An important distinction to note is the source of DAG. In addition to PIP2 hydrolysis by PLC-β, which generates IP3 and DAG, hydrolysis of phosphatidylinositol 4,5-bisphosphate (PI(4,5)P\(_2\)) by either a different isoform of PLC or the sequential action of phospholipase D (PLD) and phosphatidate phosphohydrolase (PA-PHA), produces DAG alone and does not result in the mobilization of intracellular Ca\(^{2+}\). It has been postulated that the rate of force development and the duration of contraction is related to the activation of different isoforms of phospholipid hydrolytic enzymes and PKC [62]. Thus, the rate and extent of DAG synthesis by the various phospholipases and the presence or absence of IP3 co-production may be correlated with the type of contractile response exhibited by the smooth muscle (e.g. short and transient vs. slowly developing and sustained). While PLD activity has been detected after exposure to norepinephrine, endothelin and angiotsensin II, the significance of this enzyme in mediating VSMC contraction is unclear. PLD activation may be a secondary response to strong activation of PKC as occurs experimentally with phorbol ester stimulation. It is also possible that PLD may play a more important role in mediating trophic, rather than tonic, effects. In VSMCs, termination of DAG/PKC signaling is accomplished predominantly by hydrolysis of DAG by lipases to yield free fatty acids and glycerol [62]. However, DAG can also be recycled to synthesize phospholipids and triacylglycerols.

Another mechanism of increasing intracellular Ca\(^{2+}\) is by permitting entry of extracellular Ca\(^{2+}\) through receptor-operated channels without a change in membrane potential [63]. Norepinephrine, endothelin, vasopressin and angiotensin II cause the opening of Ca\(^{2+}\)-permeable, nonselective cation channels. While these channels are termed “nonselective”, they do exhibit greater permeability to extracellular Ca\(^{2+}\) compared to other cations. In addition, their activity is not dependent on intracellular Ca\(^{2+}\) levels and can thus be distinguished from SOC’s. The activation of α1-adrenergic receptor by norepinephrine is a well-studied example of VSMC contraction mediated by receptor-operated channels. This process is independent on G-protein (Gq), PLC and DAG, but is independent of IP3 and PKC [63]. Yet, phosphorylation events are known to activate receptor-operated channels. MLCK inhibitors prevent nonselective cation current but the direct involvement of MLCK is inconsistent with other experimental data. Thus, it is likely that DAG activates another kinase that is similar to MLCK. Recent studies suggest that receptor-operated channels and store-operated channels share extensive homology and belong to the transient receptor potential channel (TRPC) family [64]. This family of channel proteins was first identified in the photoreceptors of Drosophila, where they mediate a sustained current in response to light activation of rhodopsin. To date, 7 mammalian homologues have been identified. Each channel consists of 4 subunits and each subunit has 6 transmembrane segments. The extent to which receptor-operated channels contribute to agonist-induced contraction, relative to mobilization of intracellular stores by IP3, remains unclear. However, antisense oligonucleotide studies in rat cerebral arteries suggest that downregulation of TRPC protein reduces reflex vasoconstriction in response to increased blood pressure [65].

Lastly, it is important to note that similar pathways regulating Ca\(^{2+}\) flux also occur in nerves and in endothelial cells. However, in these cell types, they usually stimulate the production of vasoactive factors that have Ca\(^{2+}\)-dependent synthetic enzymes. In intact tissues, these vasoactive compounds often cause relaxation of VSMCs even though they have the capability to directly stimulate smooth muscle to cause contraction (e.g. kinins and acetylcholine). Thus, the proximity of smooth muscle, endothelium and nerves in vascular tissues dictates that the net response of VSMC tone is dependent on the activation of specific receptor-mediated pathways and also the type of cell in which these pathways are primarily activated.

b) Pathways involving cyclic nucleotides

Generation of cyclic nucleotides (cGMP and cAMP) by guanylyl and adenylyl cyclases is a primary mode of mediating VSMC relaxation. Vasodilators such as VIP and prostaglandins E and D activate G-protein (Gs) coupled receptors that can stimulate plasma membrane associated adenylyl cyclase, whereas soluble (cytosolic) guanylyl cyclase can be directly activated by nitric oxide or carbon monoxide by binding to the heme moiety of the enzyme. Guanylyl cyclase activity is also present in the cytoplasmic domains of natriuretic peptide receptors. In penile cavernosal smooth muscle, C-type natriuretic peptide (CNP) receptor mRNA has been detected and CNP can stimulate cGMP accumulation and induce tissue relaxation [66,67]. However, the importance of membrane associated guanylyl cyclase in the normal function of genital tissue VSMC remains to be determined. Negative regulation of cyclic nucleotide
generation can facilitate contraction of VSMCs. The primary example is that of α2-adrenergic receptors, which act through Gi to inhibit adenyl cyclase.

Increased levels of intracellular cAMP and cGMP cause the activation of cAMP-dependent and cGMP-dependent protein kinases (cAK and cGK) [68-70]. Each cyclic nucleotide-dependent kinase can be activated by both cAMP and cGMP, although cross-activation requires approximately 10-fold higher concentrations of cyclic nucleotide [46]. Thus, in addition to specific activation, there is potential cross-activation of cAK (also called protein kinase A) and cGK (also called protein kinase G), which may be a mechanistic basis for signal cross-talk. However, while cAK and cGK may phosphorylate a number of common substrates, several lines of evidence indicate that the activation of cGK by cGMP and cAMP is the predominant mechanism by which cyclic nucleotides decrease intracellular Ca²⁺ to cause VSMC relaxation [46,71-74]. It should be noted that this does not rule out or diminish the participation of cAK-mediated pathways. For example, cAK (but not cGK) can inhibit Ca²⁺-calmodulin activation of MLCK through phosphorylation of MLCK [75]. Therefore, it is possible that cAK may play a more important role in Ca²⁺ desensitization of the contractile apparatus, rather than in reducing intracellular Ca²⁺ concentration. Nevertheless, as discussed below, it is likely that cyclic nucleotides provide redundant regulation of smooth muscle relaxation.

Cyclic GMP-dependent protein kinases are derived from 2 different genes that encode type I (cGKI) and type II (cGKII). Type I cGK is a dimer consisting of two identical subunits comprising a molecular mass of 156 kDa, and is widely distributed throughout the body. In smooth muscle, only cGK is expressed and exists as 2 splice variants (cGKIA and cGKIB). Type II cGK is a monomer of 86 kDa, and has limited tissue distribution, having been found only in intestinal epithelium, kidney and brain [76]. While specific roles of the 2 different cGKI isoforms are an area of continuing investigation, there is evidence that both isoforms differ considerably in their functional properties[77-79]. Immunoprecipitation studies in smooth muscle indicate that cGKIB is associated with IP3R and a 125 kD protein known as IP3R-associated cGKI (IRAG); both of which act as substrates for the kinase [80]. Phosphorylation of IP3R and IRAG decreases agonist-induced Ca²⁺ release from the SER. Recently, deletion mutation studies demonstrated that IRAG is a critical protein in mediating cGMP-dependent relaxation of smooth muscle [81]. In addition, cGKI is known to phosphorylate phospholamban, a small membrane-associated protein (6 kD homopentamer) that constitutively inhibits SERCA. Phosphorylation of phospholamban inactivates its inhibitory control of SERCA and increases Ca²⁺ re-uptake into the SER, where Ca²⁺ is bound by proteins such as calsequestrin and calreticulin. Interestingly, cAMP-mediated relaxation was unaffected by mutated, non-functional IRAG [81], whereas cAK can phosphorylate phospholamban to increase Ca²⁺ re-uptake [82]. Thus, the combined actions of cGKI and cAK can inhibit Ca²⁺ release from intracellular stores and also stimulate Ca²⁺ re-uptake.

Additional and perhaps equally important pharmacomechanical mechanisms by which cGMP and/or cGKI may cause relaxation involve activation of the plasma membrane Ca²⁺-ATPase pump, inhibition of IP3 generation, inhibition of Rho-kinase, stimulation of MLCP, and phosphorylation of heat shock proteins [71,76]. These mechanisms have been demonstrated in various cells, but their relevance to VSMCs in genital tissues has not been explicitly shown. The plasma membrane Ca²⁺-ATPase produces Ca²⁺ efflux independent of Na⁺ and its activity may be stimulated by cGMP directly or through intermediate enzymes/metabolites that are regulated by cGKI. PLC activity can also be inhibited by cGMP to reduce IP3 production. Some studies suggest that Rho-kinase and MLCP can both be phosphorylated by cGKI to antagonize Rho-kinase activity and stimulate MLCP. Since phosphorylation of MLCP by cGKI and Rho-kinase cause opposite effects on phosphatase activity, it is assumed that the phosphorylation sites are different. Lastly, the constitutively expressed 20 kD heat shock protein (HSP20) is associated with actin filaments and has been postulated to regulate smooth muscle contraction. Both cGK and cAK have the ability to phosphorylate HSP20, which presumably leads to desensitization of the contractile apparatus.

In the penis, immunostaining for cGKIα and cGKIβ has been observed within the smooth musculature and the endothelium of cavernous arteries and sinuses. Double-staining protocols revealed the co-localization of α-actin, cGMP, eNOS and cGKI isoforms, the expression of cGKI isoforms was confirmed by Western blot analyses [83]. Findings from in vitro functional studies are also in support of a significance of the cGKI in the control of human penile erectile tissue [84,85].

c) Phosphodiesterases

One of the main mechanisms by which cyclic nucleotide signaling is terminated is by the action of phosphodiesterases (PDEs), a heterogenous group of hydrolytic enzymes. PDEs are classified according to their preference or affinity for cAMP and/or cGMP, kinetic parameters of cyclic nucleotide hydrolysis, relative sensitivity to inhibition by various compounds, allosteric regulation by other molecules, and chromatographic behavior on anion exchange columns. PDEs share a catalytic domain of ~270 amino acids, an N-terminal regulatory domain responsible for binding cofactors, and a C-terminal domain of unknown function. Eleven families of PDE isoenzymes can be distinguished [86-91]. Some of these isoenzyme families contain more than one
gene (isogenes) and some genes are alternatively spliced so that more than 50 isoenzymes or variants have been described to date [92-95].

Thus far, 6 out of these 11 isoenzymes (PDE1, 2, 3, 4, 5 and 11) have been proven to be of pharmacological importance. Since the distribution and functional significance of PDE isoenzymes varies in different tissues, isoenzyme-selective inhibitors have the potential to exert specific effects on the target tissue. Although mammalian tissues express several members of PDE families or more than one variant of an individual family, there are numerous examples where an individual PDE is predominantly found in a specific location. Preferential expression of PDE5 in the corpus cavernosum and the cGMP-mediated relaxation of the cavernous smooth muscle during sexual stimulation have made inhibition of this enzyme by sildenafil, vardenafil and tadalafil a clinical benefit in the management of erectile dysfunction (ED). PDE5 was first detected as the major cGMP binding protein in lung and later characterized as a cGMP-binding cGMP-specific PDE. The purified protein is a homodimer of 99.6 kDa subunits and binds two zinc atoms per monomer (Kd ~0.5 mM) which are necessary for catalysis. PDE5 has two allosteric sites for cGMP binding (Kd ~1.3 and 3 mM). Occupancy of these sites is necessary for PDE5 phosphorylation which has been shown to occur in rat vascular smooth muscle cells via cPKG-dependent mechanisms. The amino acid residues comprising the active site of PDE5 have been examined by site directed mutagenesis studies and characterization of the mutant enzymes. Substitution of only four amino acids alters the cGMP selectivity of PDE5 toward cAMP by more than 100 fold. Within the active site, substitution of His643 and Asp754 (common to all PDEs) and His603, His607, His647, Glu672, and Asp714 produced marked changes in kcat while substitution of His643 and Asp754 (common to all PDEs) and His603, His607, His647, Glu672, and Asp714 produced marked changes in kcat while substitution of Tyr602 and Glu775 dramatically increased the Km (wildtype ~2 mM) without affecting the velocity of the enzyme.

Nevertheless, since PDEs form a biochemically and structurally diverse family of proteins, there might be more than one PDE isoenzyme or isogene serving as potential drug target in the treatment of ED. In the 1990s, the presence of PDE isoenzymes 2, 3, 4, and 5 was reported in cytosolic supernatants of human erectile tissue [96]. In addition, the expression of mRNA transcripts specifically encoding for 14 different human PDE isoenzymes and isoforms in human cavernous tissue was shown by means of RT-PCR and Northern Blot analysis: PDE1A, PDE1B, PDE1C, PDE2A and PDE10A, which hydrolyze both cyclic AMP and cyclic GMP; the cyclic AMP-specific PDE isoenzymes PDE3A, PDE4(A-D), PDE7A and PDE8A, and the cGMP-specific PDEs PDE5A and PDE9A [97].

The intracellular level of cAMP in human erectile tissue is mainly regulated by the cAMP-degrading PDE isoenzymes 3 and 4. Evidence for the presence of PDE 3 and 4 in human erectile tissue has been shown and messenger RNAs encoding for PDE3A, PDE4A-D, PDE7A and PDE8A, all of which are known to hydrolyze cAMP, were shown by means of RT-PCR and Northern blot analyses [97,98]. Results obtained in vitro suggest that PDE3 and PDE4 might be the predominant isoenzymes in the human corpus cavernosum) [97,99]. A significant role of PDE4 and cAMP in the control of human erectile tissues is further supported by the finding that immunoreactions specific for PDE4 and PDE4A were detected in cavernous endothelial and neuronal structures [84]. Interestingly, it has been shown that the reversion of tension mediated by an α1-adrenoceptor of isolated human corpus cavernosum induced by sildenafil and tadalafil were reversed by the protein kinase A inhibitor Rp-8-CPT-cAMPS, suggesting an involvement of cyclic AMP-mediated mechanisms in the action of PDE5 inhibitors. On the basis of these observations, an important complementary role might be considered for the adenylyl cyclase/cAMP/cAK pathway in the control of cavernous smooth muscle tone. This provides a rationale to further investigate the effects of selective PDE4-inhibitors, as well as compounds inhibiting both PDE5 and PDE4, in models for erectile dysfunction [100].

2. ELECTROMECHANICAL COUPLING – CONTRACTION AND RELAXATION PATHWAYS

Pathways that regulate VSMC tone and are associated with changes in membrane potential are defined as electromechanical coupling mechanisms. The primary electromechanical mechanism of contraction in VSMCs involves depolarization and the opening of voltage-gated L-type Ca\(^{2+}\) channels to allow influx of extracellular Ca\(^{2+}\). While VSMCs in genital tissues do not exhibit inherent autorhythmicity, they do exhibit cyclical phasic activity associated with changes in electrical signal. Most likely due to the release of paracrine and autocrine substances including neurotransmitters, this activity is inhibited by nifedipine, an L-type Ca\(^{2+}\) channel blocker [101]. Contractile responses caused by norepinephrine, endothelin-1 and angiotensin II are partly mediated by L-type Ca\(^{2+}\) channels [102-104]. Recent studies indicate that L-type Ca\(^{2+}\) channels can be activated by phosphatidylinositol 3,4,5-trisphosphate (PIP3) which is derived from PIP2 through the action of phosphoinositide 3-kinases (PI3K) [102]. PI3K’s are associated with the plasma membrane and can be activated by G-protein coupled receptors or tyrosine kinases.

Mobilization of intracellular Ca\(^{2+}\) through the IP3 pathway can also trigger noncapacitative entry of extracellular Ca\(^{2+}\). Ca\(^{2+}\)-activated nonspecific cation channels (distinct from receptor-operated channels) allow influx of extracellular Ca\(^{2+}\) along with Na+, K+, and Cl− ions.
which depolarizes the VSMC. This depolarization can activate L-type Ca\(^{2+}\) channels to further increase Ca\(^{2+}\) entry. In addition, the presence of Ca\(^{2+}\)-activated Cl- channels in penile corpus cavernosum suggests that Cl- influx may also play a role in depolarizing the VSMC [105]. Specific blockers of Cl- channels produce transient periods of penile tumescence and prolong neurogenic erection.

A major mechanism of VSMC relaxation is the activation of K\(^+\) channels. Activation of cGK and cAK has been associated with the opening of Ca\(^{2+}\)-activated maxi K\(^+\) (BK\(^{Ca}\)) channels in the plasma membrane, causing hyperpolarization. Various mechanisms involving direct and indirect phosphorylation/dephosphorylation events mediated by cGK or cAK have been postulated for the activation of BK\(^{Ca}\) channels in smooth muscle from different vascular beds. However, the precise mechanisms remain undefined. Hyperpolarization mediated by BK\(^{Ca}\) channels has been shown to be an important mechanism of NO-cGK-dependent relaxation in the cavernosal smooth muscle of the penis [106]. Some vasodilators that stimulate cAMP production have also been shown to activate ATP-sensitive K\(^+\) channels (K\(_{ATP}\)) in penile cavernosal tissue and resistance arteries [107,108]. Collectively, changes in membrane potential due to increased K\(^+\) efflux inactivates L-type Ca\(^{2+}\) channels to inhibit Ca\(^{2+}\) influx. NO may also cause VSMC hyperpolarization independent of cGMP and cGK. In aortic smooth muscle cells, NO has been shown to directly activate BK\(^{Ca}\) channels [109].

As its name suggests, BK\(^{Ca}\) channels are activated by Ca\(^{2+}\). When contractile pathways are activated and intracellular Ca\(^{2+}\) concentration is high, BK\(^{Ca}\) channels may provide negative feedback regulation. During the past decade, there has also been increasing evidence that transient, localized bursts of intracellular Ca\(^{2+}\) release or sparks in VSMCs can cause relaxation through BK\(^{Ca}\) channels [110,111]. These sparks are limited to microdomains of the SER that are situated just below regions of plasma membrane containing a collection of BK\(^{Ca}\) channels. The proximity of these Ca\(^{2+}\) release sites to the effector channels enables the local concentration of Ca\(^{2+}\) to become sufficiently high such that a hyperpolarization response is triggered without global changes in intracellular Ca\(^{2+}\). The K\(^+\) currents elicited by Ca\(^{2+}\) sparks have been referred to as spontaneous transient outward currents (STOCs). The regulation of Ca\(^{2+}\) sparks is not well understood, but nyladine receptors, which are also present on the SER of VSMCs are thought to play an important role in their generation. In both vascular and non-vascular smooth muscle cells, Ca\(^{2+}\) sparks have also been shown to activate Cl- channels to cause spontaneous transient inward currents (STICs) that depolarize the smooth muscle and lead to contraction [111]. In VSMCs of genital tissues, the regulatory role of Ca\(^{2+}\) sparks, STOCs and STICs remain to be studied.

## V. MAJOR REGULATORS OF PENILE CORPUS CAVERNOsum SMOOTH MUSCLE CONTRACTILITY

### 1. NITRIC OXIDE (NO)

NO is the primary mediator of NANC parasympathetic input and endothelium-dependent relaxation in the corpus cavernosum [19]. A highly reactive and unstable gas, NO can regulate a wide array of physiological functions in mammals. It is apparently synthesized on demand (with little or no storage) from the amino acid L-arginine and molecular oxygen by a family of enzymes known as NO synthases (NOS). Three distinct isoforms of NOS have been identified which were originally named after the tissues in which they were first described. Neuronal NOS (nNOS or type I) and endothelial NOS (eNOS or type III) are Ca\(^{2+}\)/calmodulin-dependent, constitutive isoforms. Inducible NOS (iNOS or type II) is a Ca\(^{2+}\)-independent isoform that is mainly expressed in macrophages and other tissues following an immunological stimulus [112]. After the gaseous transmitter has been released from nerve endings or the endothelium, NO can readily cross plasma membranes to enter target cells, such as the cavernosal smooth muscle cell. NO promotes the synthesis and accumulation of the second messenger molecule cGMP by the activation of the soluble guanylyl cyclase (sGC), which is the main intracellular receptor for NO. sGC is a heterodimeric protein that consists of an α- and β-subunit, both presenting a homologous domain constituting the catalytic center known to generate cGMP. The enzyme also contains a prosthetic heme attached to a histidine residue of the β-subunit, which is essentially required for the activation of the enzyme by NO. Although the binding of NO occurs in the β-subunit, both subunits are required for the stimulation of enzyme activity [113,114]. The activation of sGC is considered the most significant step in the signal transduction cascade which leads to a reduction in free cytosolic Ca\(^{2+}\) and, finally, penile erectile smooth muscle relaxation. However, NO has also been shown to interact directly with other cellular targets including receptors, ion channels and pumps, which may modulate smooth muscle cell contractility, independent of the cGMP pathway (115-117). Thus, in addition to guanylate cyclase, NO has other intracellular targets, which may play a role in the regulation of vascular smooth muscle contractility.

### 2. PROSTAGLANDINS

Prostanoids (eicosanoids, prostaglandins) are twenty-carbon derivatives produced by the action of cyclooxygenases on the common precursor arachidonic acid [118]. Prostanoids act locally and exert both trophic and tonic effects in an autocrine and paracrine manner. In the corpus cavernosum, prostanoids may play an important role...
in the regulation of extracellular matrix production. However, this discussion will limit its focus to the effects of prostanoids on smooth muscle contractility. The precise physiologic role of prostaglandins in penile erection remains poorly defined. In vitro, prostaglandins appear to be responsible for the rhythmic spontaneous contractile activity observed in isolated corpus cavernosum tissue [19,119]. In addition, the anti-platelet aggregating effects of PGI2 (prostacyclin) and NO, both released by the endothelium, may be important in preventing coagulation of blood, since blood flow within the cavernosal bodies is negligible during full penile tumescence.

The five primary active prostanoid compounds are the prostaglandins PGD2, PGE2, PGF2α, PGI2 and thromboxane A2 (TXA2) [119,120]. Isolated rabbit corpus cavernosum has been shown to synthesize PGE1, PGF2α, TXA2 and PGI2 while human corpus cavernosum smooth muscle cells in culture produce PGE2 and PGF2α [121,122]. The expression and/or activity of prostaglandin H synthase (PGHS1 and PGHS2) mRNA and protein has also been reported in rabbit corpus cavernosum and in cultured human corpus cavernosum smooth muscle cells [119,121-123]. It has been demonstrated that prostanoids can induce both relaxation and contraction in penile corpus cavernosum. In certain disease states, prostanoid imbalance may contribute to erectile dysfunction. For example, tissue levels of TXA2 are significantly increased in rabbits subjected to iliac artery endothelial injury and high cholesterol diet [124]. However, the clinical relevance of such findings remain controversial. PGE is the only endogenous prostaglandin that appears to elicit relaxation of human trabecular smooth muscle; the others causing constriction or having no effect on smooth muscle tone. Exogenous PGE2 and PGE1 relax isolated cavernosah tissue at submicromolar concentrations while PGE2 causes contraction at concentrations of 10μm or greater. The synthesis or pharmacologic action of PGD2 has not been examined in corpus cavernosum and the receptors for this prostanoid are localized primarily in the retina, brain, and small intestines, suggesting highly localized sites of action.

There are five major groups of prostanoid receptors termed DP, EP, FP, IP and TP which mediate the effects of PGD, PGE, PGF, PGI and thromboxane, respectively [118]. EP receptors have been most extensively studied and are further categorized into four pharmacologic subclasses (EP1, EP2, EP3, EP4). Several different isomers of the EP3 receptor have been identified and are found from alternative splicing of a single gene product. The multi-functional, dose-dependent effects of PGE2 may be explained by the coupling of EP receptor subtypes and isoforms to different second messenger systems. In general, the EP1, EP2, EP3 and EP4 receptors mediate smooth muscle contraction (by stimulating phosphatidylinositol hydrolysis or inhibiting adenylate cyclase, while EP2, EP3 and EP4 receptors mediate smooth muscle relaxation by coupling to Gs protein and stimulating adenylate cyclase to increase intracellular cAMP. In certain cases, the same isoform (e.g. EP3II receptor) has been reported to both increase intracellular cAMP possibly by a Gs-coupled mechanism and decrease cAMP via a pertussis toxin sensitive Gi-coupled mechanism, depending upon the density of receptors in the plasma membrane.

3. THE SPECIAL ROLE OF OXYGEN

Oxygen tension plays an active role in regulating penile erection [121,123,125]. Measurements of cavernosal blood PO2 in human volunteer subjects indicate that oxygen tensions change rapidly during the transition from the flaccid to the erect state. In the flaccid state, cavernosal blood PO2 is comparable to that in venous blood (~35 mm Hg). Following intracavernosal administration of papaverine and phentolamine to induce erection, cavernosal blood PO2 increases to arterial levels (~100 mm Hg), reaching 85% of the peak value within the first minute. Maintenance of constant oxygen tension is a critical imperative in most tissues of the body but the penis is the only organ which changes from venous to arterial oxygen tensions during the course of its normal function. This transition is the basis of a unique regulatory mechanism that takes advantage of key synthetic enzymes which utilize molecular oxygen as a co-substrate. NOS and prostaglandin synthase are two well-studied examples of a class of enzymes known as dioxygenases. At low oxygen tensions, measured in the flaccid state of the penis, the synthesis of nitric oxide is inhibited, preventing trabecular smooth muscle relaxation. This inhibition of nitric oxide synthesis is probably necessary for the maintenance of penile flaccidity. Following vasodilation of the resistance arteries, the increase in arterial flow raises oxygen tension. In the oxygen enhanced environment, autonomic dilator nerves and the endothelium are able to synthesize nitric oxide, mediating trabecular smooth muscle relaxation. The synthesis of prostanooids is similarly regulated in the flaccid versus the erect state [121-123]. Therefore, oxygen tension may regulate the types of vasoactive substances present in this vascular bed. For example, at low oxygen tensions, endothelin may predominate, while at high oxygen tension, nitric oxide as well as prostaglandins are made due to the requirement of oxygen for their synthesis.

