK then phosphorylates the serine-19 residue of MLC20. In the presence of ATP, this phosphorylation enables actin to activate the myosin ATPase and initiates cross-bridge cycling. Crystal structure studies of myosin complexed to analogues of ATP and the ATP-ADP transition state suggest that a single power stroke can achieve approximately 10 nm of linear displacement [49].

Beginning with a state in which myosin cross-bridges are bound to actin with high affinity in the absence of ATP, one complete cycle consists of the following events (see Figure 2):

- Phosphorylation of MLC20 by Ca⁡²⁺-calmodulin-MLCK complex activates myosin’s ATPase.
- ATP binds the globular head of myosin and causes it to dissociate from the actin filament. This dissociation alters the cross-bridge angle to prepare for the power stroke.
- In this dissociated state, myosin hydrolyzes ATP and rebinds with actin in a low affinity state.
- Release of the hydrolyzed inorganic phosphate increases the affinity of myosin for actin and
generates the power stroke of the globular myosin head, shortening the contractile apparatus.

- Dissociation of ADP from myosin enables another molecule of ATP to bind the myosin cross-bridge and continue onto a second cycle.

This series of events continues until MLC20 is dephosphorylated by myosin light chain phosphatase (MLCP). Assuming that energy stores are not limiting, maintenance of high intracellular Ca\(^{2+}\) concentrations assures that MLCK remains active and perpetuates cross-bridge cycling.

**2. REGULATORY MOLECULES INFLUENCING THE CONTRACTILE APPARATUS**

**a) Myosin light chain phosphatase and Rho-kinase**

At any given level of intracellular Ca\(^{2+}\), the contractile apparatus may become further sensitized by the inhibition of MLCP, such that the rate of myosin dephosphorylation (inactivation) is reduced and the action of MLCK becomes more efficient. Thus, modulation of MLCP activity is thought to be important for regulating smooth muscle contraction. MLCP is a holoenzyme consisting of a type 1 phosphatase (PP1cδ), a myosin-targeting subunit (MYPT1 – also called MBS for myosin binding subunit), and a 20 kD subunit of unknown function [50,51]. The activity of MLCP can be modulated by a variety of factors. Two of the more well-recognized mechanisms involve both direct and indirect effects of Rho/Rho-kinase pathway. Rho proteins are small GTPases classified as a subgroup of the Ras superfamily and can be activated by the binding of agonists to G-protein coupled receptors [52]. Activated Rho can in turn activate Rho-kinase (also called ROK or ROCK), a serine/threonine kinase. Rho-kinase can then phosphorylate multiple substrates including MYPT1, the 17 kD protein kinase C-potentiated inhibitor protein (CPI-17), and MLC20 [52-54]. Phosphorylation of MYPT1 and CPI-17 results in the inhibition of PP1c phosphatase activity, whereas phosphorylation of MLC20 would stimulate activation.

**Figure 2: Mechanism of smooth muscle contraction. Adapted from Kim NN, Vascular physiology of erectile function, In: Carson CC, Kirby RS, Goldstein I, Wyllie MG, editors, Textbook of Erectile Dysfunction, 2nd Edition. New York, USA: Informa Healthcare, 2009.**
of myosin. In genital smooth muscle, the RhoA/Rho-
kine pathway and its effects on MLCP have been
shown to play an important role in regulating smooth
muscle contractility in both male and female genital
smooth muscle [55-58], whereas the importance of
MLC20 phosphorylation by Rho-kinase remains
unclear. The presence of CPI-17 protein has
been detected in human and rabbit penile corpus
cavernosum [55], but its functional significance
remains to be determined.

b) Potential regulatory roles of actin-associ-
ated proteins in VSMCs

Inasmuch as myosin may be considered the mole-
cular motor that mediates contraction, experimental
evidence suggests that cross-bridge cycling rates
and tension development in smooth muscle are not
necessarily proportional to MLC20 phosphorylation
[46, 59]. These discrepancies are partially attributable
to the presence of other proteins associated with ac-
tin that may regulate myosin-actin interactions. In-
cluded in this list of proteins are caldesmon, calponin,
and tropomyosin. While much of the experimental
evidence regarding these actin-associated mole-
cules remains controversial, ignoring these potential
regulatory mechanisms reduces our understanding
of the contractile apparatus to an oversimplification.