4. VASOACTIVE INTESTINAL POLYPEPTIDE (VIP)

VIP-immunoreactive nerves are widely distributed throughout the genitourinary system [19,126]. Immunocytochemical detection of VIP indicates that the highest concentrations are found in the proxi-
mal penile corpus cavernosum. Isolated corpus cavernosum tissue from various species, including human, monkeys, rabbit and dog, exhibit relaxatory responses to VIP. VIP and NO synthase containing nerves are often co-localized in penile tissue [19]. The density and distribution of VIPergic nerves within the penis has led many to postulate that VIP, in addition to NO, is an important NANC neurotransmitter regulating penile erection. Along with the anatomical evidence, the role of endogenous VIP in mediating penile erection is further supported by the observations that anti-VIP antibodies and the VIP receptor antagonist VIP 10-28 inhibit nerve-mediated relaxation in isolated cavernosal tissue strips [19]. However, the role of VIP as a modulator of trabecular smooth muscle tone remains inconclusive since the effects of the peptide in vivo are not necessarily consistent with the in vitro findings. Intracavernosal administration of VIP in animals and humans has yielded varying results, ranging from no effect to partial turgence to full erection. Thus, while descriptive studies on the neuroanatomy and the observed relaxatory effects of VIP are supportive of its potential role in mediating or enhancing the onset and maintenance of penile erection, these responses are not well characterized and the physiologic mechanisms underlying its action have yet to be completely elucidated.

5. ENDOTHELIN

Endothelin-1 (ET-1), a member of the endothelin family of peptides, is one of the most potent vasoconstrictors yet described [127,128]. This peptide has also been shown to have growth factor activity, stimulating mitogenesis in fibroblasts, smooth muscle, and endothelial cells. In blood vessels, it is thought to act as a paracrine hormone in the endothelial control of vascular smooth muscle tone and structure of the blood vessel wall. Similar to nitric oxide, endothelin release from the intimal lining of blood vessels can be induced by shear stress. However, little is known about the physiological or cellular mechanisms which regulate its production in the penis. In human corpus cavernosum, ET-1 is synthesized by the endothelium and elicits strong, sustained contractions of corpus cavernosum smooth muscle [129,130]. Two major subtypes of endothelin receptors (ET\textsubscript{A} and ET\textsubscript{B}) have been characterized and cloned. Both receptor subtypes have been identified in penile corpus cavernosum. They are distributed on both the endothelium and the smooth muscle and are distinguished by their binding affinity for ET-3 [131]. Exogenous ET-1 or ET-2 causes equipotent contraction in isolated cavernosal tissue strips, whereas ET-3 induces much weaker contraction in corpus cavernosum. While the receptor binding affinity of ET-1 and ET-2 is not necessarily greater than that of other contractile factors, the rate of dissociation (k\textsubscript{d} = 2.4 \times 10^{-3} /h for ET-1) is significantly slower than many ligands [131]. This may account for the unique ability of endothelins to maintain long-lasting, sustained contraction in corpus cavernosum smooth muscle. Despite its action as a potent vasoconstrictor, the role of endogenous endothelin in penile cavernosal tissue has not been clearly defined. In animal models, acute administration of an endothelin receptor antagonist has potentiated erectile function, but this same antagonist has not proven to be beneficial in clinical studies [132]. It has been suggested that endothelin may also exert vasodilatory effects at low concentrations through a “super-high” affinity form of the ET\textsubscript{B} receptor. Although this vasodilatory role of endothelin in penile erection remains unclear, it has been demonstrated in the rat that ET-3 and submaximal doses of ET-1 increase intracavernosal pressure, potentially by stimulating NO production [133].

VI. SIGNAL TRANSDUCTION PATHWAYS REGULATING NON-CONTRACTILE RESPONSES IN VSMCS

Changes in VSMC growth and extracellular matrix production can have a profound impact on the function of genital tissues. The extracellular matrix itself is a dynamic structure that plays an important role in modulating cell morphology, movement, growth, differentiation and survival by regulating cell adhesion, cytoskeletal machinery and intracellular signaling. Given the perspectives on variations in VSMC phenotype that were summarized in the introduction of this chapter, it is possible that smooth muscle cells may transform from primarily contractile to primarily synthetic cells (or vice versa) in response to changes in their environment (e.g. chronic disease states or acute injury). Alternatively, there may be an inherently heterogeneous population of VSMCs in a given vascular tissue at any one time. In addition to growth factors and cytokines, vasoactive factors have also been shown to have trophic effects in the vasculature, suggesting that many of the same intracellular mediators that cause contraction or relaxation are also involved in trophic responses in VSMCs. While the overall integration of various stimuli and coordination of responses in a single cell is poorly understood, it is likely that the net response of any given VSMC is dependent upon the overall gene expression profile. Synthetic VSMCs are primarily characterized by a significantly decreased expression of contractile proteins. Thus, activation of signaling pathways that may have mediated tonic responses in contractile VSMCs can modulate cell growth or matrix production in a synthetic VSMC. Many of these pathways have been discussed in previous sections of this chapter, but the specific mechanisms regulating gene expression and cell growth remain, in large part, to be elucidated. For example, the NO-cGK pathway and its effects on gene expression is an area of active study. While
it appears that cGKI modulates the ERK pathway (also called mitogen-activated protein kinase or MAP kinase) to modulate proliferation and migration of VSMCs, the molecular targets of ERK that eventually control gene transcription have not been clearly defined [134].

Many growth factors stimulate cell surface receptors with intrinsic tyrosine kinase activity in their cytoplasmic domains. This tyrosine kinase activity is considered essential to regulating cell growth. Several of these receptors have been linked with the activation PLC-γ. Also, as mentioned in the previous section on pharmacomechanical coupling, PLD may be more important for mediating trophic responses than contractile responses. Some variations in responses to growth factors and vasoactive substances may be due to the different mechanisms of activation for different PLC isoforms. In addition to preferential activation of PLC-γ by tyrosine kinases, the β1 and β3 isoforms of PLC are activated by the αq subunit of Gq, whereas the β2 and β3 isoforms can be activated by the βγ subunits of Gi. As described in previous sections of this chapter, PLC activity gives rise to DAG and stimulation of PKC. Stimulation of PKC has been shown to have both proliferative and anti-proliferative effects to platelet-derived growth factor (PDGF), epidermal growth factor (EGF) and angiotensin II [62]. While the reasons for this variability remain unclear, it must be stressed that multiple isoforms of PKC exist and each isoform has numerous substrates. Aside from its effects on the contractile apparatus and ion channels, PKC has also been shown to modulate DNA synthesis, potentially through the phosphorylation of transcription factors [62]. Among the most intriguing of these is nucleolin, a multi-functional protein located primarily in the nucleolus. In addition to its activities as a regulator of ribosomal DNA transcription and ribosomal assembly, nucleolin has been shown to regulate DNA decondensation and act as a plasma membrane receptor and shuttling protein between the cell surface and the nucleus [135].

To date, it is widely accepted that several disorders of the male sexual response, such as male erectile dysfunction (ED) and orgasmic dysfunctions, can be therapeutically approached by influencing the function of the vascular and non-vascular smooth musculature of the genital tract. In order to achieve a pronounced drug effect without significant adverse events, especially on the cardiovascular system, a certain degree of tissue selectivity is mandatory. Selective intervention in intracellular pathways regulating smooth muscle tone has become a promising strategy to modulate tissue function.

VII. SUMMARY AND PERSPECTIVE

Although an impressive amount of knowledge has been accumulated regarding smooth muscle biology and vascular physiology, it is important to keep in mind that many questions still remain and are being actively investigated. While a central and enduring question has been how Ca²⁺ can elicit different responses within a given cell, it is becoming more apparent that unique spatial and temporal differences in intracellular Ca²⁺ flux play an important role in this regulation. Even in the well-established field of contractile proteins, novel findings are not uncommon. Future studies in genital tissue physiology will benefit from the application of knowledge gained from the fields of smooth muscle and vascular biology.

C. DIABETES AND METABOLIC SYNDROME

K Chitaley and J S Paick

I. OVERVIEW

Diabetics are at increased risk for various maladies, including retinopathy, neuropathy, nephropathy and vascular disease. Prolonged, uncontrolled hyperglycemic insult results in altered signaling at the cellular level underlying the development and progression of these diseases. Erectile dysfunction (ED) is often characterized in part by insufficient non-adrenergic/non-cholinergic nerve stimulus, and/or an inability to dilate feeder arterioles of the penis resultant from vascular disease. As the diabetic population is susceptible to these changes, ED is indeed prevalent in this cohort. Although phosphodiesterase 5 (PDE5) inhibitors have revolutionized the field of ED treatment, these drugs are less effective in certain subsets of the population, including diabetics. Rendell et al. reported that 56% of patients with type II diabetes respond to PDE5, compared to 87% of non-diabetic patients[1]. Furthermore, Penson et al. found that the effects of treatment often decline over time in diabetics, as after 12 months of pharmacologic treatment, mean International Index of Erectile Function (IIEF) scores for type II diabetics reversed to baseline[2]. The remainder of this section will focus on epidemiological, clinical and basic science studies that have examined the prevalence, treatment and mechanisms underlying diabetic-ED. For the sake of this chapter, the work outlined will review mainly type 2 diabetic-ED and the metabolic syndrome (MetS), highlighting studies of type 1 diabetic-ED when relevant. Various reviews of valuable reference include: Hidalgo-Tamola et al.[3], Moore et al.[4], Vrentzos et al.[5], Musicki et al.[6] and DiSanto[7], amongst others.

II. EPIDEMIOLOGIC DATA

1. DIABETES MELLITUS

Diabetes mellitus is a common chronic disease, affecting 0.5-2% worldwide. In clinics that treat ED, the prevalence of diabetes as co-morbidity has remained at 20-25%, irrespective of whether the clinic is endocrine-based or andrology-based[8;9]. ED in diabetics is more common than retinopathy or nephropathy[10]. It was reported that up to 75% of men with diabetes have a lifetime risk of developing ED, much higher rates than 52% in men of ages 40-70 years in the Massachusetts Male Aging Study (MMAS)[11-13]. The prevalence of ED in diabetic patients was 40%, with a range of 27.5-75%[14]. This wide variation of the prevalence may be attributed to the heterogeneity of the studied population. Since the severity of ED was dependent on the duration of diabetes, glycemic control and the presence of complication, the prevalence of ED may be affected by the presence of above-mentioned factors[15]. Studies have revealed a prevalence of 49% rate of ED in patients with type 1 diabetes and 34% and 24% of severe and mild to moderate ED respectively, in patients with type 2 diabetes [16;17]. The onset of ED occurs at an earlier age in those with diabetes mellitus and presents within 10 years of the onset of diabetes in more than 50% of patients with any type of diabetes[18].

According to the MMAS, the prevalence of ED in diabetic men was three times higher than that of non-diabetic men. Giuliano et al.[19], evaluated the patients who sought medical care for hypertension and/or diabetes. Erectile function was assessed by IIEF-5. Of the 7689 patients, 2377 men had diabetes and ED was present in 71%. They found higher prevalence (77%) of ED in men with both hypertension and diabetes. The largest study of the prevalence of ED in men with diabetes was undertaken by Fedele and his colleagues[20]. Among the 9868 Italian men, the overall prevalence was 35.8%, and increased with age, such that it was 4.6% in men in their 20s and 45.5% in men older than 60 years.

2. METABOLIC SYNDROME

The prevalence of obesity has increased in the last decade. Comorbidities of obesity include type 2 diabetes mellitus, hypertension, and lipid abnormalities, all of which contribute to cardiovascular disease (CVD) and may be associated with endothelial dysfunction and oxidative stress[21]. Also, obesity significantly contributes to insulin resistance and impaired glucose tolerance and plays an important role in the pathophysiology of insulin resistance[22]. MetS, which is also called insulin resistance syndrome or syndrome X includes glucose intolerance, insulin resistance, obesity, dyslipidemia and hypertension. The MetS has been defined by several expert groups including World Health Organization (WHO)[23], National Cholesterol Education Program’s Adult Treatment Panel γ (NCEP:ATP γ)[24], European Group for the Study of Insulin Resistance[25] and International Diabetes Federation (IDF)[26]. All above-mentioned groups agree on the essential components of MetS but differ in the detail and criteria. At this time, a final definition is awaited.

Since the presence of the MetS independently indicates increased risk of cardiovascular disease,
which is closely correlated with ED, several epidemiological data have identified MetS as potential risk factors of ED. Grover et al.[27] evaluated the effect of various cardiovascular risk factors on ED in a primary care setting. ED was found in 49.4% according to a score of less than 26 on the IIEF EF domain in a cross-sectional survey of 3921 Canadian men. The presence of diabetes (odds ratio 3.13), undiagnosed hyperglycemia (odds ratio 1.46), impaired fasting glucose (odds ratio 1.26) and the presence of MetS (odds ratio 1.45) was identified as an independent risk factor for ED. Bansal and associates[28] evaluated the specific criteria in 154 consecutive consultations for ED. Three out of five criteria for MetS were met in 43% of men with ED, as compared to a reported 24% in a general population. Gunduz et al. [9] examined the prevalence of MetS in 79 patients with coronary artery disease and lipid metabolism disorder. ED was diagnosed in 59 (74.7%) patients. In 38 patients with MetS, all had ED. Although ED was not correlated with cholesterol levels, combination of hypercholesterolemia, hypertension and obesity (BMI>30) was found to be independent risk factor for ED. Conversely, Esposito et al.[30] looked at the prevalence of ED in men with the MetS and age and BMI matched control group. Higher prevalence of ED (26.7%) was found in MetS group than control group (13%). They also noted the prevalence of ED increased as did the number of components of the MetS. Similar relationship was revealed by Bai et al.[31]. They revealed increased risk of ED according to the accumulating number of metabolic abnormalities. ED severity was also correlated with the number of components of MetS. In a clinical study conducted by Demir et al.[32], 89 out of 268 patients, who constituted the MetS group, had a significantly decreased IIEF EF domain score, and EF domain score significantly decreased with the increasing number of metabolic risk factors. A similar finding was shown by Bansal et al.[28]. In an Austrian cohort of 2371 men, the prevalence of MetS was 33.8% and the presence of MetS was turned out to be associated with decreased IIEF-5 score in a multiple linear regression analysis. In addition, they found significant relationship between ED and MetS only in men with 50 years old or older. However this is not always the case, Paick et al.[33] did not find a significant relationship between ED severity and MetS parameters, except hypertension, in impotent men suggesting that the relationship between MetS and ED severity may not be cut, or may be selective for certain components. Could the presence of ED be the predictor of future MetS? Prospective data from MMAS revealed the importance of BMI and the presence of 1 or 2 conditions of MetS for future prediction of MetS[34]. In addition, they stated that ED was predictive of the MetS in men with BMI less than 25 with an adjusted relative risk of 2.1. Accumulating evidence indicated a certain relationship between testosterone and MetS and/or type 2 diabetes. Kaplan et al.[35] found an inverse relationship between mean baseline total T levels and number of NCEP-ATP III components expressed in 864 men (mean age 52 years). In large cross-sectional analysis, Laaksonen et al.[36] provided the evidence of declining T levels in MetS, suggesting an inverse relationship between total T levels and odds ratios for having MetS in 1,896 non-diabetic men. Similar results have been reported by Rodriguez et al.[37], in analysis of the Baltimore Longitudinal Study of Aging where men were followed for a mean of 5.8 years. They confirmed in a longitudinal study what others have found in cross-sectional studies, in that the prevalence of MetS increased with age, and that this was associated with lower androgen levels. They also found that lower total T levels, along with lower SHBG levels, predicted a higher incidence of the MetS.

III. CLINICAL FINDINGS

1. DIABETES MELLITUS

In 12% of type 1 diabetic men, ED was the first symptom of diabetes[38]. Men with diabetes suffer ED 5-10 years earlier than age-matched control subjects[15]. Almost 100% of patients with diabetic neuropathy will have ED[39]. The diabetic men with peripheral neuropathy are likely to have ED due to increased undiagnosed coexisting autonomic neuropathy. The prevalence of coronary artery disease (20%) and peripheral vascular disease (5%) among men with diabetes is far higher than in the general population. Pathologic changes in the cavernous arteries[40], ultrastructural changes in the cavernous smooth muscle[41], and impaired endothelium-dependent relaxation of the corporeal smooth muscle[42] have been noted in penile specimens from diabetic men with ED. Hirshkowitz and associates[43] reported that impotent men with diabetes have fewer sleep-related erections, shorter tumescence time, diminished penile rigidity, decreased heart rate response to deep breathing, and lower penile blood pressure than age-matched non-diabetic men. Current literatures support the idea that the presence of ED in diabetic patients could be the harbinger of fatal cardiovascular disease. Gazzaruso et al.[44] demonstrated that higher prevalence of ED in diabetic patients with silent coronary artery disease than those without any evidence of myocardial ischemia. The presence of ED was associated with more than 14 times higher risk for silent coronary artery disease in diabetic men. In the subsequent study, the same authors reported that ED was associated with higher major cardiovascular morbidity and mortality in diabetic patients with silent coronary artery disease[44]. This evidence indicates the presence of
ED in diabetic patients could predict the future major cardiovascular events.

What is the importance of glycemic control? Bodie et al.[45] assessed laboratory abnormalities for 3,547 men with ED and found that a large number of men presenting with a primary complaint of ED had elevated HbA1c levels. Also, HbA1c levels have been shown to increase with the severity of ED[46;47] and was found to be an independent predictor of the EF score in 78 men with diabetes type 2[15]. Thus, it is likely that adequate glycemic control could reverse ED. However, there have been conflicting results about the beneficial effects of strict glycemic control on the erectile function. Some studies reported improved erectile function following the reduction of HbA1c, while others reported no significant change despite the aggressive blood sugar control. Further well-designed prospective study will clarify this issue.

Hypogonadism is often associated with diabetic ED patients. Corona et al.[48] investigated the presence of hypogonadism in 1200 men with ED and 16% had diabetes mellitus. Hypogonadism was found in 24.5% of men with diabetes, versus 12.6% in the rest of the sample. The authors also found a relationship between the prevalence of hypogonadism in 1,027 diabetic and non-diabetic patients presenting with ED. With diabetics having a significantly greater prevalence of hypogonadism, especially in the sixth decade of life compared to non-diabetics, diabetics had a significantly increased prevalence of hypogonadism than did non-diabetics[49].

The PDE5 inhibitors have revolutionized the management of ED and oral drug therapy is currently first-line therapy for this condition. These agents act by potentiating the action of intracavernosal NO, thereby leading to a more sustained erection. It is often said that diabetic ED patients are difficult-to-treat population with current PDE5Is. There have been studies suggesting that T supplementation in human diabetics with ED receiving pharmacological treatment might be advantageous in the diabetic men in whom PDE5I given for ED do not work. Kalinchenko et al.[50] assessed diabetic ED patients and found that different baseline T levels in these patients determined a differential response to sildenafil. Responders typically had a total T value of 18.6±1.2nmol/L, while non-responders had a total value of 6.9±1.3 mmol/L. The authors found that co-administration of oral T with sildenafil reverses ED in those who showed insufficient response to sildenafil alone.

In addition to lower baseline T level, glycemic control was associated with the response to PDE5Is. Park et al.[51] found that uncontrolled diabetes was one of a predictors of a poor response to sildenafil in 162 consecutive elderly ED patients (mean age 64.1 yrs). Fonseca et al.[52] also showed that the efficacy of tadalafil treatment in 519 diabetic patients was a function of glycemic control. The authors found that though this treatment had a significant benefit in all HbA1c ranges, there was a downward trend of drug efficacy with increasing HbA1c values.

2. METABOLIC SYNDROME

MetS and increased waist-to-hip ratio have been associated with a higher proportion of moderate to severe ED in men older than 50 yr[53]. Conversely, ED may be predictive of MetS presence in men with a body mass index (BMI) of <25 kg/m[2.34] This interesting finding suggests that ED may be a warning sign for MetS in men otherwise considered at low cardiovascular risk.

Studies indicate the possible role of inflammation and endothelial dysfunction in the development of ED for patients with MetS. Men with MetS had an increased prevalence of ED, reduced endothelial function score, and higher circulating concentrations of hsCRP compared with men without metabolic disorders[30]. Another interesting study revealed higher circulating hsCRP levels in obese men with ED as compared to obese men without ED and erectile function score was negatively associated with BMI, waist-to-hip ratio, and hsCRP[54]. These 2 studies clearly showed the relationship between MetS, the inflammatory-endothelial activation and the prevalence of ED.

As mentioned earlier, low circulating androgen levels are clearly a risk factor for MetS and the reverse relationship is true as well. ED might occur as a possible consequence of hypogonadism and MetS. A recent study by Zhody et al.[55] elegantly related hypogonadism to ED and MetS by analyzing BMI measurements in 158 obese men. A significant statistical association was found between increasing BMI and the following parameters: systolic blood pressure, serum T, penile duplex parameters, TG, HDL, and LDL. With increasing BMI, the frequency of hypogonadism and ED increased, while total serum T showed a strong negative correlation. To assess the effect of BMI on vasculogenic ED, the authors examined this relationship in the absence of other risk factors and found that for a BMI<25, 3 out of 13 men (23.1%) had vasculogenic ED as compared to 32 out of 54 men (59.3%) with a BMI≥25.

What about the effect of testosterone treatment on MetS and ED? Makhida et al.[56] argued that hypogonadism is a central feature of the MetS and that testosterone treatment, in addition to restoring eugonadal hormone concentrations, is of a beneficial impact on the MetS itself, slowing the progression to diabetes and CVD. It is interesting that testosterone therapy might ameliorate components of the MetS and decrease cardiac risk because for many years testosterone was thought to be the factor that produced earlier cardiac disease in men versus women. A recent meta-analysis by Haddad et
al.[57] confirmed that T therapy does not carry any increased risks of cardiovascular events. In fact there is evidence to suggest that low T levels are associated with coronary artery disease [58]. As opposed to Maksida’s argument, Chen et al. [59] argued that although total T levels are inversely related to the likelihood of having MetS, it does not have a role in the development of type 2 diabetes. Moreover, Basu et al.[60] treated elderly men with T for 24 months, and did not observe any improvement in carbohydrate metabolism or insulin secretion and/or action. Therefore, despite the established relationship between hypogonadism and MetS, there is no consensus that T therapy will correct the components of MetS.

Can treating MetS improve ED? Currently, no direct pharmacologic therapy for MetS is available. In contrast, lifestyle change, including dietary changes and exercise leading to weight loss, are the cornerstones of therapy. Esposito et al.[61] assessed the effect of weight loss and increased physical activity on men with ED and endothelial dysfunction associated with obesity. BMI decreased significantly in the intervention group compared with usual-care controls. Weight loss was associated with a decrease in serum concentrations of interleukin-6 and CRP. Erectile function scores improved significantly with lifestyle intervention but remained stable in the control group. A significant proportion of men in the intervention group reported a return of normal sexual function. In multivariate analyses, changes in BMI, physical activity, and CRP were independently associated with improvement in erectile function. Thus, lifestyle changes are associated with improvement in sexual function in obese men with ED, while simultaneously improving endothelial function and markers of inflammation.

IV. BASIC SCIENCE MECHANISMS

The majority of basic science studies to date that examine mechanisms of diabetic-ED have done so using animal models of type 1 diabetes. Available studies outlining ED in animal models of type 2 diabetes and MetS have recently been reviewed[3]. An overview of these studies is outlined below.

1. NITRERIC DYSFUNCTION

Erection is activated by NO release from nNOS at NANC nerve terminals. Maintenance of cavernosal vasodilation is thought to occur through the activation of eNOS in endothelial cells, presumably in response to shear stress. Impaired vasodilatory signaling often results from NANC nerve dysfunction and/or endothelial dysfunction, leading to ED. Various studies in animal models of type 1 diabetic-ED support the presence of dysfunctional or altered dilatory signaling. Numerous studies have demonstrated streptozotocin-induced type 1 diabetic rodents and alloxan-induced type 1 diabetic rabbits to have impaired cavernosal relaxation to electrical field stimulation as well as decreased ICP following electrical cavernosal nerve stimulus, indicative of nitreric dysfunction[62-68]. However, although nitrergic dysfunction is established to play a key underlying role in type 1 diabetic-ED, the contribution of impaired nerve signaling to ED in the context of type 2 diabetest in animal models is unclear. In type 2 diabetic, BBZ/WOR mice, a trend toward decreased penile nNOS content was detected[69]. Using immunofluorescent staining, Kawano et al. demonstrated a decrease in nNOS in dorsal nerves in OLETF rats[70]. Similarly, Xie et al. found a decrease in penile nerve fiber nNOS staining evaluated nicotinamide adenine dinucleotide (NADPH)-diaphorase staining of corporal tissue, in high fat diet-fed mice[71]. Recent studies assessing cavernosal vasodilation in response to electrical field stimulus have demonstrated significantly decreased nitrergic-mediated relaxation in type 2 diabetic, db/db mice[72]. However, the extent of the impaired relaxant response was modest, leading the authors to question the true pathophysiologic relevance of this finding to the ED phenotype.

2. ENDOTHELIAL DYSFUNCTION

Endothelial dysfunction is characterized by a decrease in NO bioavailability resulting from decreased endothelial nitric oxide synthase (eNOS) expression or activity, or increased NO scavenging. A study by Jesmin et al. demonstrated lower expression of penile eNOS protein and mRNA in OLETF rats[73]. Additional to decreases in eNOS expression, the activation of eNOS is itself a highly regulated process[6]. eNOS can be activated by hemodynamic stimuli, such as shear stress, as well as through protein signaling, such as that mediated by acetylcholine or vascular endothelial growth factor (VEGF). Both shear flow and VEGF signaling have been demonstrated to lead to eNOS phosphorylation on ser1177, an event associated with increased enzymatic activity. This phosphorylation event is mediated by the serine-threonine protein kinase Akt, and is thought to be relevant for penile erection[74]. In addition to phospho-regulation of eNOS, enzyme activity and subsequent NO production are also regulated by substrate concentration, co-factor availability and enzyme coupling. Although proper activation of eNOS is established to play a role in penile erection, the relevance of dysfunctional eNOS enzyme regulation remains relatively speculative in regards to diabetic-ED, and is reviewed by Musicci et al. [6]
strated attenuated relaxation to acetylcholine in cavernosal tissue from high fat diet-fed mice and Zucker obese-diabetic rats, respectively. Luttrell et al., found a similar impairment of endothelium-dependent dilation of penile tissue from another mouse model of type 2 diabetes, the db/db mouse. This mouse has a genetic mutation of the leptin receptor, resulting in the spontaneous development of hyperglycemia, obesity and insulin resistance by 2 months of age[72].

3. OXIDATIVE STRESS

Increased reactive oxygen species (ROS) and inflammation can result from prolonged hyperglycemia and may result in scavenging of NO. Chronic hyperglycemia induces free radical production through formation of advance glycation end-products (AGE), lipid peroxidation, polyol pathway activation, superoxide production and activation of protein kinase C[76]. AGE production can stimulate cytokine expression on monocytes and macrophages as well as upregulate endothelial adhesion molecules which induce vascular damage[77]. The resultant decrease in bioavailable NO is characteristic of endothelial dysfunction in conditions ranging from ED to atherosclerosis. Increased penile and serum AGE levels have been detected in STZ-induced rats. Further, treatment with a cross-link breaker, ALT-711, or aminoguanidine (which prevents AGE formation) attenuated the impairments in neurogenic and endothelial-mediated cavernosal relaxation in the type I diabetic mice[78;79]. Elevated ROS is also demonstrated in men with ED as well as in animal models of type 1 diabetes. Various studies have reported elevated superoxide in penile tissue from STZ-treated rodents and alloxan-treated rabbits. Further, impairments in acetylcholine and neurogenic-induced relaxation in these models was prevented with treatment with superoxide dismutase or a peroxynitrite decomposition catalyst, supporting a delirious role of oxidative stress in type I diabetic ED[80-82].

Despite evidence suggesting a role of elevated oxidative stress in ED associated with type I diabetes in men and animal models, data examining the role of oxidative stress in animal models of type 2 diabetes or MetS are scant. Decreased antioxidant levels may result in elevated ROS and oxidative stress in type 2 diabetic patients. Glutathione (GSH), an important cell antioxidant, acts as an electron donor to decrease ROS, as well as a cofactor for NOS-mediated NO synthesis. Depressed GSH levels may contribute to decreased NO synthesis. Kovanez et al. measured glutathione/glutathione disulphide (GSH/GSSG) ratio in Zucker diabetic fatty rats as an estimate of oxidative stress levels[83]. They found prolonged treatment with pioglitazone, a PPARg agonist said to have anti-inflammatory effects, to improve (although not normalize) the GSH/GSSH ratio[83], suggesting that glyemic stabilizing agents may have some additional benefit in decreasing damaging ROS agents.

Elevated plasma homocysteine levels are speculated to be a novel risk factor for the development of ED[84]. Homocysteine-induced vascular injury can occur through direct endothelial damage, impaired nitric oxide production, free radical formation, and platelet activation[85]. The exact mechanism in which hyperhomocysteinemia contributes to ED is unclear but appears to involve oxidative stress and superoxide formation. Jones et al. examined cavernosal vasoreactivity in rabbits made hyperhomocystenic by treatment with a methionine-supplemented diet. Cavernous from these rabbits demonstrated an impaired endothelium-dependent relaxation response to carbachol which was reversed by treatment with the superoxide scavenger, superoxide dismutase, or catalase[86].

4. CAVERNOSAL HYPERCONTRACTILITY

Increased contractile function of the cavernous can result from heightened sympathetic activation or potentiated intracellular contractile signaling of smooth muscle cells. Many animal models of diabetic-ED have pointed to cavernosal hypercontractility as a pertinent mechanism underlying the disease phenotype. A recent review extensively outlines potential pro-signaling pathways in the penile smooth muscle cell that may contribute to diabetic-ED[7].

A study by Carneiro et al. suggested the presence of increased sympathetic overactivity in type II diabetic-ED[87]. Contractility was measured in response to electrical field stimulation with the addition of inhibitors of NANC and parasympathetic nerves or to direct activation with phenylephrine[87]. Heightened contractility was detected in the db/db mouse in response to electrical field stimulation but not to phenylephrine, suggesting sympathetic overactivity as the cause. However, Luttrell et al., found increased contraction in cavernous from db/db mice in response to both sympathetic nerve activation with electrical field stimulation, as well as direct contractile activation with phenylephrine, when normalized to penile weight[72]. This study agrees that increased contractile signaling in present in db/db cavernousum, but suggest that this is mediated by penile smooth muscle, and not solely heightened sympathetic nerve activity.

Wingard et al. recently examined the mechanism underlying heightened contractile signaling in the type 2 diabetic rodent[75]. Using the Zucker obese diabetic rat, they detected potentiated cavernosal contraction to both phenylephrine and endothelin-1. They further delineated this increased contractile signaling to be due to overactivity of protein kinase C and Rho-kinase, two primary kinases mediating smooth muscle cell tone.

RhoA/Rho-kinase signaling promotes smooth muscle contraction through a calcium sensitizing mechanism, mediating contraction in response to adren-
ergic agonists and endothelin-1. The inhibition of Rho-kinase activity is sufficient to induce an erectile response in rodents, demonstrating the importance of this pathway in the maintenance of penile flaccidity[3]. Various studies have demonstrated increased RhoA/Rho-kinase expression and signaling in type 1 diabetic animals, as well as an enhanced sensitivity to Rho-kinase inhibition[88-90]. These data suggest that abhorrent elevations in RhoA/Rho-kinase signaling may contribute to diabetic-ED via an overly heightened smooth muscle tone. Other activators of smooth muscle contraction may be potentiated in diabetes as well[7], however, their exact contribution to the disease phenotype remains to be delineated.

5. VENO-OCCCLUSIVE DYSFUNCTION

The limiting of blood outflow through mechanical compression of the emissary veins against the tunica albuginea is essential for the maintenance of elevated corporal pressures and a rigid erection. Various studies in animal models of type 2 diabetes have suggested that a veno-occlusive disorder may underlie the ED phenotype. Kovanez et al. examined veno-occlusive function in the Zucker diabetic fatty rat by monitoring intracavernosal pressure changes during and following saline infusion[83]. They found the diabetic rats to have an inability to sustain adequate intracorporal pressure after the cessation of penile saline infusion, suggesting the presence of a veno-occlusive disorder. These studies have recently been validated in the db/db mouse model of type 2 diabetes[72]. The db/db mice demonstrated both an inability to sustain maximal intracorporal pressure in response to electrical stimulation of the cavernosal nerve, as well as an inability to sustain elevated pressures after cessation of exogenous saline infusion[72]. The study by Kovanez et al. further demonstrated that prolonged treatment with peroxisome proliferator-activated receptor γ (PPARγ) antagonist, pioglitazone, improved the veno-occlusive function in the diabetic fatty rats, suggesting a possible pathway for disease treatment[83].

Structural, matrix, or cellular content changes may underlie impaired veno-occlusive function. Various studies in animal models of type 2 diabetes have revealed altered cavernosal collagen expression and smooth muscle/collagen ratio[71;72;83]. Recently, elastin, an extracellular matrix component in sinusoids and the tunica albuginea, was reported to be decreased in the cavernosum of db/db mice[72]. Consistent with the reduced elastin content, decreased mRNA expression for tropoelastin, a precursor of elastin, and fibrillin-1, a scaffold protein, were also detected in cavernosum from db/db vs. control mice[72]. It is tempting to speculate that structural alterations in the tunica albuginea in type II diabetics may lead to altered distensibility of the corpora required for veno-occlusion and the maintenance of ICP.

Elevated levels of pro-apoptotic proteins such as caspase-3 and decreased expression of anti-apoptotic proteins such as Bcl-2, have been associated with decreased VEGF expression. This suggests that decreased VEGF in type 2 diabetic penile tissue may result in increased apoptosis and loss of erectile cells[73]. Jesmin et al. found decreased VEGF expression and increased expression of apoptotic markers in the Otsuka Long-Evans Fatty (OLETF) rat[73]. Decreases in cavernosal endothelium-dependent dilation, along with an abnormal endothelial cell number and smooth muscle/collagen ratio, have been observed in conjunction with lowered VEGF expression in the high cholesterol-diet fed mouse[91]. In this same model, Further, Xie et al. found treatment with basic fibroblast growth factor, to improve endothelium-dependent cavernosal vasoreactivity in a rabbit model of hypercholesterolemia[92]. Karaboga et al. found alterations in cavernosal smooth muscle actin in a rabbit model of chronic hypercholesterolemia to be irreversible, suggesting the potential importance of prevention, and not just treatment, strategies for erectile health[93].

V. CONCLUSIONS

The numbers of patients with type 2 diabetes and MetS continue to rise. It is clear that organic ED in these cohorts is underlined by multifaceted, complex mechanisms, involving nerve, vascular, and hormonal signaling at its core. Current pharmacologic treatments remain insufficient for these populations, and the need for improved therapeutics is evident. For example, combination therapies with PDE5 inhibitors and antioxidants or androgen replacement may be a promising. However, it is clear that more clinical and basic science studies are warranted.

I. INTRODUCTION

Adequate vascular function is essential for erectile function. Vascular system is responsible for providing blood supply to the erectile tissue sufficient for allowing the corporo-veno-occlusive mechanism required for erection. Thus, any alteration of the vascular system may compromise erectile function. In 1940, the French surgeon René LeRiche associated the aorto-iliac obliteration with impotence when observed that a majority of patients, even young, with occlusive arterial disorders at the bifurcation of the aorta into the two major arterial trunks of the common iliac arteries presented “inability to keep a stable erection, the blood being insufficient to fill the spongious processes” [1,2]. The cause for erectile dysfunction in these patients can probably be ascribed to the presence of a flow limiting stenosis caused by atherosclerotic lesions in the large artery. This is associated with a reduced blood flow to corpus cavernosum during erection.

Although vascular disease in arteries supplying the penis obviously impedes erectile function by limiting blood flow, systemic vascular dysfunction is also intimately related to erectile dysfunction (ED). Cardiovascular disease shares with ED the same risk factors, namely hypertension, hypercholesterolemia, diabetes and smoking [3,4]. In addition, ED is highly prevalent in patients with cardiovascular diseases [5,6], suggesting that ED is another manifestation of vascular disease [7]. In fact, ED is actually considered a sentinel symptom of silent generalized cardiovascular disease.

II. ATHEROSCLEROSIS / VASCULAR ISCHEMIA AND ERECTILE DYSFUNCTION

There are a huge number of studies demonstrating the association of erectile dysfunction to systemic vascular diseases. On one hand, there is a high prevalence of erectile dysfunction in patients having, coronary artery disease (CAD) [8-10], peripheral arterial disease [11,12] and cerebrovascular disease [13,14]. In addition, the prevalence of ED seems to be increased as the severity of vascular disease augments. This is shown in a study where prevalence of ED was evaluated in 285 patients with CAD divided into groups depending on the burden of atherosclerotic lesions. Prevalence of ED was higher in patients with acute coronary syndrome presenting stenosis in more than one coronary vessel (55%) than that in patients having only one vessel affected (22%, not different to controls). The prevalence of ED was further elevated in patients with chronic coronary syndrome (65%) which is due to significant coronary stenosis frequently involving multiple arteries and sites [15]. In agreement with these observations, patients with significant lesions (a stenosis rate >50%) in two or more coronary arteries had worse erectile function, measured by using the Sexual Health Inventory for Men (SHIM) score, than patients with normal coronary arteries or single-vessel CAD, appearing SHIM score as an independent parameter to define the presence of significant lesions in two or more coronary arteries [16].

On the other hand, cardiovascular diseases are prevalent among patients with ED. In fact, early asymptomatic vascular disease has been detected in men complaining of ED. Coronary artery disease has been revealed in patients reporting ED without any other symptomatology of vascular disease. A prospective study in 50 patients with ED revealed that 19% of them presented silent, asymptomatic CAD, as detected by angiography [17]. Similar results had been previously obtained in 58 patients with ED. In this study, 24.1% of patients were diagnosed with symptomatic or asymptomatic ischemic heart disease, being peak systolic velocity in the cavernous artery a predictive factor of ischemic heart disease in ED patients [18]. ED has also associated to the presence of peripheral atherosclerotic lesions. Among 238 patients with ED, 66.4% presented atherosclerotic lesions, while among 52 age-matched patients without ED lesions were only present in 36.5% of them. An elevated prevalence of femoral (40.3% vs 11.5%) and carotid (25.2% vs 9.6%) plaques was also detected in ED patients [19]. These observations led to consider ED as an early manifestation of generalized vascular disease. ED symptoms were found to precede CAD symptoms in 58 to 67% of the patients [8]. In fact, in patients with chronic coronary syndrome complaining of ED, symptoms appeared prior to CAD detection in 93% of cases [15]. ED is manifested before other signs of vascular disease because penile artery diameter is smaller (1-2 mm) than the coronary (3-4 mm), carotid (5-7 mm) or femoral (6-8 mm) artery, then the symptoms caused by atherosclerosis in penile vasculature appear earlier [20,21]. A plaque with sufficient size to cause the blockage of blood flow through the penile artery and ED, would produce only 30-40% stenosis in arteries of larger diameter [22]. Thus, ED would be a sentinel symptom that warns of a probable underlying systemic vascular disease [23]. This consideration impacts the clinical management of patients presenting
with ED for prevention of potential life-threatening events, especially when other vascular risk factors are present.

The development of animal models of atherosclerosis has provided key evidences demonstrating the marked impact of atherosclerotic vascular disease on erectile function and proposing pathophysiological mechanisms. A rabbit model was firstly developed where atherosclerotic lesions were induced by balloon-deendothelialization of the iliac arteries and feeding a cholesterol- and triglyceride-rich diet. Most of animals (93%) having 50% or greater luminal occlusion of the iliofemoral arteries presented vasculogenic erectile dysfunction [24]. The erectile dysfunction in these animals can probably be ascribed to both a limited iliac blood flow and corporal veno-occlusive dysfunction due to a decreased expandability of the trabecular smooth muscle [25,26]. The authors have later demonstrated in the same animal model that chronic ischaemia provoked by stenosis of the proximal iliac artery is also associated with functional changes in the distal part of the penile vasculature such as decreased NOS activity, reduced endothelium-dependent and neurogenic NO-mediated relaxation in cavernosal tissue [27,28]. NO inhibits endothelial eicosanoid and superoxide production [29]. This observation may explain that in the rabbit model the impaired NO formation is associated also with increased production of contractile thromboxane and prostaglandin formation and potentiation of neurogenic contractions of the cavernosal smooth muscle [27,28]. Further studies demonstrated a time-dependent reduction of the expression of nNOS and eNOS in the cavernosal tissue from these animals, while a parallel increase of the expression of iNOS was also observed [30]. The above-mentioned studies, although extensive are concerned with the combined effect of hypercholesterolemia and ischaemia and do not allow to distinguish the influence of chronic ischaemia alone on the erectile apparatus. However, the reduced NOS activity has been confirmed in a rabbit model of cavernosal ischemia induced by surgical occlusion of iliac arteries [31]. In this model, decreased NOS activity was accompanied by impaired endothelium-dependent and neurogenic NO-mediated relaxation of ischemic cavernosal tissue. An elevation of the cavernosal content of endogenous inhibitors of NOS was proposed to be responsible for these effects [31].

On the other hand, a rabbit model where a long-term (80 weeks) but low-level (0.3%) cholesterol-enriched diet was administrated demonstrated the generation of atherosclerotic lesions without previous de-endothelialization of iliac arteries and the development of vasculogenic ED [32]. However, ED was only manifested in rabbits showing severe atherosclerosis but not in those presenting only moderate atherosclerosis. In fact a significant negative correlation between intima/media ratio of iliac arteries and erectile responses was observed [32]. The apolipoprotein E knockout mouse, a known experimental model of atherosclerosis, develops an impairment of erectile responses at 26 weeks of age (the first age evaluated) after receiving a Western type diet (0.15% cholesterol plus 42% milk fat) starting at 4 weeks of age. This reduction of erectile responses was accompanied of manifested atherosclerotic lesions in the aorta [33]. These mice, fed with 1.5% cholesterol diet, at earlier ages also show reduced endothelium-dependent and endothelium-independent relaxations, and impaired NO/cGMP pathway, while cavernosal tissue presented structural alterations [34].

As mentioned above, hyperlipidemia is a risk factor for ED. Association of ED to hyperlipidemia has been found in several clinical studies. In ED patients, a positive correlation between high LDL and cavernosal venous insufficiency was found [35]. When blood levels of different lipid fractions were determined in 943 patients with ED and 242 patients with no ED aged over 40 years, the incidence of abnormally elevated levels of LDL was significantly higher in patients with ED. There were no differences regarding total cholesterol, triglycerides or HDL but the incidence of hyperlipidemia, defined as more than one elevated lipid fraction, was also significantly higher in ED patients [36]. In a prospective study including 315 patients (215 with ED), logistic regression of data showed that low levels of HDL were predictive of ED, with no significant differences in triglycerides or LDL [37]. However, a case-control study with 100 patients in each arm, revealed a significant increase in total cholesterol and LDL in ED patients [38]. Hypercholesterolemia at baseline was also shown as a predictor of ED 25 years later in 570 patients included in the Rancho Bernardo Study [39], while high incidence of previously undiagnosed hypercholesterolemia (40%) and hypertriglyceridemia (28%) was observed among patients attending consultation for ED [40]. On the other hand, a pilot study showed that patients with pure hypertriglyceridemia displayed ED prevalence values (42.9%) higher than those obtained in men with normal cholesterol (24.2%) or even with pure LDL elevation (29.4%), although the low number of patients precluded a significant result [41]. In contrast, a survey of 1,899 men aged 30-79 in Boston area revealed the absence of association of untreated hyperlipidemia and ED [42]. In conclusion, although several evidences suggest an association of ED and dyslipidemia, there is no consistency in the involvement of the different lipid fractions, and a more precise analysis of this condition as independent risk factor for ED is still required [43].
With respect to a feasible pathophysiological mechanism, hypercholesterolemia appears to have an effect “per se” on the vasculature. Oxidized low density lipoproteins (ox-LDL) inhibit the endothelium-dependent NO-mediated relaxations in rabbit large arteries [44], but this does not appear to be the case in small systemic arteries [45] or the trabecular smooth muscle [46]. In the latter study the lipoproteins did not interfere with the NO/cGMP-pathway, but ox-LDL induced contractions [46], and these contractions are probably mediated through increases in intracellular inositol phosphate and calcium [47]. In contrast, chronic hypercholesterolemia reduces endothelium-dependent relaxations, but not the endothelium-independent relaxations in the corpus cavernosum [48-50]. In contrast to the endothelial NO/cGMP-pathway, the neuronal vasodilation does not appear affected in hypercholesterolemic rabbits [28]. The selective affection of the endothelial NO/cGMP-pathway in hypercholesterolemia could be ascribed to an increased superoxide production [50]. Superoxide could result from enhanced NADPH oxidase activity, since the inhibition of this enzyme improves endothelium-dependent relaxation of cavernosal tissue from rabbits fed with 1% cholesterol for 8 weeks [51]. L-arginine supplementation reverses the impairment of the endothelium-dependent relaxations [28], and this observation supports that increased endogenous production of NOS inhibitors contributes to endothelial dysfunction. In fact, increased plasma levels of asymmetric dimethyl arginine (ADMA), an endogenous inhibitor of NOS, has been detected in rats after 5 months of 2% cholesterol diet. At the same time, these rats displayed erectile dysfunction and systemic endothelial dysfunction [52]. Vascular endothelial growth factor (VEGF) and fibroblast growth factor (FGF) are two key angiogenic factors which promote endothelial cell proliferation and are involved in the processes of endothelial repair and neovascularization after vascular injury. These growth factors also influence NO production. VEGF and VEGF receptor 2 (VEGFR-2) are downregulated in corporal tissue of rats eating a 4% cholesterol diet [53]. mRNA levels of VEGF were also reduced in rabbits fed with 1% cholesterol diet. This reduction preceded the impairment of endothelium-dependent relaxation [54]. The involvement of an unbalance of angiogenic factors in the pathophysiology of hyperlipidemia-induced ED was supported by the improvement of endothelial relaxation of cavernosal tissue from hypercholesterolemic rabbits after intracavernosal administration of VEGF and FGF-2 [55,56]. FGF-2 administration also induced the expression of VEGF as well as increased the expression of nNOS and the phosphorylation of eNOS at Ser 1177 (the most active form) [56]. Gene transfer of VEGF and angiopoietin-1 (other angiogenic factor) restored erectile responses in hypercholesterolemic rats, increasing eNOS phosphorylation and cGMP accumulation in cavernosal tissue [57].

These pathophysiological mechanisms suggest that hypercholesterolemia could alter the NO/cGMP pathway and induce endothelial dysfunction that would result in erectile dysfunction. However, since hypercholesterolemia is used for developing atherosclerosis in animal models, further studies must clarify if these mechanisms are specifically attributed to hypercholesterolemia or to ischemic vascular disease.

On the other hand, the pharmacological treatment of hyperlipidemia with statins was thought to be associated with an increased risk for erectile dysfunction [58,59]. However, in large study with 4444 patients with coronary heart disease treated with simvastatin or placebo for up to 6 years, the frequency of ED was not associated to the treatment with simvastatin [60]. Therefore, in patients treated with statins an underlying diseased vasculature rather than the drug appears the cause of erectile dysfunction. In fact, lipid-lowering therapy in hypercholesterolemic patients improves systemic endothelium-dependent vasodilatation probably due to an increased bioavailability of NO [61,62]. In nine patients with hypercholesterolemia as the only risk factor for ED, the correction of elevated cholesterol levels with atorvastatin improved erectile function [63], while in 25 patients with similar characteristics, combined administration of atorvastatin enhanced the IIEF score increase induced by sildenafil [64]. This suggests that the dysfunction of the endothelial NO/cGMP-pathway in hypercholesterolemia is reversible. However, atorvastatin has been reported to augments the number of patients recovering erectile function after prostatectomy which were also treated with sildenafil. Interestingly, these patients were not hyperlipidemic [65].

IV. HYPERTENSION AND ERECTILE DYSFUNCTION

Hypertension is an independent risk factor for development of erectile dysfunction [3,66,67]. In fact a high prevalence of hypertension has been found in ED patients. The analysis of a representative care claims database identifying 273,325 patients with ED in the US, revealed that the prevalence of hypertension in this ED population was as high as 41.6% [68]. In a further analysis, using a similar approach evaluating 285,436 men with ED and 1,584,230 men without ED, prevalence of hypertension in ED patients was more than twice the prevalence of hypertension in men without ED (41.2% vs 19.2%, respectively) [69]. Conversely, a high prevalence of ED is generally observed in hypertensive patient populations. Although, some former studies reported low presence of ED in hypertensive patients (14.4%) [70] and similar prevalences of ED in normotensive and hypertensive patients [71,72], the majority of the
evidences have revealed an elevated prevalence of ED in hypertensive men from different geographic areas [73-78].

However, hypertension is a risk factor not only for ED but also for cardiovascular disease. Then, the impact of hypertension on erectile function is contributed by the cardiovascular complications following hypertension, such as ischaemic heart disease and renal failure which are associated to even higher prevalence of ED [3,67,79]. Age, body mass index (BMI), hormonal profile, penile arterial flow, risk factors for arterial disease, and the presence of neurological and psychological abnormalities were evaluated in 32 consecutive hypertensive and 78 normotensive impotent men [80]. The overall analysis showed little differences between hypertensive and normotensive men with the exception that hypertensive men had marginally higher rate of ischaemic heart disease (P=0.06) and lower testosterone levels [80]. Other studies have also detected lower levels of serum testosterone in hypertensive patients [81,82], a fact that could be relevant to the development of ED in these patients. In fact, sexual activity correlated with testosterone levels in both hypertensive and normotensive patients [83].

The potential determinants for ED in hypertensive population have been investigated. In a sample of 358 patients with essential hypertension, ED was associated to older age, longer duration of hypertension and a more severe hypertension. ED was also related to the antihypertensive therapy [75]. Other revealed determinants for ED in hypertensive patients (52 with ED and 34 with normal erectile function) were the presence of subclinical atherosclerosis, the impairment of arterial function, systemic inflammation and higher levels of the endogenous inhibitor of eNOS asymmetric dimethylarginine (ADMA) as a possible marker of endothelial dysfunction [84].

Blood pressure control is tuned by key physiologic systems that act at central and peripheral levels and involve CNS pathways, hemodynamic processes, hormones, neurogenic factors and vascular factors. Hypertension likely results from alteration or disbalance of any of these processes. Since pathways controlling blood pressure are also key for erectile physiology, the alteration resulting in hypertension could also results in ED.

Experimentation with animal models of hypertension has brought light to the mechanisms related to ED in hypertension. Erectile function, evaluated by measuring intracavernosal pressure expressed as percentage of mean arterial pressure (MAP), which is the usual way to express erectile responses in animal models, was reported to be decreased in stroke prone-spontaneously hypertensive rats (SHR-SP) and DOCA-salt hypertensive rats, although the absolute increases in intracavernosal pressure did not appear very different [85,86]. Other studies showed ICP tracings that reveal moderately reduced ICP increases to cavernosal nerve stimulation in spontaneous hypertensive rats (SHR). These responses were markedly inhibited in SHR after normalization by MAP [87,88]. SHR also presented reduced endothelium-dependent relaxation and NO-donor-induced relaxation of cavernosal smooth muscle, being the impairment of endothelial relaxation mediated by prostanoïd products [87]. The longitudinal study of erectile responses in SHR rats showed that the reduction of ICP/MAP responses preceded the development of hypertension. This study also revealed that cavernosal endothelium-dependent and NO-donor-induced relaxations occurred before systemic vascular alterations were manifested [88]. This suggests that erectile tissue is at the front line of the development of endothelial dysfunction and would be an early target end organ.

Neurogenic relaxation of cavernosal tissue could also be affected by hypertension since these responses have been reported to be reduced in SHR. This impairment would involve not only a reduction of NO-mediated relaxation but also a reduced relaxation mediated by carbon monoxide neurotransmission [89]. Treatment of SHR with several anti-hypertensive agents improved neurogenic relaxations. Amlodipine enhanced NO-mediated relaxation and NO-derivatives and cGMP in cavernosal tissue after electrical field stimulation (EFS), while hydralazine potentiated CO-mediated relaxation [90]. However, both NO- and CO-mediated neurogenic relaxations were enhanced by treating SHR with the antioxidant, α-tocopherol. The antioxidant caused an increase of EFS-induced cGMP accumulation in cavernosal tissue but also produced an improvement of endothelium-dependent relaxation [91]. This suggests that oxidative stress may play a significant role in the alterations caused by hypertension on erectile function. In fact, an augmented production of superoxide anions could result from increased activity of NADPH-oxidase driven by angiotensin II [92].