Both caldesmon and calponin have the ability to bind
actin and myosin and can inhibit myosin ATPase ac-
tivity to suppress development of smooth muscle
tone [46, 59]. In some studies, binding of Ca2+-acti-
vated calmodulin to caldesmon or phosphorylation of
caldesmon by protein kinase C (PKC) or extracel-
ular regulated kinase 1 (ERK1) can antagonize the
inhibitory effect on myosin ATPase [59]. However,
whether caldesmon is a natural substrate for PKC or
ERK1 in the VSMC is subject to speculation. Interest-
ingly, calponin has been shown to bind desmin and
phospholipids, as well as ERK and PKC. Immuno-
precipitation studies demonstrate that calponin can
associate with ERK and PKC as a trimeric complex.
Additional evidence suggests that calponin binds the
regulatory domain of PKC and may facilitate its ac-
tivation. In other studies, ERK has been shown to
be activated at the cell surface by phosphorylation
events, which result in translocation of ERK to the
contractile filaments, where it phosphorylates calde-
smon and stimulates contraction [59].

Taken together, these data suggest that calponin
may facilitate agonist-induced signal transduction
by facilitating PKC activation in the plasma mem-
brane. Further, calponin may mediate the targeting
of ERK and PKC to the plasma membrane. Lastly,
tropomyosin is intimately associated with actin fil-
ments, forming a continuous strand made of coiled-
coil monomers. In the absence of troponins, smooth
muscle tropomyosin appears to participate in coop-
erative interactions between actin and myosin, as
well as with caldesmon. Thus, through changes in
their associations between actin and myosin and
other key signaling molecules, calponin, caldesmon
and tropomyosin may regulate cross-bridge cycling
and VSMC tone in a manner that could not be ac-
complished by calcium alone.

c) Latch – a unique characteristic of VSMC
contraction

A hallmark of smooth muscle function is its ability to
maintain tension for prolonged periods without a cor-
respondingly high consumption of energy. Thus, the
rate of ATP hydrolysis is not proportional to the num-
ber of myosin heads engaged in generating force.
This efficiency in maintenance of tone has been
termed the latch state and is critical for sustaining the
“basal” non-aroused state in genital tissues, which
requires the smooth muscle to remain contracted for
most of the time. The mechanism by which VSMCs
can achieve latch remains unknown. However, de-
creased MLC20 phosphorylation and low myosin
ATPase activity have been associated with latch
[47]. In addition, after attaining the latch state, mam-
nalian smooth muscle is not able to redevelop force
when cross-bridges are subjected to a quick re-
lease by the addition of ATP in the absence of Ca2+.
These data suggest that the latch state results from a
decrease in the rate of cross-bridge detachment from
the actin filament. Under normal physiological
conditions, ATP availability is not restricted and any
dephosphorylated myosin bound to actin in the high
affinity state would quickly bind ATP and dissociate
from the actin filament. Thus, this mechanism could
not account for a slow rate of cross-bridge detach-
ment. For these reasons, it has been proposed that
dephosphorylated myosin remains bound to actin
in the high affinity state while still binding ADP. This
type of interaction could also facilitate cooperative
attachment of non-phosphorylated myosin to actin
to help stabilize the latch state. Recently, it has been
proposed that calponin participates in the latch state
by simultaneously binding actin and myosin to sta-
bilize cross-bridge interactions and slow the rate of
detachment [60].

IV. SIGNAL TRANSDUCTION
PATHWAYS REGULATING VSMC
TONE

Pathways that regulate smooth muscle contractility
ultimately influence intracellular Ca2+ levels and/or
alter the calcium sensitivity of the contractile proteins
(Figures 3 & 4). Thus, vasoactive substances via
pharmacomechanical coupling and/or changes in
cell membrane potential via electromechanical
coupling can change intracellular Ca2+ concen-
trations, which regulate the contractile apparatus, as
described in the previous section. However, intracel-

lular Ca\textsuperscript{2+} concentrations need not change for contraction or relaxation to occur if the sensitivity of the contractile apparatus to Ca\textsuperscript{2+} is changed. This additional mode of Ca\textsuperscript{2+}-independent regulation can result in sensitization through inactivation of MLCP or desensitization through the inactivation of MLCK.

Both phosphatase and kinase activity can be inhibited by phosphorylation events (e.g. phosphorylation of MLCP by Rho-kinase). In light of these fundamental mechanisms that alter smooth muscle tone, the main signal transduction pathways that regulate intracellular Ca\textsuperscript{2+} levels and contractile apparatus sensitivity to Ca\textsuperscript{2+} will be summarized in the following sections.