In addition to these functional alterations of erectile physiology, it has been revealed that hypertension also induce structural modifications of erectile tissue. SHR show hyperproliferation of smooth muscle in cavernosal tissue and penile vasculature, which correlates with blood pressure values. Increased fibrosis was also observed [93]. Ultrastructural studies of cavernosal tissue of SHR also revealed mitochondrial damage in smooth muscle and endothelial cells and neurodegeneration [94]. Hypertension-induced alterations were improved after antagonism of type 1 angiotensin II receptors (AT1) [95,96]. AT1 blockade was also related with increased endothelial nitric oxide expression in sinusoidal endothelium [97]. In fact, the impact of hypertension on erectile structures is effectively prevented by long-term administration of sildenafil only when combined with an AT1 blocker. This combined treatment also improved
with more efficacy the endothelium-dependent relaxation of cavernosal tissue in SHR [98]. The interaction of PDE5 inhibition and the inhibition of renin angiotensin system has also been demonstrated in the renal vasculature of SHR [99]. Although the blockade of β1-adrenergic receptors with atenolol did not prevent hypertension-induced alterations of penile structures [95], other selective β1-blocker, nebivolol, reduced smooth muscle proliferation and collagen deposition in penile tissue of SHR and improved endothelial relaxation [100]. Nebivolol has been demonstrated to cause NO-dependent vasodilation [101] and augment NO production in corpus cavernosum in mice [102]. These results suggest that the alterations caused by hypertension in erectile structures of SHR would be related to increased angiotensin II and reduced NO availability, although confirmation in other models of hypertension should be required.

V. CIGARETTE SMOKING AND ERECTILE DYSFUNCTION

Among the risk factors shared by both cardiovascular disease and ED, cigarette smoking should also be considered. It has been clearly demonstrated that cigarette smoking is significantly and independently associated to coronary heart disease, including death [103-106]. In fact, the Framingham Heart study showed that cardiovascular mortality in men increased by 18% for each 10 cigarettes smoked daily, and smoking exerts a synergistic effect with other risk factors for favouring coronary artery disease [107]. On the other hand, cigarette smoking is also clearly related to ED. In the Massachusetts Male Aging Study (MMAS) smoking was not directly associated with ED but potentiated the likelihood of ED associated to other risk factors [3]. A follow-up of this study revealed that the smokers were more likely to have moderate or severe ED than non-smokers (OR 1.97) after adjusting by age and other covariates [72]. It was also revealed that passive smoking increased ED incidence [72]. Other studies showed both an increased prevalence of ED among smokers as well as a higher number of smokers among ED patients [11,108-110]. Although less markedly than active smokers, passive smokers seem to be at higher risk for ED than men not exposed to smoke, and the risk increases as the exposure increases [72,111]. However, since smoking is a determinant for vascular disease, its effects on ED could be due to the vascular damage. Although, some studies support this hypothesis [112,113] other studies suggest that smoking is associated to ED independently of cardiovascular disease [114,115]. In a large population of Chinese men without cardiovascular disease, smoking was still associated to ED [116].

These cross-sectional studies do not allow for establishing a causative effect of smoking in ED, however, a dose-response, i.e. the relative risk for ED increases as the number of cigarettes smoked increase, is shown in several studies [114-117]. The reversibility of the risk by removing the exposure to smoke is a key component in a possible causality. Some reports showed increased risk for ED in former smokers than in never smokers [114,118] although the relative risks trend to be lower than that in current smokers [108,112]. Erectile function improved in 25% of patients with ED 1 year after quitting tobacco smoking, while none of the men who continued smoking showed improved erectile function [119]. In fact, a significant improvement in nocturnal penile tumescence and rigidity was observed in 10 heavy smokers after 24 hours of smoking cessation [120]. These results are supported by recent demonstration of a significant improvement in penile end-diastolic velocity in 20 smoker patients with ED 24-36 hours after they ceased from smoking [121].

For considering that cigarette smoking may cause ED, plausible biological-pathophysiologic mechanisms should be provided. In this sense, smoking induces endothelial dysfunction. Cigarette smoking has been shown to induce an impairment of systemic endothelium-dependent vasodilation [122-124] and reduce NO biosynthesis [125]. The impact of smoking on vascular NO/cGMP pathway is supported by the reversion of acute smoking-induced endothelial dysfunction by sildenafil [126]. NO/cGMP pathway has shown to be affected also in cavernosal tissue. A reduction of penile NOS activity was observed after passive smoking in rats, although erectile responses were not reduced. In this study, decreased expression of penile nNOS was also reported while eNOS expression was unaffected [127]. These results are consistent with the significant reduction of nNOS, but not eNOS, expression in rabbit cavernosal tissue after administration of cigarette smoking extract in vitro. Cigarette smoking decreased NOS activity and cGMP content in cavernosal tissue, probably due to the induction of an elevated activity and expression of arginase together with an increase of the content of the endogenous NOS inhibitor, ADMA [128]. Cigarette extract has also been shown to inhibit neurogenic relaxation of mouse corpus cavernosum [129]. Mice exposed to cigarette smoke for 3 weeks presented a reduction of erectile responses to cavernosal stimulation or acetylcholine administration. While penile constitutive NOS and PKG activities were reduced, superoxide production and inducible NOS activity were increased leading to an elevated peroxinitrite generation [130]. Oral administration of a PDE5 inhibitor to smoke exposed mice augmented penile constitutive NOS activity while reduced inducible NOS activity and superoxide formation, then decreasing penile peroxinitrite. This resulted in improved erectile responses [130]. Thus, cigarette smoking would be related to down-regulation of NO/cGMP pathway in penile tissue, probably related to increased oxidative stress [129,130]. On the other
hand, acute nicotine administration caused a significant reduction of physiological erectile responses to erotic films in healthy non-smoker men [131], an effect that could be related to an increase of vascular constriction by stimulation of peripheral sympathetic nerves [132], although nicotine has been shown to alter vascular endothelium-dependent relaxation [133].

VI. PATHOPHYSIOLOGICAL MECHANISMS IN VASCULAR ERECTILE DYSFUNCTION

Arterial vasodilatation and relaxation of the corpora cavernosa play a pivotal role for penile erection, and therefore impaired neurogenic or endothelium-dependent relaxation of erectile smooth muscle will be expected to result in erectile dysfunction. The key mediator of penile smooth muscle relaxation is NO. As above described, vascular disease is clearly related to reduced availability of NO in erectile tissue, compromising the adequate smooth muscle relaxation and hence penile erection.

In addition to impaired relaxant pathways, an increase in production/activity of factors driving penile smooth muscle contraction would antagonize vascular and cavernosal relaxation and therefore would difficult erectile function. While the impairment of relaxation of penile smooth muscle is constantly found in association with vascular ED, the presence of augmented contraction is not a constant in this situation. However, evidences exist addressing this issue.

Finally, the continuous presence of vascular dysfunction would result in the alteration of vascular and cavernosal erectile structures hindering the arterial supply and the corporo-veno-occlusive mechanism.

1. INCREASED VASOCONSTRICTION

Enhanced basal and myogenic tone has been observed in arteries from hypertensive rats [134]. It is unclear whether enhanced myogenic constriction reflects a primary pathological defect contributing to the hypertensive state or a secondary adaptative process protecting the exchange vessels from elevated pressures [135]. Although, the role of myogenic tone in the penile vasculature for erection remains to be clarified [136], the increased vasoconstriction could contribute to decreased arterial inflow and erectile response in renal hypertensive rats.

Contractile activity of smooth muscle is triggered by intracellular calcium concentration increase but calcium sensitizing pathways allow the maintenance of contractile tone after the decay of calcium concentration. The RhoA/Rho kinase pathway plays an important role in calcium sensitization and tonic contraction of smooth muscle. Cardiovascular diseases are associated with an enhancement of RhoA/Rho kinase activity [137]. Hypercholesterolemia induces calcium sensitization of smooth muscle cells in humans and
Endothelin-1 (ET-1) is a potent endogenous vasoconstrictor released by endothelial cells. ET-1 induces contraction and proliferation of smooth muscle by acting on endothelin-A (ET$_A$) receptors. In contrast, endothelial ET$_A$ receptors promote NO synthesis and vasodilation. ET-1 levels are elevated in plasma from patients with atherosclerosis, hypertension and hypercholesterolemia [146-148]. Studies with ET$_A$ receptor antagonists suggest an increased activity of endogenous ET-1, at least in hypertensive patients, contributing to enhanced vascular resistance [149]. An increased activity/production of ET-1 could also antagonize erectile process. Patients with organic ED show higher venous and cavernosal ET-1 levels [150]. Enhanced responses to ET-1 in corpus cavernosum of DOCA-salt hypertensive mice have been reported [151] while in cavernosal tissue from DOCA-salt hypertensive rats the expression of ET$_A$ receptor was augmented, contractile responses to ET-1 were increased and relaxation caused by ET$_A$ activation was reduced [152]. A decrease in ET$_A$ receptors in cavernosal tissue from hypercholesterolemic rabbits was also detected [153]. Although these evidences would point to a pathophysiological role of ET-1 in vascular ED, preliminary evaluation of an ET$_A$ receptor antagonist on the treatment of ED yield no positive results [154].

Angiotensin II (Ang II) is the final effector of renin-angiotensin system (RAS). Exerts its actions via type 1 (AT1) and type 2 (AT2) receptors. AT1 receptors mediate smooth muscle contraction and proliferation. Both circulating and tissue Ang II are important modulators of vascular physiology. There is evidence of the existence of tissue RAS in the penis. Ang I and Ang II were detected in the human corpus cavernosum endothelial and smooth muscle cells [155]. AT1 receptors are expressed in rabbit cavernosal endothelium and smooth muscle [156] and Ang II causes contraction of human corpus cavernosum in vitro [157]. An elevation of Ang II levels as probably occurs in hypertension would negatively impact erectile tissue relaxation and erectile function. ACE expression has been shown to be up-regulated in rats with arteriogenic ED [158]. In fact, administration of an AT1 antagonist has been shown to improve erectile function in hypertensive patients with metabolic syndrome [159], although the long-term administration of an angiotensin-converting enzyme (ACE) inhibitor improved cavernosal perfusion in atherosclerotic ED patients but this improvement was not significantly different from placebo [160].

2. IMPAIRED NEUROGENIC VASODILATATION

Impaired neurogenic relaxation was observed in a rabbit model of cavernosal ischemia [31] while was unaffected in a rabbit model of hypercholesterolemia [28]. As mentioned above, NO and CO contribute to neurogenic relaxation of rat cavernosal tissue and both components are reduced in SHR [89]. Immunohistochemical and functional studies of isolated penile small arteries indicate that NO is the main neurotransmitter mediating these non-adrenergic non-cholinergic relaxations to electrical field stimulation [161-163]. In penile arteries from renal hypertensive rats (one-kidney, one-clip model) neurogenic relaxation of rat cavernosal tissue and corpus cavernosum of DOCA-salt hypertensive mice have been reported [151] while in cavernosal tissue from DOCA-salt hypertensive rats the expression of ET-1 precursor was augmented, contractile responses to ET-1 were increased and relaxation caused by ET$_A$ activation was reduced [152]. A decrease in ET$_A$ receptors in cavernosal tissue from hypercholesterolemic rabbits was also detected [153]. Although these evidences would point to a pathophysiological role of ET-1 in vascular ED, preliminary evaluation of an ET$_A$ receptor antagonist on the treatment of ED yield no positive results [154].

Angiotensin II (Ang II) is the final effector of renin-angiotensin system (RAS). Exerts its actions via type 1 (AT1) and type 2 (AT2) receptors. AT1 receptors mediate smooth muscle contraction and proliferation. Both circulating and tissue Ang II are important modulators of vascular physiology. There is evidence of the existence of tissue RAS in the penis. Ang I and Ang II were detected in the human corpus cavernosum endothelial and smooth muscle cells [155]. AT1 receptors are expressed in rabbit cavernosal endothelium and smooth muscle [156] and Ang II causes contraction of human corpus cavernosum in vitro [157]. An elevation of Ang II levels as probably occurs in hypertension would negatively impact erectile tissue relaxation and erectile function. ACE expression has been shown to be up-regulated in rats with arteriogenic ED [158]. In fact, administration of an AT1 antagonist has been shown to improve erectile function in hypertensive patients with metabolic syndrome [159], although the long-term administration of an angiotensin-converting enzyme (ACE) inhibitor improved cavernosal perfusion in atherosclerotic ED patients but this improvement was not significantly different from placebo [160].

3. ENDOTHELIAL DYSFUNCTION

Impaired endothelium-dependent vasodilation has been demonstrated in patients presenting cardiovascular risk factors and diseases (diabetes, hypertension, hyperlipidemia, hyperhomocysteinemia, smoking...) [165] and the presence of endothelial dysfunction in the coronary circulation of hypertensive patients can predict major cardiovascular events [166]. Coronary endothelial dysfunction has also been associated to the presence of ED in patients with early atherosclerosis but without obstructive coronary arterial disease [167]. Other studies
have demonstrated the association of systemic endothelial dysfunction to ED. These studies determine the endothelium-dependent flow-mediated dilation (FMD) of the brachial artery by measuring arterial diameter after reactive hyperemia using an ultrasound system. In the absence of CVD, 27 men without ED and 30 patients with ED were compared. FMD was significantly reduced in ED patients, although nitroglycerine (NTG)-induced dilation was also impaired [168]. Patients with vascular risk factors but no ED (n=40) had reduced FMD with respect to control subjects (n=25). However, when ED was present in addition to vascular risk factors (n=40), FMD was significantly further reduced. These patients also showed reduced NTG-induced dilation [169]. In 56 patients with ED of different severities but without CVD or other diseases, the impairment of FMD correlated to the severity of ED. The patients with severe ED presented more reduced FMD of the brachial artery [170]. Recently, using an especially adapted plethysmography system, endothelium-dependent dilation in the penis has been assessed. Among 59 patients without overt CVD, 40 had ED and the other 19 were taken as controls. Patients with ED had reduced basal penile blood flow and increased penile vascular resistance. Moreover, endothelium-dependent penile blood flow increases generated by reactive hyperemia were reduced in patients with ED. At the same time, endothelial function in the forearm vasculature was not significantly altered in ED patients [171].

In addition to the impairment of endothelium-dependent dilation, ED is also associated to other manifestations of endothelial dysfunction. In 141 analyzed patients, those patients with coronary artery disease showed increased levels of inflammatory and prothrombotic markers. However, patients with ED having or not coronary artery disease presented higher values than patients without ED [172].

4. PENILE STRUCTURAL ALTERATIONS

Objective reduction of smooth muscle cells has been demonstrated in patients with organic erectile dysfunction [173]. PGE1 and PGE2 formation is oxygen-dependent and increasing oxygen tension is associated with a rapid increase in unstimulated PGE2, followed by suppression of TGF-ß-induced fibrillar collagen synthesis in the rabbit and human corpus cavernosum and vice versa [174-176]. A decrease in cavernous trabecular smooth muscle and an increase in connective tissue are correlated...
with diffuse venous leakage and a failure of the venoocclusive mechanism, hence resulting in erectile dysfunction [26,177,178]. Therefore, arterial insufficiency followed by diminished oxygenation of corpus cavernosum, decreased PGE$_2$ production, and increased fibrosis play a role in erectile dysfunction [179]. Structural changes of the arterial and erectile tissue would result in increased resistance of the penile vasculature [180]. These structural alterations could contribute to the development of corporo-venoocclusive fail in hypertension. Thus, the increased vascular resistance in penile arteries and structural remodelling of cavernosal tissue would participate in the pathophysiology of vascular ED.

5. IN CONCLUSION

The presence of cardiovascular risk factors would cause functional impairments of penile vascular and cavernosal tissue, mainly affecting endothelium-dependent relaxation and also neurogenic relaxation. The endothelial dysfunction is probably accompanied by a reduced capacity of endothelial repair and regeneration associated to cardiovascular diseases, which exacerbates the functional impairment. This situation causes an alteration of penile vascular and cavernosal structures that also contributes to erectile failure. Reduced NO availability by enhanced ROS production or by NOS inhibition would be responsible for functional, and even structural anomalies, although other mechanisms such as increased vasoconstriction (ET-1, Ang II, Rho kinase) would participate in these alterations. Further research is required for evaluating the contribution of modified activity of hyperpolarizing factors and membrane ion channels in vascular ED. In addition, studies regarding the impact of cardiovascular disease on penile resistance arteries are still sparse.

A range of studies suggest that erectile dysfunction (ED) is predominantly a vascular disorder caused by endothelial dysfunction [1-2]. It is notable that ED and cardiovascular diseases share considerable risk factors such as hypertension, hypercholesterolemia, diabetes, obesity, depression and cigarette smoking [3]. Given that ED has been there long before the first onset of cardiovascular diseases (CVD), ED may be an early clinical marker of subclinical systematic vascular disease and increased cardiovascular risks [4-6]. This recognition of ED as an early marker for cardiovascular disease may provide a good therapeutic opportunity for ED patients who have cardiovascular risk factors (CRFs) at an early stage. The bridge between ED and CVD is endothelial dysfunction which is a common pathophysiologic process of both conditions [6]. This chapter will discuss the important role of endothelial dysfunction in connecting ED with CVD. Moreover, this chapter involves the issues of endothelial dysfunction as a diagnostic and therapeutic standard for ED and CVD.

1. THE PREVALENT RATES OF CARDIOVASCULAR DISEASES OR CARDIOVASCULAR RISK FACTORS IN MEN WITH ED.

Massachusetts Male Aging Study [7] investigated the sexual quality of 1,290 healthy men aged between 40 and 70, and found that 52% of interviewees complained certain degrees of ED. This study reported age as a risk associated with the incidence of ED. Moreover, ED was connected closely with heart diseases, hypertension, diabetes and dyslipidemia. The results have attracted the attention that ED is likely to be a common condition in men with CVD or CRFs. Similarly, American/European Men’s Attitudes to Life Events and Sexuality (MALES) Study [8] showed that prevalent rates of CRFs such as diabetes and hypertension significantly increased in men with ED compared to those without. Brant A, et al. [9] has explored the association between ED and risk of coronary artery disease (CAD). 1402 community-dwelling men with regular sexual partners and without known CAD were screened biennially for the onset of ED and CVD. The incidence of CAD was significantly higher in men with ED than those without. In Kew-Kim Chew’s study [10], postal questionnaires were sent out randomly to 1,580 participants. The results showed that cardiovascular risks or diseases were more prevalent among aging participants with ED and severe ED.

2. THE INCIDENCE OF ED IN MEN HAVE CARDIOVASCULAR DISEASES OR WITH CARDIOVASCULAR RISK FACTORS.

Kloner RA, et al [11] carried out a Sexual Inventory through questionnaire and showed that 75% men with chronic stable coronary artery diseases had certain degrees of ED, among which the percentage of severe ED was 25%. This suggested that ED was a common condition in men with stable coronary disease. European and North, Central and South American participating MALES Study investigated the prevalence of ED in 27,839 men aged 20-75 [12] and demonstrated that ED was more prevalent among men with cardiovascular risk factors than those without. These CRFs included diabetes, hypertension, angina and high cholesterol. In Chew’s study [10], postal questionnaires were sent out randomly to age-stratified male population. ED was significantly more prevalent among participants with hypertension, ischemic heart diseases, stroke and peripheral arterial diseases.

These findings suggest that ED has tight connection with CVD and CRFs. Men with ED are more likely to have cardiovascular diseases or cardiovascular risks such as obesity, diabetes mellitus, hypertension, and dyslipidemia than those without. Accordingly, the prevalent rates of ED increase in men with cardiovascular diseases or cardiovascular risks [13].

Endothelium, producing several signaling molecules which have the effect of promoting vasodilation, inhibiting platelet aggregation and antibiosis, is a major regulator of vascular homeostasis [14]. Endothelial dysfunction, characterized by impairment of nitric oxide synthesis, altered anticoagulant, anti-inflammatory and vascular remodeling properties, could increase the permeability of vessels to plasma constituents (such as low-lipoproteins) and affect endothelium dependent vasodilatation. Endothelial dysfunction which contributes to the development of atherosclerosis [14] is a common characteristic of vascular diseases such as ED and CAD.
II. ENDOTHELIAL DYSFUNCTION AND CARDIOVASCULAR DISEASES

Atherogenesis, with endothelial dysfunction as its character, is the common pathophysiological basis of many CVD [15]. The process of atherogenesis can be divided into several steps. Endothelial dysfunction is the first stage of atherosclerosis during which patients have normal vascular imaging of vessel wall but abnormal vasodilation [16]. The last step of atherosclerosis is characterized by obstructive vascular changes, which would lead to symptomatic cardiovascular diseases. Endothelial dysfunction is also important at the late stage of atherosclerosis by changing compositions of plaque and influencing plaque stability [17]. Based on its important role in the development of atherogenesis, endothelial dysfunction could be crucial in diagnosis, treatment and prognosis of CAD. It has been found that endothelial dysfunction can be used to predict long-term coronary events in patients with or without symptomatic CAD [18]. Treatment of endothelial dysfunction associated cardiovascular risks or vascular conditions, such as hypertension, hypercholesterolemia and obesity have been proved to improve the prognosis of CAD [19].

III. ENDOTHELIAL DYSFUNCTION AND ED

Endothelial dysfunction, characterized with deficient synthesis, release, and activity of vasodilatation mediators from the vascular endothelium, would result in impaired ability to maintain penile erection, culminating in ED [20]. Recent studies suggest an intimate association between endothelial dysfunction and ED [21].

1. THE ROLE OF ENDOTHELIAL FUNCTION IN PHYSIOLOGY OF ERECTION

The penis consists of two corpus cavernosa and one corpus spongiosum that surrounds the urethra. The main blood supply of penis is from the dorsal and cavernous arteries, while venous return occurs mainly through superficial dorsal veins and deep dorsal vein. Erection tissue is characterized by abundant irregular sinusoids which connect with each other. There are plenty of trabecularms consisting of abundant smooth muscle fiber among the sinusoids. Actually, penis is a vascular organ, and penile erection is a vascular event.

Penile erection is a complex and coordinated process, which is the result of series of events involving sexual stimulation, neural conduction and endothelium responses. Vascular endothelium lining the cavernous sinus plays a key role in the physiology of erection through synthesis of vascoactive mediators, particularly NO. Briefly, responding to sexual stimulation, NO is released from vascular endothelium of corpus cavernosa as well as cavernous nerve terminals under the catalysis of eNOS (endothelial nitric oxide synthase, eNOS) and nNOS (neuronal nitric oxide synthase, nNOS). NO activates guanylyl cyclase in penile smooth muscle cells which increases the concentration of cyclic guanosine monophosphate (cGMP). The elevated concentration of cGMP results in relaxation of both arterial and trabecular smooth muscle cells which rises penile blood flow and enlarges the sinusoidal spaces. The process of erection is accomplished when the penile venous outflow are occluded as the intercavernous pressure rises [22].

2. THE ROLE OF ENDOTHELIAL DYSFUNCTION IN THE DEVELOPMENT OF ED

Erectile dysfunction in men is mostly vasculogenic [23, 24]. Endothelial dysfunction is a key process in the development of ED. Vascular cell adhesion molecule-1 (VCAM-1), soluble intercellular adhesion molecule-1 (sICAM-1), endothelin-1 (ET-1) and P-selectin are markers of endothelial cell activation. Bocchio et al. [25] compared these circulating markers among patients with ED but without CRFs, patients with both ED and CRFs and healthy controls. This study demonstrated that markers of endothelial cell activation were significantly higher in patients with ED than those healthy subjects. Similarly, El傍 er et al. [26] investigated endothelial function in patients with ED, and found that patients with endothelial dysfunction had both significantly impaired erectile function evaluated by International Index of Erectile Function-5 (IIEF-5) and higher asymmetric dimethyl L-arginine (ADMA) plasma levels which is a marker of endothelial dysfunction. De Angelis L et al.[27] found that both blood pressure and platelet aggregation, which were both markers of endothelial function, were significantly reduced in men with ED compared with those without.

Similar with serum markers, physical assessment of endothelial function also changes in ED patients. Kaiser et al. [28] assessed vasodilation in patients with vasculogenic ED. Brachial artery flow-mediated dilation and vasodilation to nitroglycerin were significantly lower in patients with ED, compared to those in healthy controls. Similarly, Kaya et al. [29] demonstrated that endothelial-dependent brachial artery flow-mediated vasodilation and endothelial-independent vasodilation to nitroglycerin were lower in patients with ED than those without.

Endothelial dysfunction is a common character of vascular diseases including ED and CVD. It is believed that ED is one manifestation of systemic endothelial dysfunction. Patients with ED but no symptom of clinical cardiovascular diseases may have a peripheral vascular defect in endothelial-dependent
vasodilation. Therefore, it is easier to diagnose or evaluate the severity of ED condition through endothelial function assessment.

**IV. ED AND CVD: ED COULD BE A PREDICTOR OF CVD**

ED and cardiovascular disease have a common pathological basis—endothelial dysfunction. Furthermore ED and cardiovascular diseases share a lot of common risk factors. A good deal of data indicate that many patients with cardiovascular disease have symptoms of ED. Prostate Cancer Prevention Trial (PCPT) demonstrated that the onset of ED was a significant predictor of subsequent cardiovascular events [30]. ED is the most effective predictive factor for coronary artery disease in patients with diabetes [31]. The issue is whether ED can be an effective clinical predictor of cardiovascular diseases.

**1. EVIDENCES THAT ED PRECEDES CARDIOVASCULAR EVENTS**

It has been demonstrated that ED and CVD share common risk factors.

These risk factors are mainly asymptomatic at their early stages. Take coronary heart disease and type 2 diabetes for examples. Approximately 50% of men who suffered from coronary heart disease or died suddenly, showed no previous symptoms before death [32]. And type 2 diabetes cannot be diagnosed until 4-7 years after its initial onset [33]. Therefore, it is not easy to diagnose CVD or CFRs at an early stage. However, irreversible vascular damages probably have already existed for years before the occurrence of obvious symptom of CVD or CFRs [34]. ED as one manifestation of systemic vascular disease can be an ideal marker for diagnosis of CVD or CFRs at their early stages.

Various findings suggest that there is a close relationship between ED and CAD, and ED precedes cardiovascular events at least 2-3 years. Montorsi et al. [35] investigated the relationship between ED and acute coronary syndrome, and revealed that 99 patients out of 147 men presenting with acute coronary syndrome had experienced event ED approximately 3 years prior to the onset of acute coronary syndrome. The report of COBRA (association between erectile dysfunction and coronary artery disease) further proved this point. 93% of patients with a chronic ED syndrome complained ED symptoms before the onset of CVD with a mean interval of 24 months.

**2. MECHANISM THAT ED COULD BE A CLINICAL MARKER OF CVD**

A high prevalence of ED has been reported in men with CVD. The fact that ED and cardiovascular diseases share numbers of common risk factors, leads to the clinical consensus that most cases of ED are probably part of the spectrum of CVD [36]. The mechanisms that ED could be a clinical marker of CVD include vascular beds of corpus cavernosum, blood vessel sizes of dorsal artery and endothelial dysfunction.

**a) Vascular bed of corpus cavernosum**

Penis with relatively higher content of endothelium and smooth muscle than any other organs of the body is actually a vascular organ. It is more vulnerable to the changes of oxidative stress and systemic NO which is also the main etiological factor for systemic vascular diseases including CVD. Therefore, the penile vascular bed may be a sensitive indicator of systemic cardiovascular diseases [37].

**b) Blood vessels size of penis arteries**

Penile arteries, which are typically 1 to 2 mm in diameter, are narrower than the coronary arteries (3-4mm) [38], so that they are more vulnerable to the atherosclerosis and endothelial dysfunction. The blood flow of penis would be restricted sooner by the development of atherosclerosis process than those of heart and other organs [39, 40]. Relatively, it needs to form a greater plaque burden to restrict coronary blood flow and lead to heartstroke. Therefore, the atherosclerosis process may manifests as symptom of ED before the symptom of coronary artery disease. This artery size/lumen occlusion theory is the most common hypothesis adopted to explain the reason why ED occurs before clinical cardiovascular diseases [41].

**c) Endothelial dysfunction**

The other mechanism connects between ED and CVD is endothelial dysfunction which is one of the earliest changes of the spectrum of atherosclerosis [42, 43]. Endothelial dysfunction is a manifestation of malfunction of vascular endothelial cells, which is caused by cardiovascular risks including hypertension, dyslipidemia, diabetes, cigarette smoking and other noxious factors such as inflammation and infection. Angina would not occur until occlusion of coronary artery formed by atherosclerosis. Functional ED caused by endothelial dependent/independent smooth muscle relaxation, probably occurs before the development of structural, occlusive penile arterial disease and also before the symptom of angina. Therefore, ED may be one of the first signs of systemic vascular diseases [44].

**3. CORRELATION BETWEEN SEVERITY OF ED AND EXTENT OF CVD**

As mentioned above, ED could be a predictor of silent CVD. This section will discuss the relationship between severity of ED and extent of CVD. In a questionnaire-based study of male patients with ischemic heart diseases, patients’ penile erection conditions (through IIEF-5) and numbers of vascular lesions (through angiography) were recorded.
Interestingly, patients with one-vessel disease had significantly better sexual life compared with patients with multi-vessel diseases [45]. Similarly, the Association between erectile function and coronary artery disease (COBRA) [46] demonstrated severe ED (IIEF-5 score <10) was evidently more frequent in patients with multi-vessel disease than those with one-vessel disease. ED usually precedes cardiovascular events at least 2-3 years. However the time intervals between the onset of ED and CVD in patients with single vessel disease were longer than those with multi-vessel disease [46].

These findings suggest that there is a close association between the severity degree of ED and of coronary artery atherosclerosis. That is, the severity of ED is correlated with the extent of CVD. Patients with severe ED are more likely to have multi-vessel CVD than those with mild or moderate ED. The severity degree of ED can reflect the degree of vessel atherosclerosis.

It is apparent that ED could be the effective clinical marker of CVD. The close association between ED and CVD illustrates the implication that once the diagnosis of ED is established, patients with ED should be recommended to undergo a full medical screening for CVD or CRFs, especially endothelial dysfunction. Then, how about the clinical assessment of endothelial functions?

V. ASSESSMENT OF ENDOTHELIAL DYSFUNCTION

Since ED can be a clinical marker of cardiovascular risks or silent cardiovascular diseases. Patients with ED are recommended to take an assessment of risk factors for cardiovascular risks. Risks like smoking, hypertension, dyslipidemia, diabetes, obesity and secondary lifestyle, should be identified by history taking, physical tests and appropriate laboratory tests.

Endothelial dysfunction is the first step of atherosclerosis generation [47], and can be demonstrated in patients with the cardiovascular risk factors [48, 49]. However, specific markers for endothelial dysfunctions are yet to be established.

1. PHYSIOLOGIC ASSESSMENT OF ENDOTHELIAL FUNCTION.

Endothelial function can be assessed through physiological methods such as Flow-mediated dilation of the brachial artery and Peripheral arterial tonometry measuring reactive hyperemia.

a) Flow-mediated dilation of the brachial artery

Flow-mediated dilation (FMD) of the brachial artery is the most popular assessment of endothelial function [50]. FMD-reflected endothelial function is relative to coronary endothelial function [51] and cardiovascular risk factors [52]. And many recent studies suggest that FDM also has association with ED. Chiurla et al. [53] demonstrated worse FMD in men with ED, as opposed to better FDM in men without ED. Kaiser et al. [28] has similar finding in 30 men with ED and without manifestation of CVD.

Briefly, patients’ arms is occluded with a blood pressure cuff for 5 minutes and subsequently released. Endothelium-dependent vasodilation can be quantified by ultrasound. The mechanism of this test is that arterial occlusion and subsequent release can lead to reactive hyperemia and local endothelial activation.

b) Peripheral arterial tonometry measuring reactive hyperemia.

Peripheral arterial tonometry measuring reactive hyperemia (RH-PAT) is a more recent method of assessing endothelial function. RH-PAT has been verified to correlate well with coronary endothelial function and has extensively relation to early CAD (coronary artery disease, CAD) [54-56]. Chouraqui P et al. [57] investigated RH-PAT in patients with myocardial ischemia, and found that RH-PAT results were significantly impaired in patients with exercise-induced myocardial ischemia.

RH-PAT is a 15-minute noninvasive assessment that can be performed in an office setting. Briefly, patients’ upper arm is occluded by a blood pressure cuff to induce reactive hyperemia. And endothelial function can be quantified by a finger probe to assess digital volume changes accompanying pulse waves [58]. Compared with FMD, RH-PAT has the same function in reflecting peripheral endothelial function [59]. And RH-PAT is particularly useful in reflecting cardiovascular risk factors such as diabetes [60, 61] and metabolic syndrome [62].

2. SERUM BIOMARKER OF ENDOTHELIAL DYSFUNCTION

Endothelial dysfunction has been considered as a major cause of ED, even in patients without evidence of organic vascular disease. However, specific serum markers for endothelial dysfunction are yet to be established. Some serum markers that can be used to assess endothelial function are listed.

a) Endothelin-1 (ET-1)

ET-1, a vasoconstrictor and pro-inflammatory factor, is normally secreted from endothelial cells [63]. It has been verified that the blockade of ET-1 receptor leads to improved endothelial function which increases availability of NO. Therefore, ET-1 is a serum marker associated with endothelial dysfunction [64].

b) Asymmetrical dimethylarginine (ADMA)

ADMA is an analogue of L-arginine and a competitively inhibitor of NOS [65]. High plasma level of ADMA reflects impaired endothelial function [66]. Furthermore, it has been shown to be a predictor of
cardiovascular events. Therefore, ADMA is a link between ED and CVD [67].

c) C-reactive protein (CRP)

As an inflammatory factor, C-reactive protein (CRP) has extensively connection with endothelial dysfunction, cardiovascular events and ED [68, 69]. Elevated plasma CRP level has been found to significantly correlate with vascular ED diagnosed by penile Doppler [70]. CRP can be used to assess endothelial function.

d) Cellular adhesion

Markers of cellular adhesion, such as E-selection [71], intercellular adhesion molecule-1 (ICAM-1) [72, 73] and vascular cell adhesion molecule-1 (VCAM-1) [74] have been verified to have connection with endothelial dysfunction and increased risk of CVD.

e) Transforming Growth factor-beta 1

It is believed that the plasma level of Transforming Growth factor-beta 1 (TGF-beta 1) is a diagnostic indicator of vascular disease [75]. Seong et al. [76] investigated the plasma level of the TGF-beta 1 in 62 patients with ED, and demonstrated a significant elevation compared with the control group and a more significant elevation in patients with vasculogenic ED.

f) Endothelial dysfunction inductor protein (EDIP)

Lopez et al have investigated a peculiar protein called endothelial dysfunction inductor protein which can cause endothelial lesions when activated or upregulated [77]. EDIP reduces the expression of endothelial nitric oxide synthesis and shortens the messenger RNA’s half-life [78] through interaction with the endothelial nitric oxide synthesis (eNOS). EDIP can be detected in periphery blood mononuclear cells using Western-Blot technique.

g) Nitric oxide (NO) pathway

The role of NO in physiology of erection is well known. NO pathway can be a parameter for characterizing endothelial dysfunction. Levels of eNOS, guanylate cyclase, cGMP and phosphodiesterase type 5 (PDE5) in lymphocytes can be analyzed to evaluate endothelial function. Both eNOS and soluble guanylate cyclase levels are increased in ED patients, compared with healthy controls [77].

The severity of endothelial dysfunction has been demonstrated to be correlated with ED [79, 80]. And endothelial function was significantly worse in subjects with arteriogenic ED as demonstrated by penile Doppler than those with other forms of ED. Therefore, assessment of endothelial dysfunction may be considered as a routine test to diagnose arteriogenic ED compared to invasive penile Doppler. Furthermore, screening endothelial dysfunction in the ED population is necessary in assessing cardiovascular risk [81].

VI. STRATEGIES TO IMPROVE ENDOTHELIAL FUNCTION AND PREVENT CARDIOVASCULAR EVENT IN MEN WITH ED

There is an interval between the onset of ED and CVD. This leading time provides an opportunity for early diagnosis and treatment of cardiovascular risk factors.

Here are some suggestions for patients with cardiovascular diseases or ED [44]:

1. ED should be a routine part of the cardiovascular history recording and systematic review in all men of 25 years and older regardless of their level of sexual function.

2. Men who are discovered to have ED must be thoroughly assessed for cardiovascular risk and occult systemic vascular disease.

3. Men with ED should be treated as if they already have vascular diseases. All men with cardiovascular risks should embark on lifestyle modification such as having healthy diet, doing exercise and quitting smoking.

1. CARDIOVASCULAR RISK REDUCTION IN PATIENTS WITH ED

There is no doubt that treatment of LDL cholesterol and hypertension reduces cardiovascular and cerebrovascular events in patients with cardiovascular risk factors. However, it is controversial that risk factors management could reduce the development or progression of ED. Maybe it is too late to reverse vascular damages that caused ED by the time when vascular damages have caused cardiovascular diseases [82]. But some studies suggest that the reduction of cardiovascular risks benefits patients with ED by improving the response to PDE5 inhibitors [83].

a) Blood pressure

The ideal blood pressure is < 140/90 mmHg for the general population and < 130/80 mmHg for patients with diabetes or chronic kidney diseases [84].

Hypertension is one of the common risk factors for cardiovascular diseases. However, ED is a frequent complication of hypertension management. There are evidences that the risk of ED is greater in patients who take specific classes of antihypertensive drugs including diuretics, methyldopa, clonidine, and beta-blocks than those take other antihypertensive drugs. Especially, the nonselective antihypertensive drugs have been found to have greater impacts on erectile function. Relatively, calcium-channel blockers and angiotensin converting enzyme inhibitors (ACEI) are reported to have less negative effects.
on sexual function [85]. Administration of ACEI in men with arterial ED demonstrated favorable effects for ED [86]. Similarly, another study showed that angiotensin II-receptor antagonist valsartan has some advantages for the quality of sexual life compared with beta-blocker carvedilol, despite their similar antihypertensive effects [87]. Therefore, it is important to ensure that the antihypertensive drugs have the lowest possible potential for causing ED in patients who are under anti-hypertension treatment. However, there is a contradiction between treatment for hypertension and the cause of ED. It is crucial to obtain the best balance between antihypertensive efficiency and the quality of sexual life.

**b) Cholesterol**

The ideal LDL (the bad cholesterol) goal is <100mg per 100ml in patients with known coronary disease and <70mg per 100ml in high-risk patients with coronary disease (such as acute coronary syndrome, multiple risk factors) [84]. HDL cholesterol (the good cholesterol): HDL is recommended to be > 40mg per 100ml.

Statins are regular drugs for reducing the plasma cholesterol level. In addition, it is well known that statins has beneficial effects such as improvement of endothelial function, decrease of inflammatory and thrombogenesis, and stabilization of atherosclerotic plaque. Recent studies indicate that statins have favorable effects on erectile dysfunction. This favorable effect of statins can be, at least partially, attributed to their action on the endothelial function through their anti-inflammatory properties [88]. A pilot study showed that atorvastatin may improve erectile function and patients’ responses to oral sildenafil [89].

c) Fasting blood sugar

American Diabetes Association considers a fasting blood sugar of 100 to 125mg per 100ml to be pre-diabetes and 126mg per 100ml or higher to be diabetes. Fasting blood glucose of ED patients with cardiovascular risks are recommended to be <100mg per 100ml [84].

d) Antioxidants

Production of oxygen-free radicals is considered to lead to endothelial dysfunction quenching endothelium-mediated NO-synthesis. Therefore, antioxidants which can seavenge oxygen-free radicals have been explored and applied as a possible therapy for endothelial dysfunction. Some studies revealed that a single dose of vitamin C has beneficial effect on endothelial function-mediated FMD in smokers and patients with CHD [90, 91]. Neunteuffl et al. [92] explored whether vitamin-E and lipid-lowering therapy have synergetic effects on improving endothelial function, and found that among hypercholesterolemic patients, improvement of endothelial function was significantly more apparent under statins and vitamin-E combined therapy than those under statin therapy alone. However, the long-term effect of antiveidants to improve endothelial function is still unclear.

### 3. SECONDARY LIFESTYLE

Patients under cardiovascular risks are recommended to stop smoking by attending a smoking cessation program that covers behavioral modification as well as various medicines to aid patients in quitting smoking [84].

Patients with stable cardiovascular disease are recommended to exercise (walking on a flat surface) for no more than 30 minutes a day 5 days a week, at least [84].

ED patients with high cholesterol and diabetes should be referred to professional dieticians.

### 4. PHOSPHODIESTERASE TYPE 5 INHIBITORS (PDE5I)

Phosphodiesterase-5 inhibitors have the first-line drugs for ED. It decreases breakdown of cyclic guanosine monophosphate in the smooth muscle cells, and enhances the downstream effects of NO [93]. PDE5I not only favorably improves erections, but also has beneficial effects on endothelial function [94]. It has been reported that daily administration of PDE5I can cure patients with ED through chronic activation of the eNOS pathway [95, 96]. Chronic administration of tadalafil for one month resulted in reduction of CRP, VCAM-1 and ET-1, which are important markers for endothelial dysfunction [97, 98]. Similar results were seen with sildenafil which is taken three times daily in men with type 2 diabetes mellitus [99, 100]. Several trials showed that chronic administration of tadalafil could increase mobilization of circulating endothelial progenitor cells (EPCs) and improve peripheral endothelial function measured by flow-mediated dilation of brachial artery [101, 102] in men with ED. PDE5-Is have a favorable effect on inflammatory activation due to increased activity of the NO-cyclic guanosine monophosphate axis (NOCGMP) [103]. In patients with cardiovascular risk factors, upregulation of nicotinamide adenine dinucleotide phosphate (NADPH)-oxidase and formation of superoxide would impact the function of endothelium. The mechanism of PDE5-I’s anti-inflammatory effects is to enhance the NO-cGMP pathway which also augments relaxation of smooth muscle cells [104].

This finding revealed that chronic administration of PDE5I is not only good for patients with ED, but also can improve systemic endothelial function. It seems that chronic PDE-5I therapy is required to achieve sustained improvement of endothelial dysfunction, which would be beneficial for patients with cardiovascular risks. On the basis of currently available evidence, it is likely that endothelial dysfunction and systemic cardiovascular pathology may be modulated by PDE5-I on a daily dosage.
VII. CONCLUSIONS:

Endothelial dysfunction is a key pathophysiologic process of both ED and CVD. Evidence has been accumulated that ED may be an independent predictor of future CV events in patients without onset of heart disease. According to this, each patient with ED should be considered as a cardiac patient until proven otherwise. Urologists should pay more attention to ED in each middle-aged man. And there is no need for patients to be embarrassed to talk about sexual dysfunction with their physicians. Once diagnosis of ED is established, patients with ED should undergo complete assessment to exclude the possibility of CVD or CRFs. Endothelial dysfunction is one of the most important markers to reflect one’s ED and CVD conditions. And strategies should be taken to improve endothelial function to repair ED and prevent cardiovascular events.

F. DRUGS CAUSING ERECTILE DYSFUNCTION

Ulf Simonsen

I. INTRODUCTION

Erectile dysfunction is a common symptom amongst older men and will inevitably co-exist with other physical conditions prevalent in this population such as depression, diabetes and cardiovascular disease which are themselves risk factors for ED [1-3]. In addition sexual symptoms related to medication can involve a combination of complaints concerning sexual desire, arousal and orgasm rather than being concentrated on ED alone. Self-reported and questionnaire data concerning ED as a side effect of medication should therefore be interpreted with caution. In order to confidently establish a causative relationship three conditions should be satisfied: (1) There should be a higher prevalence of ED amongst men taking the drug calculated from data with placebo control and stratification for known risk factors of ED; (2) A greater prevalence of ED should also be found for the target drug compared to another drug with an equivalent therapeutic effect using data from a randomised controlled trial, again with allowance for confounding variables; (3) Finally, a credible physiological mechanism for the causation of ED by a particular drug should be postulated and proven by experimental studies. Animal models can be useful in this regard to generate hypotheses concerning the inhibitory action of prescribed drugs on erectile function by means of experiments on isolated cavernosal tissue or the effect on sexual behaviour in intact animals [4]. Concerning clinical effects, the occurrence of ED is rarely a primary end point in therapeutic trials and therefore the above conditions for proving a causative association are unlikely to be met in full. The difficulties of this approach are exemplified by longitudinal data from the Massachusetts Male Ageing Study (MMAS) showing that only non-thiazide diuretics and benzodiazepines, agents not previously strongly linked to ED, were independently associated with ED [5]. Despite the excellent design of this study, power was limited by the need for allowance of multiple confounding variables. Historically, review articles generally based opinion on uncontrolled data but the recent emergence of standardised methodology for systematic reviews and meta-analyses have increased the validity of our conclusions concerning the effect of drugs on sexual function.

II. CARDIOVASCULAR DRUGS AND ERECTILE FUNCTION

Erectile dysfunction and heart disease have common factors [2, 6], and therefore, patients with sexual dysfunction should always be examined for the presence of underlying cardiovascular disease and risk factors. However, comparing untreated and treated patients with heart disease or hypertension revealed that medication increases the relative risk for development of erectile dysfunction [5].

1. TREATMENT OF HYPERTENSION AND ERECTILE DYSFUNCTION

Current recommendations for treatment of hypertension suggest thiazide diuretics as first line, while angiotensin-converting enzyme (ACE) inhibitors, angiotensin II type 1 (AT1) receptor antagonists, calcium channel blockers, and beta-adrenoceptor antagonists are indicated as first line agents in specific high risk conditions (JNC7). Often two or more antihypertensive medications will be required to achieve goal BP <140/90 mm Hg (or <130/80 mm Hg in diabetic) hypertensive patients [7]. All drugs have ED listed as a potential side effect but well designed controlled clinical trials give conflicting results concerning causative relationships [8]. Animal studies do suggest possible mechanisms using in vitro and in vivo methodology [9].

a) Diuretics

This class of drug has been extensively studied following early trials which showed a high prevalence of self-reported ED. Possible mechanisms include decreased vascular resistance and lowered zinc levels leading to reduced androgen production although experimental animal data is lacking. Appropriate controlled studies with ED as an end-point give consistent results despite trends towards lower dosage schedules [10]. Older treatment regimens using higher doses of a thiazide showed a significant increase in ED compared to placebo [11]. Addition of a thiazide to existing treatment with propanolol or methyldopa also increased the prevalence of ED, whilst this effect did not occur when the thiazide was combined with an ACE inhibitor [12]. Data from a large UK trial showed that twice as many men taking thiazides for treatment of mild hypertension reported ED compared to those treated with propanolol or placebo, this being the commonest reason for withdrawal from the bendrofluazide arm of the study [13]. Similar findings were documented from the Treatment of Mild Hypertension Study (TOMHS) where the prevalence of ED at 2 years in men taking a low dose thiazide was twice that of both the placebo group and those on alternative agents [14]. Interestingly after 4 years of treatment prevalence of ED in the placebo group approached that of the thiazide group, a finding not fully explained by drop outs. It may be that thiazide therapy unmasks latent ED at an earlier stage rather
then being directly causal. A study comparing sexual side effects in hypertensive patients treated with a thiazide to those on placebo or atenolol also found a higher rate of ED in the thiazide group although the effect was ameliorated by weight loss [15]. It is interesting that treatment with non-thiazide diuretics was implicated as an independent factor for ED in the MMAS since these drugs have not been systematically assessed for unwanted sexual effects [5] although it is established that spironolactone has anti-androgenic properties. In addition they are infrequently used for hypertension alone. In summary it is likely that thiazide diuretics are associated with ED in men with hypertension, although this may represent unmasking of an existing problem and the effect can be reduced by lifestyle changes. The underlying pathophysiological mechanism is still unknown.

**b) β-Adrenoceptor antagonists**

Receptor studies show that only 10% of adrenoceptors in penile tissue are of the β-adrenoceptor subtype and activation leads to relaxation [4] and vasodilation of penile arteries [16]. This response is attenuated in vitro by non-selective drugs such as propranolol, possibly by blocking postjunctional β2 adrenoceptors [16, 17], but not by cardiac selective agents such as practolol and atenolol. However, direct cavernosal injection of propranolol in the intact animal has no effect. Depending on the lipophilicity of the beta-adrenoceptor antagonists (e.g. propranolol is hydrophilic while atenolol is hydrophobic) may also exert an inhibitory effect within the central nervous system, perhaps leading to lowered sex hormone levels [18]. Data from the MMAS confirmed higher usage of this class of medication amongst men with ED, although the significance of the association disappeared when confounding variables were taken into account. Interestingly cardiac selective blockers were the predominant type used by men in this study. Thus, the effect of β-adrenoceptor antagonists on erectile function to a large degree can be explained by their mechanisms of action, e.g. they are either general β-adrenoceptor antagonists, selective β1-adrenoceptor antagonists, or also possess vasodilatory properties (Figure 1). Non-selective drugs such as propranolol were associated with higher prevalence of ED compared to patients treated with placebo or ACE inhibitors [12, 13]. Later trials using agents with higher selectivity for the β1 adrenoceptor such as acebutolol have shown a substantial reduction in ED as a side effect with no difference being found against the placebo and ACE inhibitor groups [14]. This also applies to the use of selective β1-adrenoceptor antagonists in the prophylaxis of angina [19]. The clinical evidence therefore suggests that older non-selective drugs such as propranolol were associated with higher prevalence of ED but this effect is not seen with β1 selective adrenoceptor antagonists. The general β-adrenoceptor antagonists which also causes vasodilation by blocking α1-adrenoceptors, carvedilol and labetalol have in case of carvedilol in a cross-over study been reported to be associated with worsening in sexual function [20], while similar data are not existing for labetalol. Some of the recently introduced β1-adrenoceptor antagonists such as nebivolol have also vasodilatory effects mediated by release of nitric oxide. In cross-over studies nebivolol in contrast to the selective β1 adrenoceptor antagonists, metoprolol and atenolol, did not decrease sexual intercourse activity in hypertensive men, and may even have positive effects on erectile function [21, 22].

**c) α-Adrenoceptor drugs**

Animal studies have demonstrated a positive effect on erection for α-adrenoceptor antagonists, particularly those acting on the α1 adrenoceptor, by increasing or prolonging the relaxant response of cavernosal smooth muscle [23]. In addition, prejunctional α2-adrenoceptor activation modulates the release of nitric oxide, suggesting a putative vasodilatory role of α2-adrenoceptor antagonists [24]. Direct cavernosal injection of α1-adrenoceptor antagonists has been shown to cause erection in both experimental animals and humans, but this effect is not observed with drugs selective for α2-adrenoceptors [23]. In clinical trials drugs such as doxazosin used to treat hypertension [14] or lower urinary tract symptoms [25] are not associated with complaints of ED and indeed had lower rates than placebo groups. Drugs stimulatory to the α2 adrenoceptors such as clonidine result in diminished erectile function both clinically and experimentally by peripheral and central mechanisms [17, 23]. The centrally acting drug, methyldopa, has also been associated with ED in controlled trials compared with placebo and other antihypertensive agents [12] and may act by antagonising hypothalamic α2 adrenoceptors.