1. PHARMACOMECHANICAL COUPLING

In general, most vasoactive substances exert their effects through intracellular signaling mechanisms that involve at least some aspect of pharmacomechanical coupling (contraction or relaxation in the absence of membrane potential changes). While an exhaustive review detailing the pharmacology of each vasoactive substance or class of receptors is beyond the scope of this chapter, several key pathways that regulate smooth muscle tone will be highlighted.

a) Pathways involving IP3, DAG and PKC

Vasoconstrictor agonists such as norepinephrine (\(\alpha\)-adrenergic receptors), endothelin-1 (ETA receptors), angiotensin II (AT\(_1\) receptors), prostaglandin F2\(\alpha\) (FP receptors) and thromboxane A\(_2\) (TP receptors) bind their respective receptors to activate G\(_q\), which in turn stimulates phospholipase C beta (PLC-\(\beta\)). This membrane bound enzyme hydrolyzes phosphatidylinositol 4,5-bisphosphate (PIP\(_2\)) to liberate inositol 1,4,5-trisphosphate (IP3) and 1,2-diacylglycerol (DAG). IP3 binds to specific receptors (IP3R) on the smooth endoplasmic reticulum (SER) to stimulate the release of Ca\textsuperscript{2+} from intracellular stores. IP3R’s act as Ca\textsuperscript{2+}-activated Ca\textsuperscript{2+} channels, similar to the ryanodine receptor. Binding of IP3 to these receptors not only activates the channel, but...
Also increases the sensitivity of the IP3R to Ca\(^{2+}\) and facilitates calcium-induced calcium release (CICR). It is likely that specialized regions of the SER containing IP3R's remain in close proximity to the plasma membrane, enhancing signaling efficiency through the maintenance of functional microdomains [61].

As Ca\(^{2+}\) efflux from the SER decreases the internal stores, free Ca\(^{2+}\) is recycled back into the SER by the SER Ca\(^{2+}\)-ATPase pump (SERCA). Since SERCA is not able to recycle Ca\(^{2+}\) with complete efficiency, store-operated channels (SOC's) in the plasma membrane enable entry of extracellular Ca\(^{2+}\) to replenish the internal stores (capacitative Ca\(^{2+}\) entry). The mechanism by which the SER regulates SOC's is not understood. However, it is clear that SOC's and SERCA function to prevent depletion of internal Ca\(^{2+}\) stores. Upon dissociation of agonists from their receptors, SERCA restores intracellular Ca\(^{2+}\) levels to the basal state and thereby is an important mechanism of signal termination. During prolonged periods of stimulation, SOC's may play a more important role in providing a source of Ca\(^{2+}\) for sustaining signal. It is interesting to note that very high levels of intracellular Ca\(^{2+}\) (near the micromolar range) can itself trigger desensitization of MLCK by activating Ca\(^{2+}\)-calmodulin-dependent kinase II (CaM kinase II). CaM kinase II has a significantly lower sensitivity to Ca\(^{2+}\) than MLCK and is activated only at higher Ca\(^{2+}\) concentrations. Once activated, CaM kinase II phosphorylates MLCK. This phosphorylation decreases the affinity of MLCK for Ca\(^{2+}\)-activated calmodulin and thereby reduces its kinase activity. Thus, strong stimuli that cause Ca\(^{2+}\) to rise to very high levels can trigger a feedback inhibition response.

DAG is also an important intracellular second messenger generated by PLC. DAG directly activates PKC, a family of isoenzymes that participate in diverse cellular functions and have the ability to translocate between the cytoplasm and the plasma membrane. With regard to smooth muscle tone, PKC can regulate ion channels or phosphorylate multiple substrates to facilitate contraction [46,62].

Figure 4. Signal transduction pathways regulating smooth muscle relaxation. Red arrows indicate association, binding and/or activation, whereas yellow arrows indicate inhibitory regulation. Indirect or putative interactions are indicated by dashed arrows. AM = actin-myosin contractile apparatus; BKCa = calcium-activated maxi-K+ channel; cAK = cAMP-dependent protein kinase; cGK = cGMP-dependent protein kinase; CaMK = calmodulin-dependent kinase; CO = carbon monoxide; HSP20 = 20 kilodalton heat shock protein; IP3R = IP3 receptor; IRAG = IP3R-associated cGK substrate; KATP = ATP-dependent K+ channel; MLCK = myosin light chain kinase; MLCP = myosin light chain phosphatase; NO = nitric oxide; PLmb = phospholamban; SER = smooth endoplasmic reticulum; SERCA = SER calcium ATPase. New York, USA: Informa Healthcare, 2009.
these mechanisms are less well-defined, PKC may participate in activating the ERK signaling pathway to affect caldesmon function, as previously outlined in the section on actin-associated proteins. Through similar mechanisms, PKC may also mediate Ca\(^{2+}\)-independent contraction, since several of the PKC isoforms are insensitive to Ca\(^{2+}\) while still being activated by DAG. It is also interesting to note that PKC has been shown to inhibit Ca\(^{2+}\) channel activity and promote Ca\(^{2+}\) extrusion through the Na\(^{+}/Ca\(^{2+}\) exchanger; events that would decrease intracellular Ca\(^{2+}\) and cause VSMC relaxation [62]. Thus, while there are mechanistic aspects of PKC that are not fully understood, it seems likely that PKC causes contraction through Ca\(^{2+}\)-independent mechanisms.