**d) Angiotensin Converting Enzyme (ACE) Inhibitors**

In addition to circulating angiotensin II, angiotensin converting enzyme (ACE) and chymase are expressed in erectile tissue, and functional as well as binding studies suggest angiotensin II induces contraction by activation of angiotensin II type 1 (AT1) receptors [8]. Moreover, angiotensin II increases during the detumescence phase in man [26]. However, experiments in normotensive rats suggested that the ACE inhibitor, captopril, does not cause any significant adverse effect on sexual function in awake rats [17], and enalapril may even improve erectile function in spontaneously hypertensive rats [27]. The contention is also supported by clinical studies of hypertension treatment comparing an ACE inhibitor with other agents and placebo. All three studies found either no difference compared to placebo or improved sexual function from baseline compared to other antihypertensive drugs [12, 14, 18, 28].
e) Angiotension II type 1 (AT1) receptor antagonist

In studies of hypertensive animals AT1 receptor antagonists e.g. losartan, valsartan, and candesartan reverse structural changes in the penile vasculature and appear to conserve erectile function [27, 29-31]. Moreover, in clinical cross-sectional studies AT1 receptor antagonists in contrast to other antihypertensive drugs even tend to improve erectile function [10], and in direct comparison with the β-adrenoreceptor antagonist carvedilol, valsartan has a beneficial effect on existing sexual dysfunction at baseline and have no adverse sexual effects during 12 months of treatment [20]. In case of losartan 3 month treatment was also reported to improve sexual function [32].

f) Calcium Channel blockers

Smooth muscle contraction requires increased cytosolic calcium derived from internal stores and extracellular fluid. It would therefore be anticipated that calcium channel blockers would have a permissive effect on penile erection but might inhibit bulbospongiosal contraction during ejaculation. This contention is supported by findings of in vitro studies which demonstrated a modest relaxant effect on isolated cavernosal smooth muscle [23] and penile arteries [33]. Clinical studies have demonstrated no adverse effect on erection and ejaculatory complaints seem short-lived [18]. In the TOMHS study there was no significant excess risk of ED in the amlopidine group compared to placebo-treated patients [14]. Another study also showed no increase in the prevalence of ED when hypertension was treated with diltiazem alone or in combination with an ACE inhibitor [34]. A comparative study of two calcium channel blockers showed that neither had any significant effect on sexual function although two patients withdrew from the nifedipine arm because of reduced libido [35].

g) Summary

Treatment of an asymptomatic abnormality such as mild to moderate hypertension requires agents with an acceptable side effect profile to minimise non-compliance. Despite lower dosage thiazide diuretic agents continue to be associated with higher rates of ED although this may be reduced by combination therapy and weight loss. There is no firm evidence to implicate other commonly used modern agents in the causation of ED although alpha-adrenoceptor antagonists and AT1 antagonists both tend to improve sexual function during treatment and may therefore be useful as antihypertensive therapy in men with pre-existing ED.

2. TREATMENT OF HEART DISEASE AND ERECTILE DYSFUNCTION

Erectile dysfunction is highly prevalent among patients with heart failure, because of neurohumeral changes, an imbalance of circulating vasomodulators, reduced cardiac capacity, depression, and potential adverse effects of heart failure medical treatment [36]. Thus, an array of drugs is applied for the treatment of heart disease. In most cases a multiple drug regimen is applied for conditions such as chronic heart failure, where patients are treated with diuretics for removal of surplus liquid, ACE inhibitors and/or AT1 receptor antagonists to cause peripheral vasodilation, digoxin as positive inotropic agent, antithrombotics, antiarrhythmics, anticoagulants, and hypolipidemic drugs. In addition, the aldosterone receptor antagonists, spironolactone and eplerenone, and β-adrenoceptor antagonists such as metoprolol, bisaprolol, carvedilol, and recently nebivolol have been found to enhance survival in patients suffering from heart failure [37-39]. Nitrates relieve pain, but they have not been shown to prolong survival in chronic heart failure unless they are taken in combination with the peripheral vasodilator, hydralazine [40]. Evidence regarding the effect on erectile function of most of these drugs is sparse [8], while there is some indications regarding the antidepressants often used in connection with heart failure (see below section III.2.).

a) Digoxin

Digoxin is indicated for treatment of atrial fibrillation and heart failure in functional stage III – IV according to the New York Heart Association (NYHA). However, digoxin has no life prolonging effect in patients with chronic heart failure, although it reduces the need for hospitalization [41]. In therapeutic concentrations (0.5 – 0.7 ng/ml) digoxin inhibits erectile function measured by visual sexual stimulation and by nocturnal penile tumescence in healthy volunteers [42]. The mechanism can probably by ascribed to the reported inhibitory effect of digitalis glycosides on NO-evoked vasodilation in isolated penile arteries [43] and corpus cavernosum strips [44]. In addition, a relation of digoxin to low plasma testosterone levels and decrease in sexual desire has been found [45]. Therefore, in the case of ED in patients treated with digoxin, they should consult a cardiologist to evaluate whether treatment with digoxin is necessary.

b) Anticoagulants, antithrombotics, and antiarrhythmics

The information regarding the effects of anticoagulants on erectile function is sparse. There are several case-reports suggesting heparin therapy is associated with priapism [46], and in a review of 121 cases of priapism, four of the patients were in treatment with heparin [47]. The prognosis for preservation of potency after treatment for priapism associated with heparin treatment is poor compared with the overall average with preserved erectile function in patients who have experienced priapism [47]. Treatment with the coumarin derivative, warfarin, was suggested to
be associated with an increased risk of ED in elderly men, but in this study only a few patients were actually treated with warfarin [48]. Therefore, although information regarding anticoagulants and erectile function is lacking, these drugs do not appear to impose a major risk for ED. The same appear to be the case for antithrombotic drugs evaluated over a six month period [49].

Regarding patients in treatment with antiarrhythmics and due to the risk of Q-T interval prolongation in the ECG vardenafil should not be given to patients in treatment with type 1 antiarrhythmics e.g. procainamide or type 3 antiarrhythmics e.g. sotalol and amidarone.

c) Lipid-lowering drugs (fibrates, statins)

Lipid-lowering therapy in hyperlipidemic patients with either fibrates [50, 51] and statins [52, 53] yield substantial health benefits such as diminished coronary events and deaths. High levels of total plasma cholesterol and low levels of high density lipoprotein are associated with an increased prevalence of ED [1, 54, 55]. However, ED was reported to be a frequent side-effect of treatment of hyperlipidaemic subjects using clofibrate [56] or gemfibrozyl [57]. In patients referred to a clinic for primary hyperlipidaemia an increased risk of ED was also observed in patients treated with one of four fibrate derivatives (fenofibrate, ciprofibrate, bezafibrate and gemfibrozyl) [58]. The mechanisms by which fibrates lower lipoprotein levels remain unclear, but they interact with peroxisome proliferator-activated receptors (PPARs) [59], which regulates gene transcription. In the liver activation of PPARα by clofibrate and gemfibrozyl stimulates liver microsomal esterification of estradiol and testosterone [60]. Further studies must show whether the latter mechanism of action is an explanation for the increased prevalence of ED reported in patients treated with fibrates.

In patients with hyperlipidemia and treated with statins such as simvastatin and pravastatin and referred to a clinic for primary hyperlipidaemia, an increased risk for ED was reported [55, 58]. Moreover, five patients with coronary artery disease developed ED one week after starting treatment with simvastatin, and sexual function was restored after stopping the treatment, but ED recurred when two of the patients were rechallenged [61]. No control patients were included in the latter study. In contrast, others in a cross-over study of 22 men with hypercholesterolemia randomized for placebo, simvastatin, or lovastatin, found an increase in nocturnal tumescence after 2 weeks, although the increase was not significant after 6 weeks treatment [62]. Evaluation of the frequency of ED reported in the Scandinavian simvastatin survival study, where 4444 patients with coronary heart disease were randomized to treatment with simvastatin or placebo for up to 6 y, ED was found in 28 placebo-treated patients with eight resolved cases, while ED was present in 37 simvastatin-treated patients with 14 resolved cases [63]. Therefore, so far in patients treated with simvastatin underlying diseased vasculature rather than the drug appears to be the cause of ED.

In contrast to simvastatin, positive effects on erectile function was reported for atorvastatin on erectile function: (1) Atorvastatin was reported to improve nocturnal penile activity in hyperlipidemic patients treated for 4 months [64]; (2) Atorvastatin combined with the angiotensin converting enzyme inhibitor, quinapril had positive effects on ED in men with established penile disease and suboptimal response to phosphodiesterase inhibitors [65]; (3) Atorvastatin improved the response to sildenafil [66]; (4) Combined treatment with atorvastatin and sildenafil had positive effects on ED in men undergoing prostatectomy with bilateral nerve sparing procedure [67]; (5) Atorvastatin had positive effects in patients with hyperlipidemia followed for 12 months [68]. These reported positive effects of atorvastatin, in contrast to simvastatin, on erectile function suggest that the effect of statins is not a class effect of statins. Moreover, in an observational prospective study it was reported that differences in dose, relative efficacy or relative lipophilicity of statin did not show correlation with changes in IIEF score over a 6 month period [49]. However, statins are structurally a heterogenous group of compounds and therefore, other mechanisms than the lipid lowering effects may have significance for the effect of a statin on erection e.g. (1) Atorvastatin, lovastatin, and simvastatin inhibit excretion of phosphodiesterase type 5 inhibitors by cytochrome CYP3A4, while fluvastatin and rosuvastatin inhibit metabolism of sildenafil by cytochrome CYP2C9; (2) The effect on endothelial cell calcium and vasodilatory effects of the different statins appear to differ markedly [69]; (3) Statins may improve erection by inhibition of Rho kinase as recently reported in rats with hypertension or diabetes and erectile dysfunction [70, 71].

d) Aldosteron receptor antagonists

Treatment with spironolactone and eplerenone increase survival in systolic chronic heart failure. In addition, to being an aldosteron receptor antagonists, spironolactone also blocks androgen receptors and that may explain why it is associated with sexual dysfunction. In contrast, the newer aldosteron receptor antagonist, eplerenone, is devoid of effects on sex hormone receptors.

3. SUMMARY

Heart disease and erectile dysfunction (ED) are two highly prevalent disorders that frequently occur concomitantly. Coronary artery disease, HF, and ED share several common risk factors, including diabetes mellitus, hypertension, smoking, and dys-
lipidemia. Additionally, the distinct physiologic sequelae of heart disease create unique organic and psychologic factors contributing to ED in this patient population. Standard HF therapy with beta-adrenoceptor antagonists, digoxin, and thiazide diuretics may worsen sexual dysfunction owing to medication side effects. The effect of statins on erectile function is controversial and may reflect that apart from the lipid-lowering effect, the effect of statins on erectile function is not a drug class effect, but can also be ascribed to other pleitropic effects such as Rho kinase inhibition and different effect on endothelial cell calcium. The aldosterone antagonist, spironolactone is associated with sexual dysfunction due to anti-androgenic properties, but this is not the case for eplerenone.

III. PSYCHOTROPIC MEDICATION

In common with drug treatment for cardiovascular disease, the underlying disorder for which psychotropic medication is being prescribed may be of more relevance than the resulting medication to any sexual dysfunction occurring during treatment. On the other hand neuronal receptor complexity and interrelation of pathways within the CNS make it inevitable that neurons and ganglia involved in sexual functioning will be acted upon by psychotropic drugs leading to functional changes that may be positive or negative. This distinction is illustrated by a comparative study which found that loss of sexual desire was common amongst non-medicated patients with schizophrenia whilst those on antipsychotic drugs had greater desire but increased erectile and ejaculatory disturbance [72]. Evidence of the mechanisms underlying these changes chiefly comes from laboratory study of animal models, particularly the rat. Clinical studies examining this issue tend to be of poor methodological quality and are hampered by the range of sexual symptoms encountered such as altered sexual desire, orgasmic dysfunction and ED. It is therefore difficult to give definitive statements concerning individual drugs.

1. ANTIPSYCHOTICS

Members of this class of drug have many effects within the CNS related to interaction with neuronal receptors and may also act peripherally. Their therapeutic effect is thought to relate to dopaminergic receptor blockade within the limbic and prefrontal areas of the brain. Their unwanted effects are due to alpha-adrenoceptor antagonism and anticholinergic properties together with antidopaminergic actions within the basal ganglia causing extrapyramidal side effects which commonly produce sexual symptoms [73]. The occurrence of extrapyramidal effects differentiates the older <typical> antipsychotics where they are frequent from the newer <atypical> antipsychotics where they are less common. This difference probably relates to variable affinities for particular classes of receptor [74] or avidity for particular areas of the cerebral cortex [75]. An additional effect of dopamine receptor blockade is hyperprolactinemia, which also alters sexual function by reducing dopamine release in permissive cerebral centres, is more common with older <typical> agents.

The results of animal experiments, chiefly in the rat, examining the role of CNS dopaminergic pathways in penile erection and copulatory behaviours has previously been reviewed [76]. It seems likely that D1 receptor activation in the medial pre-optic area (MPOA) of the hypothalamus facilitates erection through intermediary oxytocinergic and spinal cholinergic pathways. It is also possible that activation of D2 receptors in this area have the opposite effect [77]. Older agents such as haloperidol and flupenthixol have both been shown to reduce apomorphine-induced erections in experimental animals by means of D1 receptor antagonism [23]. In addition systemic administration of antipsychotic agents in the rabbit produced erection by a local non-dopaminergic action, possible involving antagonism of α1 adrenoceptors [78]. It can therefore be anticipated that the clinical effect of antipsychotics on sexual function will vary according to their affinity for particular receptors. This seems to be confirmed by reports in the literature of sexual dysfunctions ranging from ED to priapism [79].

In a non-randomised comparative study the prevalence of sexual dysfunction ranged from 40-70% [80]. Newer agents such as clozapine showed a lesser reduction in sexual desire although the group taking risperidone had the greatest decrease in frequency of erection. An earlier study found that thioridazine, an <atypical> agent caused ejaculatory problems rather than ED [81]. In summary, these agents have a credible mechanism of action, but their clinical effect is variable due to differing overall CNS effect. However, in case of sexual dysfunction a psychiatrist should be consulted to consider a switch from conventional to an atypical antipsychotic medication.

Summary

In summary, it is difficult to separate disease from drug effect and also difficult to obtaining reliable information from patients with psychotic illness. There is a paucity of controlled studies. Mainly older antipsychotic drugs results in decreased erection and anorgasmia, while newer anti-psychotics appear to have lower incidence of sexual dysfunction. Among newer anti-psychotics, risperidone appears to have the highest rate of sexual dysfunction, while there are insufficient data on aripiprazole and ziprasidone.

2. ANTIDEPRESSANTS

Depression by itself makes it difficult to separate effect of illness from additive effect of drugs, since
mood disorders may lead to lack of interest and emotional withdrawal from the sexual partner. Antidepressants can have numerous effects on sexual function including altered sexual desire, erection difficulties, and orgasm problems. The evidence has been summarized in a recent Cochrane review of fifteen randomised studies [82]. The main conclusion regarding co-medication to correct erectile dysfunction was an effect of sildenafil in three of the clinical trials, while the available evidence was insufficient regarding other strategies for correction of erectile dysfunction.

a) Tricyclic antidepressants

This drugs act by inhibiting the re-uptake of catecholamines in the CNS. Their sexual side effect profile is thought to relate to peripheral anticholinergic and beta adrenergic effects. It is also possible that they antagonise serotonin (5-HT) receptors. Animal studies needed to confirm these putative effects have not been performed. Controlled clinical studies suggest that orgasmic disorders in both sexes are most frequent, explaining the use of these drugs as inhibitors of ejaculation [83, 84]. Against this a case-control study showed no excess sexual dysfunction amongst patients taking a tricyclic antidepressants [85]. In summary these drugs most frequently cause orgasmic dysfunction for which the underlying mechanism is unclear.

b) Monoamine oxidase inhibitors

These drugs are now rarely used. In common with the tricyclic antidepressants they are associated with higher rates of orgasmic dysfunction in controlled trials [83], the nature of the central or peripheral mechanisms involved is uncertain.

c) Selective serotonin re-uptake inhibitors (SSRIs)

This represents the commonest class of drug currently used to treat depression. They inhibit the re-uptake of 5-HT (serotonin) into CNS neurones and can therefore produce stimulatory effects on various 5-HT receptors. It is estimated that up to 50% of patients taking these drugs experience a change in sexual function [86]. Possible mechanisms include stimulation of 5-HT2 and 5-HT3 receptors which may inhibit erogenous pathways within the spinal cord [87], decreased dopamine release in the medial preoptic area [88] and inhibition of both central and peripheral nitric oxide synthase. A controlled clinical study suggested that the improvement in sexual function resulting from alleviating clinical depression seen with SSRI treatment outweighed any negative effect of the drug [89]. Other placebo controlled randomised studies, however, did reveal increased sexual dysfunction, mainly anorgasmsia, in the SSRI treated group [90, 91]. Further studies have suggested that these adverse effects can be modified by co-treatment with other drugs such as sildenafil [73, 92, 93] or mianserin [94].

SSRIs differ in their ability to cause ED. A high incidence of ED has been observed in patients under treatment with the SSRI, paroxetine [95], while a lesser impact on sexual function has been reported in patients treated with the SSRI, citalopram [96]. This fact suggests that other mechanism(s) different from inhibition of serotonin reuptake could possibly account for ED associated to SSRI-treatment. This hypothesis is supported by the evidence that acute or chronic paroxetine, but not citalopram, caused ED in rats by inhibiting NO production [97]. Indeed, the inhibitory effects induced by acute paroxetine on erectile function in the rat can be prevented by inhibition of PDE5 with vardenafil [98]. On the other hand, venlafaxine a mixed inhibitor of serotonin and norepinephrine reuptake, produced ED in rats by increasing norepinephrine levels, since its inhibitory effects on erectile responses were prevented by phenolamine [99]. Thus, the ability to produce ED and the mechanism by which SSRIs cause ED may differ depending on the specific SSRI compound.

d) Other Antidepressants

Animal experiments suggest that stimulation of 5-HT1 receptors within the CNS helps modulate sexual function with the 5-HT1A sub-type increasing ejaculation and the 5-HT1C sub-type improving erection. This has a bearing on the use of recently developed antidepressant drugs such as mirtazapine and nefazodone which tend to have beneficial effects on sexual function possibly by activation of the 5-HT1c receptor which augments sexual response [100], although they may also antagonism at the 5-HT2C receptor [101]. The isolated reports of priapism seen with a prototype agent, trazadone, which has been shown to increase nocturnal erectile activity despite reducing REM sleep [102, 103] may be related to the 5-HT1C erogenic effect seen with its primary metabolite, m-chlorophenylpiperazine, in experimental animals [23].

e) Summary

It is difficult to separate the effect of illness from the additive effect of anti-depressant drug. SSRIs and venlafaxine may negatively affect all the steps of the male sexual response cycle (desire-arousal-excitement- оргasm). Bupropion, nefazodone, and mirtazapine have lower rates of sexual dysfunction than SSRIs. For men with anti-depressant-induced ED, the addition of sildenafil appears an effective strategy. Potentially promising strategies include also the addition of bupropion, tadalafil, and buspirone. There are insufficient randomised data assessing effect of dose reduction and e.g. drug holidays on sexual function in patients treated with anti-depressants.
3. ANXIOLYTICS

Although not previously associated with causation of ED, findings from the MMAS study implicate this class of drug in sexual problems reported by the male cohort [5]. Benzodiazepines are thought to act to potentiate the action of the neurotransmitter gamma amino butyric acid (GABA) in the reticular and limbic system but may also affect the serotonin and dopaminergic pathways. Experimental studies suggest that GABA-ergic drugs inhibit erection induced by apomorphine, a dopamine agonist [104]. Clinical correlates are scarce but a controlled study did demonstrate that a combination of lithium and benzodiazapine was associated with significantly higher rate of sexual dysfunction than treatment with lithium alone [105]. More recent anxiolytic agents such as bupropion, acting mainly by inhibiting dopamine reuptake, and buspirone which acts on 5-HT1A receptors are not associated with sexual side effects in placebo controlled trials [106] and can be used to alleviate sexual symptoms caused by other antidepressant medication [107].

4. ANTICONVULSANTS

Focal epileptic discharges from the temporal lobe may affect the function of the hypothalamic-pituitary axis, and hence the level of several hormones of importance for sexual function [108]. In addition, there are several case reports of anorgasmsia on gabapentin and carbamazepine as well as decreased libido on valproate [109, 110]. There are case reports of improved erectile function in patients switched to lamotrigine [110-112].

5. OPIATES

Long term intrathecal administration of opiates results in hypogonadotrophic hypogonadism and associated sexual dysfunction that can be restored with appropriate supplementation [113]. Administration of opioid antagonists to older men with ED however did not improve erectile function measured objectively by NPT monitoring [114]. Opioids do have a generalised depressant effect on sexual function when directly administered to the MPOA in rat brain but treatment with the opioid receptor antagonist, naloxone, had no sexual effect on healthy male volunteers [23].

6. ANTI-ANDROGENS

These drugs cause partial or near complete blockade of circulating androgens by inhibiting production or antagonism at the androgen receptor (AR). They will therefore have secondary effects on sexual function commensurate with the fall in circulating or tissue androgen levels. It is thought that in the adult androgens modify sexual behaviour chiefly by modulating sexual desire via AR within the CNS. The effects of androgen deficiency on sexual activity are variable within each individual ranging from complete loss to normal function. Experimental studies in humans suggest that spontaneous erections during REM sleep are androgen dependent whilst psychogenic erections in response to visual sexual stimulation are androgen independent [4]. An additional peripheral effect has been suggested from animal work which showed that castration decreased NOS activity within rat corpus cavernosum leading to reduced erectile activity. The addition of testosterone restored activity but this recovery was prevented by treatment with finasteride, suggesting that dihydrotestosterone may be the important androgen in peripheral sexual responses such as penile erection [115].

The anti-androgen with least effect on circulating testosterone is the 5 alpha reductase inhibitor, finasteride, which is used in the treatment of symptoms due to benign prostatic enlargement (BPE) and male pattern alopecia. In randomised placebo controlled studies of treatment with finasteride 5 mg daily for BPE approximately 5% of men complained of sexual symptoms of decreased desire and ED compared to 1% in the placebo group [116]. At the lower dose of 1 mg daily used to treat male pattern alopecia no excess sexual dysfunction was seen compared to placebo [117]. Given the animal work it seems possible that this effect is secondary to reduced availability of dihydrotestosterone in the penis.

More complete androgen ablation is achieved by competitive antagonism at the AR, so preventing transduction of response to circulating testosterone and dihydrotestosterone. Non-steroidal drugs such as flutamide and bicalutamide have relatively pure effects on the AR, whilst the steroidal anti-androgen, cyproterone acetate also has inhibitory effects on the hypothalamus. These drugs are used in the palliative treatment of locally advanced and metastatic prostate cancer either alone of in combination with a luteinising hormone releasing hormone (LHRH) agonist (complete androgen blockade). When used alone non-steroidal anti-androgens are associated with a rise in serum testosterone levels whilst combination with a LHRH agonist will reduce these to the castrate range. Again they can be expected to predominantly reduce sexual desire through a central action, an effect that occurs in up to 70% of men treated [118]. This unwanted effect is now becoming of more concern as such drugs are being used at an earlier stage of the disease.

When sexual activity in men being treated by castration or bicalutamide was compared in a small randomised trial no differences in self reported sexual activity or nocturnal penile tumescence were seen. In subsequent trials with larger sample size and longer duration, treatment with bicalutamide alone resulted in a lesser decrease in sexual desire [119]. In another large controlled trial treatment with either flutamide or cyproterone resulted in gradual loss of sexual desire in approximately 80% of men in both groups over a period of 2 - 6 years [120]. Even at a
low dose of 50 mg, bicalutamide therapy resulted in half the patients in one placebo controlled study suffering loss of erectile function [121].

The near complete androgen deprivation achieved by medical castration with LHRH agonists results in a profound loss of sexual desire which is usually accompanied by ED in controlled trials [122] This was objectively confirmed by nocturnal penile tumescence monitoring (NPT) before and after initiation of therapy in a small study [123]. These more recent findings make initial hopes that such drugs could be used to treat ED appear suspect [124].

In summary antiandrogen drugs produce the expected effects of sexual desire and erection commensurate with the degree of androgen ablation achieved.

7. MISCELLANEOUS DRUGS

Many other drugs are suggested as having sexual side effects, in particular that of ED in men, but these contentions are usually based on anecdotal case reports or post-marketing drug alerts rather than controlled trials.

a) Histamine H2 Receptor Antagonists

Cimetidine and ranitidine were previously widely prescribed for prophylaxis and treatment of peptic ulcer disease, their use has since declined as newer regimens have evolved but are increasingly available as <over the counter> medication. Case reports suggested that cimetidine was associated with ED and postulated mechanisms included anticholinergic effects and androgen inhibition. A single in vitro animal study suggested that histamine H2 receptor stimulation did cause cavernosal relaxation possibly via endothelial release of nitric oxide [23]. These reports have not been confirmed by well designed trials.

b). Retroviral Drugs

The need for evaluating sexual health in clinical trials where antiviral drugs are evaluated has recently been stressed [125]. Some studies have suggested that anti-retrovirals, in particular certain protease inhibitors e.g. ritonavir [126], may cause sexual problems or dysfunction [127-132], although this was not the case in a larger cross-sectional study [133]. The protease inhibitors are structurally very different and therefore, they may affect sexual function differently.

TABLE OF CONTENTS

INTRODUCTION

A. TESTOSTERONE

I. PHYSIOLOGICAL REMINDER
II. PATHOPHYSIOLOGICAL ASPECTS
III. TESTOSTERONE AND METABOLISM
IV. TESTOSTERONE AND CARDIOVASCULAR HEALTH:
V. ROLE OF TESTOSTERONE DEFICIENCY IN SEXUAL DYSFUNCTIONS AND EFFECTS OF TESTOSTERONE THERAPY
VI. ROLE OF TESTOSTERONE DEFICIENCY IN THE OTHER ASPECTS OF AGING
VII. DIAGNOSIS OF TESTOSTERONE DEFICIENCY
VIII. TREATMENT OF TESTOSTERONE DEFICIENCY/ANDROGEN THERAPY

B. ESTRADIOL, ESTRADIOL/TESTOSTERONE RATIO, ESTRADIOL RECEPTIVITY (406)

I. PHYSIOLOGICAL REMINDER:
II. CARDIOVASCULAR EFFECTS OF ESTROGENS:
III. ESTROGENS AND THE PROSTATE:

C. OTHER HORMONES

I. PROLACTIN
II. GROWTH HORMONE
III. MELANOCORTINS: ALPHA MSH AND OTHER PRO-OPIO-MELANOCORTIN DERIVATIVES
IV. OXYTOCIN
V. DEHYDROEPIANDROSTERONE (DHEA) (REVIEW IN 2,449)
VI. THYROID HORMONES
VII. EPIDEMIOLOGY AND MANAGEMENT OF SEXUAL DYSFUNCTIONS IN THE DIABETIC MAN

D. RECOMMENDATIONS

I. DIAGNOSIS OF TESTOSTERONE DEFICIENCY
II. TESTOSTERONE THERAPY
III. CONTRA-INDICATIONS AND CAUTIONS FOR USE
IV. MONITORING TESTOSTERONE THERAPY
V. OTHER HORMONES LIKELY TO PLAY A ROLE IN MALE SEXUAL DYSFUNCTIONS
Hormones play an essential role in cellular dialog. Testosterone is the main hormone involved in the complex dialog between the brain and peripheral organs controlling male sexual function. Its presence is a prerequisite for erection in laboratory animals. Testosterone modulates multiple mechanisms involved in the erectile machinery, including expression of the enzymes that both initiate (Nitric Oxide Synthase) and terminate (Phosphodiesterase type V) erection. In addition it is essential for sexual motivation. Whether this well established animal data could be completely extrapolated to human erections is still a subject of controversy. Testosterone plays also a broader role in overall men’s health. Many recent studies have established strong associations of low testosterone with metabolic imbalances. These may partly result from the lowering effect of obesity on blood testosterone but low testosterone predicts diabetes and metabolic syndrome occurrence in lean men too. One example is the metabolic damage that follows androgen deprivation for treatment of prostate cancer. Likewise associations of low testosterone levels with cardiovascular disease and in some studies decreased longevity have been repeatedly reported and might be a consequence of the detrimental impact of low testosterone on metabolic functions. Low testosterone has also been reported to predict depression. However conflicting data do also exist: longitudinal studies do not support the predictive value of low blood testosterone for further cardiovascular events, and available interventional studies do not confirm a beneficial effect of testosterone therapy on depression of aging men (though they were of short duration). Prospective interventional studies of sufficient power and duration are therefore required before screening for testosterone deficiency and correcting it may be considered as preventive medicine as many data suggest.

The aim of this chapter is:
- To critically evaluate the peer reviewed scientific evidence supporting or refuting the role of androgens in men’s health and aging, especially including sexual health, psychic functions, metabolic balance and vascular health.
- To refine practical recommendations for testosterone deficiency screening, diagnosis and treatment, including a review of testosterone therapy safety, and guidelines for its follow-up
- To review the role of other hormonal and metabolic disturbances in male sexual dysfunctions, including those of estradiol, adrenal steroids, pro-opiomelanocortin derivatives, prolactin, growth hormone and thyroid hormones, and when justified to provide the reader with practical guidelines for screening for, diagnosing and treating such abnormalities.

This chapter has been drawn up in starting from two previous comprehensive reviews of the covered topics: the report of the committee “Endocrine Aspects of Men Sexual Dysfunctions” of the second consultation on Sexual Medicine held in Paris in July 2003 by Morales et al (1), and the chapter “Hormones, Metabolism, Aging and Men’s Health” of the book “Standard Practice in Sexual Medicine” published in 2006 by the Standard’s Committee of the International Society for Sexual Medicine (Buvat et al 2006, [2]). The readers may find more developments on the basic aspects of the corresponding topics in these reviews and in others mentioned in our chapter.
A. TESTOSTERONE

I. PHYSIOLOGICAL REMINDER

Levels of T are expressed either in pmol or nmol/L or in pg or ng/ml (1000 pg or pmol = respectively 1 ng or nmol. The conversion factors are nmol/L or pmol/L x 0.2884 = respectively ng/ml or pg/ml, and ng/ml or pg/ml x 3.467 = respectively nmol/L or pmol/L (Table I).

1. SECRETION, TRANSPORT,

Testosterone (T) is synthesized by an enzymatic sequence of steps from cholesterol within the Leydig cells. T biosynthesis involves 2 multi-functional cytochrome P450 complexes involving hydroxylations and side-chain cleavage together with 3 and 17 ß-hydroxysteroid dehydrogenases and ∆4,5 isomerase. Testicular T secretion is principally governed by luteinizing hormone (LH). T (and its androgenic metabolite, dihydrotestosterone (DHT), exert biological effects directly through binding to the androgen receptor and indirectly through aromatization of T to estradiol (E₂), which allows action via binding to the estrogen receptors (ERs).

T circulates in blood at concentrations above its aqueous solubility by binding to several plasma proteins, especially sex-hormone binding globulin (SHBG), with a single high-affinity androgen binding site. SHBG is secreted by the liver, so its circulating levels are particularly influenced by first-pass effects of oral drugs including sex steroids. Circulating SHBG (and thereby total T) are decreased by androgens and glucocorticoids or increased by estrogens and thyroxine. Other determinants of circulating SHBG levels are up-regulation by acute or chronic liver disease and androgen deficiency and down-regulation by obesity, insulin, and growth hormone (GH) deficiency. Under physiological conditions, 60-70% of circulating T is SHBG-bound with the remainder bound to lower-affinity, high capacity binding sites (albumin) and 1-2% remaining non-protein bound. According to the free hormone hypothesis (38-40), the “free” (non-protein-bound) fraction is capable of diffusing into the target cells and binding to its receptor. This is the most biologically active fraction while the loosely protein-bound T constitutes a larger “bioavailable” fraction of circulating T. Circulating T levels demonstrate a distinct diurnal rhythm. Diurnal patterns of morning peak T levels and nadir levels in afternoon are evident in younger men but this pattern is lost in some older men (3,4).

2. AGING AND TESTOSTERONE SECRETION

Plasma levels of total, bioavailable and free T fall with aging (4). Even though age itself impacts on the decline of plasma T over the lifetime (4), ill health, more than age itself, is a potent predictor of a decline in T levels in a man’s life (5,6). Chronic illness, a high body mass index (BMI) and a large waist circumference are related to a significant decrease in total, free and bioavailable T concentrations. Apparently healthy men have significantly higher

Table 1: Conversion factors for hormones

| - Testosterone          | 1 ng/dl = 100 ng/ml, 1 ng/ml = 1000 pg/ml, 1 nmol/l = 1000 pmol/l |
|                        | 1 nmol/l = 0.2884 ng/ml = 28.84 ng/dl                           |
|                        | 1 ng/dl = 0.03467 nmol/l ; 1 ng/ml = 3.467 nmol/l              |
|                        | 7 nmol/l # 200 ng/dl, 8 nmol/l = 231 ng/dl, 10 nmol/l = 288 ng/dl, |
|                        | 10,4 nmol/l = 300 ng/dl, 12 nmol/l = 346 ng/dl, 14 nmol/l = # 400 ng/dl |

| - Free testosterone    | 1 pg/ml = 3,467 pmol/l                                       |
|                        | 1 pmol/l = 0,2884 pg/ml                                    |

| - Estradiol            | 1 pg/ml = 3,671 pmol/l                                     |
|                        | 1 pmol/l = 0,2724 pg/ml                                    |

| - Prolactin            | 1 ng/ml = 20 mU/ml                                         |
median hormone concentrations at most time points than unhealthy men (7). The decline of plasma T begins in fact in the fourth decade. There is a constant percent change per year between ages of 39-70 years. Free T declines by 1.2%/year, and albumin-bound T by 1.0%/year. SHBG, the major serum carrier of T, increases by 1.2%/year, with the net effect that total serum T declines more slowly (0.4%/year) than the free or albumin-bound pools alone, so the total testosterone level is less accurate in older men.

3. PHYSIOLOGICAL EFFECTS OF TESTOSTERONE

a) effects on sexual function:

The testis is the key organ for male reproductive and sexual fitness. A T-based, gender-related, dichotomy is an essential condition for life perpetuation, allowing the male to be always ready to take advantage of sexual (and therefore reproductive) opportunities. In fact, while in women sex steroids substantially fluctuate as a function of ovarian cycles, in men T plasma levels are relatively constant and high, because of a continuous testicular production. In adult life, T is considered the hormonal fuel of sexual desire but it also regulates all the other steps of the male sexual response, including sexual excitation and orgasm/ejaculation. Androgen receptor (AR) is highly expressed in the brain, mainly in the hippocampus, cerebral cortex and hypothalamus, and in peripheral target tissues involved in excitation (pelvic floor muscles, penis) and ejaculation (epididymis, seminal vesicles, vas deferens and prostate). Low T is often associated with reduced sexual desire and nocturnal penile erections, while association with sex-induced erection is less evident. This is because T regulates not only cyclic Guanosine-Monophosphate (cGMP) formation, through nitric oxide synthase (NOS) stimulation, but also its catabolism, through phosphodiesterase-5 (PDE5) activity. The androgen-dependent PDE5 expression could explain the reduced effectiveness of PDE5 inhibitors (PDE5i) in the treatment of erectile dysfunction in hypogonadal patients. The main physiological action of T is therefore to timely adjust the erectile process as a function of sexual desire, therefore finalizing erections to sex. Accordingly, penile erection is not a random phenomenon but a discrete, timely adjusted event, consequent to sexual desire and arousal (2,8-10).

b) effects on other functions

The by consensus recognized signs and symptoms of Testosterone Deficiency (TD) include not only sexual dysfunction, but also depressed mood, decreased vitality, decreased lean and increased fat body mass, decreased bone mineral density and osteoporosis (11). TD has been recently considered one of the many adverse consequences of overweight and obesity. On the other hand, low T levels could contribute to the accumulation of excess fat, establishing a vicious cycle. Pathogenetic mechanisms linking hypogonadism with obesity and insulin resistance appear to be complex and often multi-directional. In fact, visceral obesity can probably be considered a relevant cause of hypogonadism (directly or through obesity-induced insulin resistance); at the same time, hypogonadism could be a cause of obesity and insulin resistance (2,10).

II. PATHOPHYSIOLOGICAL ASPECTS

1. CLASSIFICATION OF TESTOSTERONE DEFICIENCIES (FIGURE 1)

The classic taxonomy of TD includes defects of various nature and degree occurring at various levels of the hypothalamus-pituitary-testis axis. TD can be caused by an abnormality in the testicles (primary hypogonadism/TD), by a pituitary or hypothalamus failure (secondary hypogonadism/ TD) or by a combination of the two (mixed hypogonadism/TD). In addition a clinical TD could result from any impairment to T action because of

Figure 1: Characteristics of male hypogonadism/testosterone deficiency, reported according to the age of onset of the disease and the patient’s phenotype. Schematic prevalence in male population is also shown. Size of ellipsis reflects on abscissa (log scale): age of onset and on ordinates (log scale): incidence (right axis) or female to male phenotype (left axis, arbitrary unit). VEOH: very early onset hypogonadism/testosterone deficiency (red ellipsis), i.e. starting during foetal life for absence of testosterone formation or activity (examples are: Leydig cell hypoplasia type 2, complete androgen insensitivity or absence of 17β-hydroxysteroid dehydrogenase, yellow ellipsis) or impaired secretion or activity of GnRH (for causes see Table 1). EOH: early onset hypogonadism/testosterone deficiency (i.e. peri-pubertal onset, as in Klinefelter’s syndrome, blue ellipsis). LOH: late onset hypogonadism/testosterone deficiency, i.e. in adulthood or aging (also termed andropause, grey ellipsis). Adapted from Morelli et al 2007(12)
increased SHBG and decreased bioavailability or because of Androgen Receptor (AR) alterations. Causes of hypogonadism are listed in Table II. The nosography depicted in Table II retains a practical utility for treatment purpose. In fact, while patients with hypothalamic or pituitary causes of testis failure (secondary hypogonadism/TD) can be successfully treated with either gonadotropins/GnRH or T, for those affected by primary testicular failure (primary hypogonadism/TD), only T must be considered. However, this classification does not take into consideration symptoms. It is well known that both primary and secondary hypogonadism, if not treated, are characterized by symptoms and signs of different severity, according to the age of onset of testicular failure more than the cause of this failure. In the case of a very early onset hypogonadism (VEO), i.e. during early foetal life, symptoms can be dramatic, spanning from an almost complete female phenotype (complete androgen insensitivity or enzymatic defects blocking androgen synthesis) to various defects in virilization (micropenis, hypospadias, cryptorchidism), as in the case of impaired secretion or activity of gonadotropins or GnRH (Figure 1), (12). In the case of a peri-pubertal appearance of the hypogonadism (early onset hypogonadism/TD, EOH), because of milder central or peripheral defects (as in Klinefelter’s syndrome), there might be a delay in the onset of puberty with an overall eunuchoidal phenotype, including scant body hair, high-pitched voice, small testis, penis and prostate (Figure 1). On the other hand in the case of a post-pubertal onset hypogonadism/TD, due to any reason, symptoms will be relatively mild, insidious and difficult to be recognised. Generally speaking, however, the incidence of hypogonadism due to known aetiologies is not so frequent. EOH and, in particular; VEOH are often due to rather uncommon problems (although not so rare, spanning from 1:500 for Klinefelter’s syndrome to 1:100000 for complete androgen insensitivity syndrome). A more frequent form of post-pubertal TD is the so called age-related hypogonadism/TD (11) defined as late onset hypogonadism (LOH) or TD Syndrome (TDS), a condition affecting aging health with an unknown aetiology and natural history, which often results from a mixed contribution of testicular and hypothalamic-pituitary failure. In addition TD in adult life is often co-morbid to several often-present conditions as obesity, type 2 diabetes mellitus, use of medications and chronic illnesses. Whether TD is the cause or the consequence of these associated conditions is still a matter of intense debate.

2. THRESHOLD LEVELS FOR TESTOSTERONE ACTION AND THE IMPORTANCE OF RECEPTOR SENSITIVITY

A clear-cut threshold for TD has not been agreed upon. Rather, recent evidence demonstrates the prevalence of psychosomatic symptoms and metabolic risk factors gradually accumulates with decreasing androgen levels. Androgen-related loss of libido or vigor increases below T concentrations of 15 nmol/L, accumulation of visceral fat below concentrations of 12 nmol/L, whilst depression and type 2 diabetes mellitus (also in non-obese men) are augmented in men with T concentrations below 10 nmol/L (Figure 2). Erectile dysfunction has been identified as a composite pathology of metabolic risk factors, smoking and depression, and T concentrations contributed to that symptom only below 8 nmol/L (13).
Table II: Etiology of male hypogonadism. The typical hormonal pattern is reported in brackets. Note that conditions reported in italics are only characterized by impaired sperm production and not by abnormal testosterone synthesis and/or activity. KAL-1: anosmin or Kallmann protein; FGFR-1: fibroblastic growth factor receptor-1; PROK-2: prokineticin-2; PROKR-2: prokineticin-2 receptor, GnRH: gonadotrophin releasing hormone; GPR-54: g-protein-coupled receptor-54; DAX-1: dosage-sensitive sex reversal congenital adrenal hypoplasia critical region on the X chromosome-1; SF-1: steroidogenic factor-1; HESX1: HESX homeobox 1; PROP-1: prophet of Pit1, paired-like homeodomain transcription factor; LHSX3: LIM homeobox 3; GnRHR: gonadotrophin releasing hormone receptor; FSHR: follicle-stimulating hormone β-subunit; LHβ: luteinizing hormone β-subunit; STAR: steroidogenic acute regulatory protein; 3β-HSD: 3β-hydroxysteroid dehydrogenase; 17α-HSD: 17α-hydroxysteroid dehydrogenase; 17β-HSD: 17β-hydroxysteroid dehydrogenase; INSL3: insulin like-3 peptide; LGR8: leucine-rich repeat-containing, G protein-coupled receptor-8, or insulin like-3 peptide receptor; FSHR: Follicle-stimulating hormone receptor.

Synopsis:
1) Decreased testosterone production
   - Hypothalamic diseases (secondary or central hypogonadism)
   - Pituitary diseases (secondary or central hypogonadism)
   - Testicular diseases (primary hypogonadism)
2) Decreased testosterone bioactivity

1) Decreased testosterone production
   a) Hypothalamic diseases (secondary hypogonadism: ↓gonadotrophins, ↓testosterone)
      - Congenital
         i) Kallmann syndrome (including KAL 1, FGFR1, PROK2, PROKR2 mutations)
      ii) GnRH gene deletion
   III) Leptin and Leptin receptor mutation
   IV) GPR-54 mutation
   V) Prohormone convertase 1 mutation
   VI) DAX-1 mutation
   VII) SF-1 mutation
   VIII) Septo-optic dysplasia (including Hesx-1 mutation)

IX) Prader-Willi syndrome
X) Laurence-Moon syndrome
XI) Bardet-Biedl syndrome
   - Acquired
   I) Hypothalamic tumors
      - Germinomas and other germ tumors
      - Gliomas
      - Astrocytomas
      - Craniopharyngiomas
      - Meningioma
      - Metastases
   II) Infiltrative and infective disorders
      - Langerhans' histiocytosis
      - Sarcoïdosis and tuberculosis, syphilis
      - Fungal, parasites, viral
   III) Head trauma
   IV) Empty sella
   V) Vascular
   VI) Drugs
      - GnRH analogs (agonists and antagonists)
      - Estrogens
      - Anabolic steroids
      - Progestogens (including cyproterone acetate and spironolactone)

XII) X-irradiation

2) Decreased testosterone bioactivity
   a) Pituitary diseases (secondary hypogonadism: ↓gonadotrophins, ↓testosterone)
      - Congenital
         I) Multiple hormone deficiency (including Prop1, LHX3, DAX-1 mutations)
      II) GnRHR mutations
      III) FSHβ and LHβ mutations
      IV) Pituitary aplasia or hypoplasia
   V) Hemochromatosis
      - Acquired
      I) Pituitary tumors
         - Functional and non-functional adenomas
         - Craniopharyngiomas
         - Metastases
         - Hematologic malignancy
         - Rathke's cyst
      II) Infiltrative
         - Primary hypophysitis
         - Sarcoïdosis and tuberculosis, syphilis
         - Fungal, parasites, viral
      III) Head trauma
      IV) Empty sella
      V) Vascular
      VI) Drugs
         - GnRH analogs (agonists and antagonists)
         - Estrogens
         - Anabolic steroids
         - Progestogens (including cyproterone acetate and spironolactone)
   
   b) Testicular diseases (primary hypogonadism: ↑gonadotrophins ± ↓testosterone)
      - Congenital
         I) Klinefelter syndrome
      II) Defects of testosterone biosynthesis (STAR, 20-22 desmolase, 3β-HSD, 17α-HSD, 17-20 desmolase, 17β-HSD)
      III) Pure gonadal dysgenesis (46 XX and 46 XY)
      IV) Congenital anorchia
   V) Leydig cell hypoplasia (including type I and II for LH/HCG receptor mutations)

- Metabolic syndrome
- Cushing Disease
- Estrogens
- Anabolic steroids
- Progestogens (including cyproterone acetate and spironolactone)
- Functional disorders
- Nutritional
- Critical illness
- Excessive exercise (rare)
- Diabetes Mellitus
- Hyperprolactinaemia (prolactinoma, hypothyroidism, antidopaminergic and serotoninergic drug-induced, opiates-induced)
- Metabolic syndrome
- Cushing Disease

- Medical conditions characterized by impaired sperm production and not by abnormal testosterone synthesis and/or activity. KAL-1: anosmin or Kallmann protein; FGFR-1: fibroblastic growth factor receptor-1; PROK-2: prokineticin-2; PROKR-2: prokineticin-2 receptor, GnRH: gonadotrophin releasing hormone; GPR-54: g-protein-coupled receptor-54; DAX-1: dosage-sensitive sex reversal congenital adrenal hypoplasia critical region on the X chromosome-1; SF-1: steroidogenic factor-1; HESX1: HESX homeobox 1; PROP-1: prophet of Pit1, paired-like homeodomain transcription factor; LHSX3: LIM homeobox 3; GnRHR: gonadotrophin releasing hormone receptor; FSHR: follicle-stimulating hormone β-subunit; LHβ: luteinizing hormone β-subunit; STAR: steroidogenic acute regulatory protein; 3β-HSD: 3β-hydroxysteroid dehydrogenase; 17α-HSD: 17α-hydroxysteroid dehydrogenase; 17β-HSD: 17β-hydroxysteroid dehydrogenase; INSL3: insulin like-3 peptide; LGR8: leucine-rich repeat-containing, G protein-coupled receptor-8, or insulin like-3 peptide receptor; FSHR: Follicle-stimulating hormone receptor.
of onset of the disease. In a consecutive series of 1647 (mean age 52.4±13.1 years) male patients with sexual dysfunction (and therefore potentially with TD) it was found that parameters significantly associated with total and free T levels in the entire cohort were waist circumference and triglyceride levels, as well as an increased prevalence of metabolic syndrome (10). The prevalence of hypoactive sexual desire (HSD) decreased as a function of T only in the youngest (17-42 years old) age quartile, as well as the reported reduction in nocturnal erections. In the oldest age quartile it was reported an inverse relationship between T levels and the prevalence of severe erectile dysfunction (ED) and a positive relationship with intercourse frequency. Accordingly, in the oldest age quartile, subjects with higher T levels showed better penile flow at penile colour Doppler ultrasound, as well as a better lipid profile. An inverse association between somatized anxiety and T levels was observed only in the oldest age quartile. It is interesting to note that from this study (10) low testosterone was associated with sexual dysfunction more often in the oldest subjects.

### III. Metabolic Syndrome and Metabolism

Metabolic syndrome (MetS) is a clustering of conditions that increases the risk of type 2 diabetes mellitus (T2DM: a clinical condition characterized by high levels of sugar in the blood and insulin resistance) and cardiovascular disease. The MetS components involve abnormalities of glucose metabolism, body composition, blood pressure, HDL cholesterol, and triglycerides. There are several definitions of the MetS (see in Table III and Guay 2008 [15], and Corona et al. 2009 [10] for reviews), although "android obesity" - nowadays known as "central or visceral obesity" – and insulin resistance are generally considered the key elements of MetS (16). Term insulin resistance underscores the inability of insulin to promote normal homeostasis of glucose, i.e a higher-than-normal concentration of insulin in order to maintain normal glycaemia and appropriate glucose utilization.

Over the last few years, the association between insulin resistance, T2DM, MetS and TD has emerged as an issue in subjects both with (17-22) and without ED (23,24). The evidence, in fact, universally shows a strong relationship between TD and MetS, and its individual components (figure 3), both in cross-sectional and longitudinal studies. Cross sectional studies have demonstrated an association between low T concentrations and T2DM since the 1990s (studies reviewed in Ding et al., 2006 [25]). In addition, prospective studies have clearly demonstrated that a low T at baseline could predict the development of T2DM (6,26-28) or both T2DM and MetS (29, 30); see for review Corona et al., 2009 a et b, Traish et al., 2008 a et b (10, 22, 23, 31). Moreover, it has also been reported that T2DM and MetS at the baseline could predict the development of TD (32-34).
TD is characterized by hypertriglyceridaemia-waist phenotype (see in Corona et al., 2009 [10] for review). Elevated waistline and triglycerides are the factors, among MetS determinants, most closely associated with insulin resistance. Interestingly, a strong inverse relationship between SHBG-unbound testosterone and pulse pressure (PP) was recently reported (35). Pulse pressure is the arithmetic difference between systolic and diastolic blood pressure and reflects arterial stiffness, another marker of insulin resistance. Cross-sectional studies have also demonstrated that MetS is associated with an increased prevalence of sexual dysfunctions, essentially characterized by worse erectile function, due to impairment in penile blood flow (36-43).

For all these reasons, men with MetS should have a T level drawn and men with TD should be evaluated for components of MetS, as these may foreshadow both diabetes mellitus and cardiovascular disease.

The effect of T therapy (Tth) in TD subjects is still a controversial issue. According to two recent meta-analyses, Tth exerts only small and clinically negligible effects on lipid fractions and blood glucose, whatever the baseline T level (44, 45). In addition, Tth is unlikely to improve the age-associated deterioration in glucose tolerance commonly observed in elderly men. However, Tth seems to improve insulin sensitivity and glycemic control in hypogonadal men with T2D or MetS (46-50).

| Table III: Diagnostic Criteria for the Metabolic Syndrome in Men According to Various Definitions (reprinted with permission from Traish AM, Guay AT et al 2009 [22]) |
|-------------------------------------------------|---------------------------------|---------------------------------|
| Components of the MetS | WHO: Criteria #1 + 2 of the other 4 | NCEP–ATP III: ≥ 3 of 5 criteria | IDF: Criteria #2 + 2 of the other 4 |
| 1. Hyperglycemia Hyperinsulinemia | FBS ≥ 110 mg/dL (≥ 6.1 nmol/L) ↑ insulin or IR or T2DM | FBS ≥ 110 mg/dL (≥ 6.1 nmol/L) or T2DM | FBS ≥ 100 mg/dL or T2DM |
| 2. Increased Body Size | WHR > 0.90 WC ≥ 94 cm BMI ≥ 30.0 | WC ≥ 102 cm | WC ≥ 94 cm |
| 3. Triglycerides | ≥ 150 mg/dL (≥ 2.3 mmol/L) | ≥ 150 mg/dL (≥ 2.3 mmol/L) | ≥ 150 mg/dL (≥ 2.3 mmol/L) |

49), though this data has still to be confirmed with more controlled trials. Weight loss and exercise ameliorate not only glycaemic control and prevent T2DM but can also raise androgen levels, as found in some studies in obese men (50-54). However, negative studies have also been reported (55,56). Nonetheless, life-style modifications should be strongly encouraged in subjects with MetS, because it has been demonstrated that in a Finnish cohort followed longitudinally for 11 years, those having MetS at baseline but not at follow-up, did not retain a statistically significant risk of having hypogonadism (32).

Experimental studies in human and animal models have recently helped in understanding the vicious circle underlying the positive interaction between MetS and TD, which is summarized in Figure 4. AR is mostly expressed in visceral fat and negatively regulates differentiation of preadipocytes to mature adipocytes (57). In addition, androgens might decrease fat mass by regulating the differentiation of mesenchymal stem cells to adipocytes (58). In humans, T acutely inhibits oleic acid uptake in omental and retroperitoneal, but not subcutaneous, adipose tissue, acting through lipoprotein lipase (59). In a recent study involving 60 aging males, testosterone therapy for 1 year, in comparison with placebo, selectively reduced visceral fat accumulation without modifying total body composition, while increasing fat-free mass and skeletal muscle mass (60). Overall, these studies demonstrate that the androgenic milieu can affect visceral fat disposition and that this action is rapid and maintained over the long term.

Lin et al. (61) demonstrated that male but not female androgen receptor (AR) knockout (ARKO) mice are characterized by progressively reduced insulin sensitivity and impaired glucose tolerance with advanced age. In addition, recent evidence (62,63) demonstrated that the specific deletion of hepatic AR is associated with the development of insulin resistance and liver steatosis in male but not female mice, suggesting a different tissue-specific role of AR in males. A mixed (primary and secondary) TD could be then considered one of the many adverse consequences of overweight and obesity. Which molecule plays the major role in this vicious circle is still unknown but reasonable candidates are estrogens, insulin, leptin, TNFα or other adipokines. Insulin can directly signal with the hypothalamus by increasing GnRH synthesis and release (64). Accordingly, patients with T2DM showed a higher prevalence of hypogonadotropic hypogonadism (65,66) and in a mouse model of central depletion of the insulin receptor the phenotype recapitulates MetS and hypogonadotropic hypogonadism (67). Data from morbidly obese men indicate that LH levels and pulse amplitude were attenuated as compared to normal weight controls (68,69). Because P450 aromatase is highly expressed by fat tissue, obesity is considered a clinical condition characterized by a relative abundance of estrogens. In fact, increased aromatisation of androgens by fat stores increases estrogen levels, which, in turn, will decrease LH secretion for a negative feedback on both hypothalamus and pituitary. In a recent study it has been demonstrated that a weekly low

![Figure 4: Proposed interactions between increased visceral fat and hypogonadism](image-url)
dose (2.5 mg) of the aromatase inhibitor letrozole can restore testosterone levels and increase LH levels in severely obese hypogonadal men (70). Overall these experimental evidences indicate that an increased visceral fat and insulin resistance can decrease the activity of hypothalamic pituitary signalling to the testis. However there are data suggesting that also the testis itself could be less sensitive to gonadotrophin stimulation in MetS: Pitteloud et al (71,72) demonstrated that hCG-stimulated T levels are positively correlated with insulin sensitivity. Insulin itself is capable of stimulating T production and, simultaneously, of inhibiting SHBG concentration (73). Hence, insulin resistance associated with obesity could contribute to low testosterone levels seen in obese men, for a direct effect on the testis (71). Leptin, the adipocyte-derived adipokine product of the ob gene, circulates in plasma at concentrations that parallel the amount of fat reserves. Leptin receptors are present in testicular tissue and an excess of leptin circulating levels may contribute to the development of reduced androgens in male obesity (74,75). Obesity is characterized by an increase in circulating TNFα levels as a consequence of inflammatory cascade activation. Morales et al. (76) demonstrated that intratesticular TNFα delivery was associated with a blunted T response to the hCG stimulation, suggesting a possible contribution of this molecule in the obesity-associated-hypogonadism. In addition to a peripheral role, TNFα can also inhibit LH release acting at the pituitary or hypothalamic level (77). Pathogenetic mechanisms linking hypogonadism with obesity and insulin resistance appear to be complex and often multi-directional., Figure 4 summarizes the proposed interactions between obesity (increased visceral fat) and hypogonadism, based on the aforementioned evidence.

**IV. TESTOSTERONE AND CARDIOVASCULAR HEALTH:**

Coronary Heart Disease (CHD), the commonest cause of death worldwide, is more common in men than in women, which suggests an unfavourable effect of the male sex hormone testosterone on the cardiovascular system. Among over 30 cross-sectional studies which examined the possible associations between T levels and CHD (reviews in 10, 78-82), none found an association of high T levels with CHD. Conversely about half found lower T levels in the patients with CHD (78). Other cross-sectional studies found inverse correlations of T levels with aortic atherosclerosis (83), peripheral arterial disease (84), and Intima Media Thickness (IMT) (85-88) or plaque area in the carotid artery (88).

Seventeen prospective cohort or nested case controlled studies have also examined the relationship between T levels and cardiovascular morbidity and mortality. In 10 studies there was no correlation between baseline T levels and subsequent development of fatal or non fatal CHD, cerebro-vascular disease, or heart failure after adjustment for confounders, during observation periods of 5 to 31 years (88-97,99). Weak correlations of high androgen levels with cardiovascular mortality were observed in 1 study (98). Conversely 2 studies reported significant correlations between low baseline T levels and cardiovascular deaths (100,101), and 2 others between low baseline T and progression of carotid artery IMT (102) or between low T and an increased incidence of stroke or transitory ischemic events (103). However, 2 other prospective studies did not confirm the correlations with IMT progression (88), and with an increased risk of stroke (89). Lastly, the Caerphilly study found a positive association of the cortisol/testosterone ratio with CHD incidence and mortality (104).

**Taken together, these observational studies do not provide a consistent evidence of a relationship between circulating T and incident or existing CVD in men though T is often low in men with CVD in the cross-sectional studies.**

**Observation of men treated for prostate cancer with Androgen-Deprivation-Therapy (ADT)** may help to understand the effects of severe hypogonadism. Several prospective studies have shown that such men develop within 3 to 6 months increased fat mass and insulin resistance (105,106), while longer administration does not seem to result in further accumulation (107). Cross sectional studies after 12 months of ADT show an increased prevalence of T2DM and MetS (106,108-110). In addition ADT seems to be followed by an increase in CV morbidity (109) reaching 20% over 12 months (111) and mortality. At least where mortality is concerned, this effect seems very rapid, but shows no further increase with prolongation of ADT (112-114) and D’Amico et al (113) found no higher overall rate of fatal MIs in the long-term.

**Current available evidence suggests that T therapy in men over 45 years is not associated with an important increase in CV adverse events.** Two meta-analyses of RPCTs (45,115) found no significant difference between the T and placebo groups for all CV events, nor for each type of event, except an increase in hematocrit over 50% which was significantly more prevalent in the T group (115) (Table IV), and might augment the risk of thrombosis. However, many RPCTs included in the 2 meta-analyses enrolled only small numbers of men, often healthy, during short durations. Larger trials, measuring CV endpoints and enrolling men with CVD for longer durations, are needed to be sure of the CV consequences of T therapy in the medium and long terms.
Interventional studies have tested the effects of T in men with CHD. Acute administration reduced peripheral vascular resistance, cardiac afterload and increased cardiac index (116). Injecting supraphysiological doses of T into the left coronary artery led to a dose-dependent vasodilatation and increased coronary flow, but this effect was not observed with physiological doses (117). These effects were mediated by non genomic, endothelium-independent mechanisms. Acute administration of intravenous T also improved exercise tolerance and reduced the angina threshold in men with stable CHD/angina (117,118).

Chronic administration of low physiological doses of T has also been beneficial. Four RCTs (119-122) reported short-term improvements in ECG changes of CHD with respect to placebo, including longer exercise time to ischemia, after a maximum of 12 weeks of T supplementation. T therapy also substantially improved cardiac condition in 2 RCTs of men with heart failure (123,124). Direct effects of T on male vasculature could explain these acute and chronic findings.

T seems to exert mostly beneficial effects on classical cardiovascular risk factors. The favourable effects of exogenous T administration on body composition (increase in lean mass and decrease in fat mass, especially in visceral adiposity, associated with CV morbidity and mortality), have already been mentioned. These effects may contribute to the improvement in glycemic control and insulin sensitivity observed in some RCTs of T therapy in hypogonadal men with T2DM and hypogonadism (46,47). The effects of physiologic doses of TT on lipids and lipoproteins are negligible (44), except the possibility of a slight but significant decrease of both total, LDL and HDL cholesterol on IM injections of T esters, that may be explained by the higher levels of circulating T that these injections may induce (125). T therapy also decreases lipoprotein (a) (126), an independent risk factor for atherosclerotic diseases (78). With concerns to endogenous T, low T in men seems to be a component of the Metabolic Syndrome, characterized by obesity, T2DM, hypertension, hypertriglyceridemia, low HDL cholesterol and a procoagulatory and antifibrinolytic state (10,78).

The main hemostatic parameters associated with cardiovascular risk are fibrinogen, plasminogen activator inhibitor type 1 (PAI-1) and plasmin-alpha-2-antiplasmin complex (PAP) (78). T shifts the hemostatic balance towards decreased coagulation. Plasma levels of fibrinogen (127) and of the antifibrinolytic PAI-1 (128) are inversely correlated with levels of androgens in men. Hypogonadal men have low fibrinolytic activity, due to increased synthesis of PAI-1 (129). Intramuscular T significantly down-regulates fibrinolysis and the hemostatic turnover rate, as concentrations of PAP decrease markedly (130). However potentially detrimental effects of T on platelets have been suggested including increased expression of platelet thromboxane-A2 receptor and increased platelet aggregation response, leading to the recommendation of associating anti-platelet therapy with aspirin in patients with CHD taking exogenous T (80).

Data on the relationship between T and blood pressure are inconsistent. There is substantial evidence that androgens play a role in determining sex-specific blood pressure, which is higher in men, at higher risk of developing hypertension. Experimental data suggests that despite the decrease in vascular tone resulting from acute administration of T, the long-term net effect of androgens may be vasoconstriction, via up-regulation of thromboxane A2 expression, norepinephrine synthesis, angiotensin II expression and endothelin-1 action. Furthermore androgens promote vascular remodeling, and stimulate renal pro-hypertensive processes involving the renin-angiotensin-aldosterone system. Androgens seem

also to promote oxidative stress in the kidney (131). However in population studies both systolic and diastolic blood pressures are inversely correlated with T levels (132). Men with prostate cancer undergoing ADT develop an elevated central artery pressure due to decreased arterial relaxation (133). Though T therapy has not been shown to affect blood pressure in RPCTs, low T levels have been shown to be associated with arterial stiffness (134,135). Pulse wave velocity, a measure of arterial stiffness, is ameliorated by normalization of T levels (135). There is therefore no contraindication to Tth in men being treated for hypertension.

**Sex steroid hormones may exert direct effects on the arterial wall** since the human vascular smooth muscle, endothelial cells, macrophages and platelets, contain receptors and converting enzymes needed for the genomic effects of T and estradiol (E2), and the local production of E2 (78).

Both beneficial and detrimental consequences may be expected from these effects (table V). Decreased **vascular responsiveness** is an early marker of atherosclerosis. This may be the result of endothelial dysfunction or of endothelium-independent disturbances in vascular smooth muscle. As a result decreased vasodilation and enhanced vasoconstriction can lead to vasospasm and angina. In addition endothelial dysfunction also contributes to coronary events by promoting plaque rupture and thrombosis (78). Akishita et al (136) found that low T is an independent determinant of endothelial dysfunction in men. T might especially be involved in endothelial repair since low T is associated with a low number of endothelial progenitor cells in young hypogonadal men (137), while T replacement is able to normalize their count (138). Sex steroid hormones and more especially T might in fact modulate most clinical and biochemical markers of endothelial dysfunction (139).

**Flow-mediated dilatation (FMD)** measured in the brachial artery is used to investigate endothelial-dependent arterial dilatation. In men with CHD, some short term studies of supra-physiologic doses of T increased FMD in brachial artery, which reflects increased nitric oxide release (140). Long term T therapy with physiological dose also improved NO mediated brachial artery vasodilatation in one study (141). Brachial artery reactivity correlates closely with coronary arterial endothelial dysfunction. These findings may therefore support the concept of T having a beneficial effect on coronary endothelial dysfunction (141). However more data support negative effects of T on vascular reactivity (79): for example FMD of brachial arteries is higher in androgen-deprived (142) and in hypogonadal patients (143). In the latter it is significantly reduced following T therapy. The sensitivity to T (CAG repeat polymorphism in the AR gene) is inversely associated with the endothelium-dependent and independent dilations of brachial arteries (144). High-dose androgens exert adverse effects on the endothelium-independent dilation in female to male transsexuals (145). The diversity of these effects may depend on differences in gender, concomitant diseases, mechanism of action, and dosage of T. **In conclusion T modulates vasoreactivity by both endothelium-dependent and –independent mechanisms, as well as by genomic and non-genomic modes of action.** Physiological concentrations appear to restrict vasodilation by activation of the AR. In contrast supraphysiological or pharmacological doses seem to potentiate vasodilation through non-genomic actions (78).

694
Atherosclerosis involves monocyte adhesion to the vascular endothelium, followed by migration into the arterial wall to form foam cells. Such process requires cell adhesion molecules such as Vascular Cell Adhesion Molecule-1 (VCAM-1). Dihydrotestosterone (DHT), a non aromatizable androgen, increases the expression of the VCAM-1 gene in endothelial cells from human males (79,146). But in the same cells T inhibits VCAM-1 mRNA expression by its conversion to E2. By this latter mechanism T might have beneficial effects on the CV system (147,148). T enhances human endothelial cell apoptosis, another important cellular mechanism in atherogenesis, by a mechanism involving the AR, but not aromatization (79,149,150).

Proliferation and migration of arterial wall’s smooth muscle cells (SMCs) are important steps in the formation of neo-intima and stenoses. In the rat T and DHT stimulate this process while E2 inhibits it (79). In the human male T and DHT stimulate vascular SMC proteoglycan biosynthesis via the AR, suggesting a pro-atherogenic effect (151). In AR-positive vascular SMCs collected from human atherosclerotic aortas, T also markedly induces the human prostate overexpressed protein 1 gene which regulates proliferation of neo-intimal SMC, what suggests a role of T in aortic atherosclerosis (152). However endogenous T has also been shown to limit coronary neo-intima formation in male swine, what suggests a protective role of T in coronary vasculoproliferative diseases such as restenosis and atherosclerosis (153). This diversity of effects may result from gender and species specificities, as well as from the T doses, since for example DHT exerts a biphasic effect on DNA synthesis in human vascular SMC, i.e. stimulation at low concentrations and inhibition at high concentrations (154), or from predominant activation of either AR or aromatization dependent mechanisms.

Macrophages also play a key role in atherosclerosis by migrating into the arterial wall where they internalize exogenous lipids which transform them into foam cells forming the fatty streaks. DHT enhances this process since it increases lipid loading of male macrophages. Conversely T also increases transfer of cholesterol esters from macrophages to high-density lipoproteins (reverse cholesterol transport), which may retard the development of fatty streaks. T treatment of murine macrophages inhibits NO release, what could explain the platelet aggregation and thrombosis risk associated with androgen treatment by eliminating the anti-aggregatory effects of NO (79,81).

In conclusion many data, especially the inverse correlation of circulating T with most classical vascular risk factors, suggest the possibility of a detrimental effect of TD on cardiovascular health. However currently available results of the prospective longitudinal observational studies cannot definitely confirm the role of low T in atherosclerosis, since a positive association was found in only a minority of such studies. Androgens have been shown to both promote and suppress pro-atherogenic and pro-inflammatory effects on all cell types involved in atherosclerosis (table V). Given current evidence it would appear that androgen effects are dependent on cell type, dose, type of androgen, and type of exposure (81). A net effect of T on the arterial wall which would reduce or even delete the vascular benefit resulting from the improvement of the other vascular risk factors might explain the preceding discrepancy. More long term prospective epidemiological studies, as well as large scale, placebo-controlled, randomized trials of T therapy including vascular parameters among the primary end-points are urgently needed to resolve this issue.

V. ROLE OF TESTOSTERONE DEFICIENCY IN SEXUAL DYSFUNCTIONS AND EFFECTS OF TESTOSTERONE THERAPY

1. ERECTILE DYSFUNCTION:

a) Prevalence of testosterone deficiency in erectile dysfunction (155):  
Serum T was below 3 ng/ml (10.4 nmol/l) in 12% of 7000 men with ED compiled from 9 large series (including 4% of 944 men less than 50 years old and 14.7% of 4342 men more than 50 years old). The real prevalence may be lower because most of those men had a single T measurement, sometimes in the afternoon, while circulating T decreases after 11am in normal men, at least up to the age of 40. In one consecutive series of 1022 men with ED, the prevalence of TD, based on 2 consecutive values < 3ng/ml before 11am, was only 6.6%, including 4% before and 9% after 50 years old (156). The prevalence of marked TD (< 2 ng/ml, 7 nmol/l) was even lower: 1.8%, including 0.8% before 50 and 2.6% after 50 years old. In another consecutive series of 2794 men with ED aged 25-80 years, T measured only once, the most often between 07:00 AM and 02:00 PM was < 2 ng/ml in 7%, < 3 ng/ml in 23%, < 3.46 ng/ml in 33%, and < 4 ng/ml in 47% of men (157). Measuring FT or BT may find higher prevalence of low values (up to 37 and 24% respectively of ED patients aged more than 50 years). Among men with ED, the symptoms the most specific of associated TD are HSD, decrease of nocturnal erections, and absence of any erection (12).
b) Basic knowledge on the role of testosterone in erectile function:

1. ANIMAL STUDIES (reviews in Buvat et Bou Jaoude 2006, Traish et Guay 2006, Morelli et al 2007 [9,12,155]): Studies in rodents show that besides its well known effects on the brain centers of sexual function, especially the hypothalamic pre-optic area and arcuate nucleus, T plays a key role in the peripheral modulation of erectile function.

- Testosterone is required for maintenance of penile structure and functional integrity: Androgen suppression via castration results in profound structural changes in penile tissue: apoptosis of the penile cavernosal and spongiosal cells, loss of elastic fibers in the tunica albuginea and, in the corpora cavernosa, of smooth muscle fibers, an essential component of the penis, regulating detumescence and erection. Elastic and smooth muscle fibers are replaced by collagenous fibers, which may result in fibrosis. Alterations in dorsal nerve structure and endothelial morphology, and accumulation of adipocytes in the subcutaneous region of the corpus cavernosum that could impede blood outflow during sexual stimulation and contribute to venous leak are also observed. Thus androgens exert a direct effect on penile tissue, and androgen suppression produces a structural imbalance in the corpus cavernosum which may explain the veno-occlusive dysfunction and ED that occur in orchidectomized animals and are reversed by T administration.

- Testosterone modulates NOS and PDE5 expression in erectile tissue: The Nitric Oxide (NO)-cGMP pathway is critical for initiation and maintenance of erections. In animals, the expression of both the endothelial and neuronal NOS, and therefore the capacity for NO production, is regulated by androgens. Castration results in marked decrease in NOS activity and cGMP formation, through both NOS dependent and independent mechanisms, as well as in marked decrease in the erectile response to pelvic nerve stimulation. T administration normalizes NOS protein expression and activity and restores the erectile response. Therefore the NO-cGMP pathway is T-dependent in rodents.

On the other hand, cGMP, the key intracavernosal signal for the relaxation of the cavernosal smooth muscle and thus erection, is inactivated by the PDE5 present in the cavernous bodies. Following sexual stimulation, PDE5 Inhibitors (PDE5-I) reduce the hydrolysis of cGMP, and allow intracavernosal cGMP accumulation that enhances smooth muscle relaxation and improves the quality of erection. In rodents, castration reduces protein expression and activity of PDE5 and T treatment upregulates it (158,159). In addition, medical or surgical castration prevents the enhancing effect of PDE5I on erections induced by electrostimulation of the cavernous nerves. T seems required for proper functioning of PDE5-Is in animals.

- Critical threshold for the effect of T on erectile function: In castrated rats, erectile function is significantly and positively correlated with T plasma levels in a dose dependent manner, up to a critical threshold corresponding to only 10-12% of normal physiological concentrations ([160]. Above this level, there is no more correlation and erectile function is similar to that of intact animals.

2. STUDIES IN MEN (review in Buvat et Boujaoude [155]):

The effects observed in laboratory animals following a total suppression of T by castration may not be extrapolated without reservation to the consequences of the partial and often mild hypogonadism observed in most hypogonadal men with ED. All the more as men, unlike rats, produce dehydroepiandrosterone. Even in case of castration, this steroid may supply some testosterone following peripheral conversion. Until now the data supporting the importance of T for the intrapenile mechanisms of erection are less substantial in humans. However the expression of PDE5 is also T-dependent in our species (158).

- Sexual function of men with severe organic TD: Data accumulated in such men show that T is required for pubertal acquisition of gender characteristics, as well as adult sexual behaviour and functional capacity, including libido, ejaculation and spontaneous erections. Randomized Controlled Trials (RCTs) of T therapy have shown that sexual desire and arousal are T-dependent and represent the main impact of T on sexual function of men. The frequency of sexual activity and spontaneous erections (especially sleep related, ie morning and nocturnal) are also clearly T-dependent. The psychic erections (ie in response to erotic stimuli) were initially thought to be androgen independent but are in fact partly T-dependent. Ejaculations and orgasm are also partly T-dependent.

- Threshold levels for testosterone effects on sexual function: Trials of T therapy in hypogonadal patients have shown that in humans also, the effects of T upon sexual function are dose-dependent up to a certain serum level from which they are maximum. Below this threshold sexual function is suboptimal. This threshold level is close to the lower limit of the normal adult range. It is consistent within an individual (161,162), but markedly variable between individuals (161-163) and may be specific to each parameter of sexual function. For example, in a study by Kelleher et al the average T level from which they requested a new implantation was 2.6 ng/ml (or 10 nm/l), but the individual levels varied.
from less than 1 to 4.5 ng/ml (162). In another series of hypogonadal males on injectable T esters, the individual threshold level varied from 1.1 to 3.6 ng/ml (161). Overall, levels below 2 ng/ml (7 nmol/l) are in most cases associated with impairment of sexual function and levels below 1.4 to 2 ng/ml with diminished nocturnal erections ([164]. Conversely, from a ceiling level of maximum 4.5 ng/ml, the effect of T is maximum, and not enhanced with additional T supplementation. According to a study by Gray et al (165), the threshold level of the effects of T on sexual function may increase with aging. Lastly there is a grey zone, between 2 and 4.5 ng/ml, in which the impact of T on sexual activity may or may not be maximum according to the sensitivity to androgens of the individual.

- **Correlations between serum T concentrations and sexual function and dysfunction in population studies:** While most men referred for marked organic TD present with low sexual desire and ED, no study found any association between the TT level and the presence and severity of ED, especially in aging men (166-168). Some studies found significant associations of erectile function with FT (169,170) or BT (171) but these studies were not adjusted for age. In a better designed study, Schiavi et al (172) recorded nocturnal erections for 4 consecutive nights in 77 men 45-74 years old, and measured hormones every 20 min during the last night. They also found a significant association between BT, but not TT, and sexual desire and arousal, as well as with the nocturnal erections. But most of the correlations with BT, including those with erections, disappeared after adjustment for age. In such cross sectional studies, no association of T with erectile function persisted when the data were adjusted for age.

- **Impact of testosterone upon the penile mechanisms of erection:** For a long time the main sites of the T effects upon men's sexual function have been considered to be located in the brain. However there are androgen receptors in the human cavernous bodies, and some studies suggest T modulates the vascular mechanisms of erection in men too. Peak systolic velocity (PSV) of the cavernosal arteries, measured following intracavernosal injection of Alprostadil in men with ED, severe TD (T < 2 ng/ml), and no vascular co-morbidity, was significantly lower than the corresponding value of control men with psychogenic ED, and increased up to the range of the psychogenic group following 6 months of T therapy (173). In another study based on Color Duplex Ultrasound (CDU) of the cavernosal arteries, Aversa et al found a highly significant correlation of the resistive index with the serum value of FT ([174]. In a study of 20 arteriogenic ED patients with low normal T non responders to Sildenafil, T therapy significantly enhanced the accelerating effect of Sildenafil on PSV measured in the cavernosal arteries (175). Conversely, in a well designed RPCT by Rochira et al (176), 24 men with severe organic TD (mean age 35±12 years, T < 2 ng/ml, almost undetectable in most cases) and a same number of normal control men underwent Nocturnal Penile Tumescence and Rigidity Monitoring for 3 consecutive nights, with administration of 50 mg sildenafil or placebo at bed time on the third night. The men with TD were tested twice: at baseline and following T therapy for at least 6 months. In those men the single sildenafil administration restored normal sleep related erections to the same extent as 6 months of T therapy, suggesting a relative independence of the peripheral mechanisms of human erections from T. Therefore the few studies of the effects of T on the penile mechanisms of human erections have given inconsistent results.

c) **Effects of testosterone therapy in patients with ED and TD:**

Evaluation of these effects should help to clarify the role of TD in ED.

1. **Testosterone therapy alone:**

T therapy consistently restores erectile function in young patients with organic TD. A meta-analysis by Isidori et al (177) integrated 17 RCTs which had studied the effects of T therapy on male sexual function of men of any age. Sexual Dysfunction (SD) was not a criterion for inclusion. With respect to placebo, a significant but moderate improvement of all aspects of sexual function was observed in the studies of men with low and low normal mean T concentration at baseline (< 12 nmol/L, 3.46 ng/ml). The magnitude of the effect on erectile function (but not on libido) was inversely related to the baseline T concentration. The presence of risk factors for vasculogenic ED (diabetes, hypertension, hyperlipidemia), comorbidities, and shorter evaluation periods were associated with greater treatment effects. The effect of age was not studied in this meta-analysis.

- **T therapy seems less effective in the men whose TD is diagnosed at the occasion of an ED complaint.**

No controlled trial has been specifically devoted to such populations but a compilation of 8 observational studies including 258 such men with serum T < 3 ng/ml (10.4 nmol/l) found that TT definitely improved erectile function in only 36% (155). Such patients are mostly middle-aged or older and their TD is generally mild (serum T is below 2 ng/ml in less than 2% of men consulting for ED) (155). Their profile is different from that of the younger men with organic and often severe TD who constitute a substantial proportion of the populations studied in RCTs. Another meta-analysis of the effects of T therapy on sexual function included only trials devoted to men with SD at baseline (178). The results tend to confirm that the poor effects of T therapy in those men whose TD was diagnosed at the occasion of an ED complaint
may be linked to their higher age. Meta-analysis of the trials that enrolled participants with T levels < 3 ng/ml (10.4 nmol/l) at baseline showed a large and significant effect on libido and a moderate, non significant and inconsistent effect on erectile function. When the studies were subdivided according to men's age, the effect on erectile function proved to be large and significant in the 2 trials having included young patients, and very small and non significant in another 2 studies having included older patients (mean age > 50 years old).

- There are several potential reasons for the poorer effects of T therapy in older men with ED and TD compared with younger ones (155). In addition to the generally lower degree of TD in men consulting for ED, TD is the main cause of ED in the younger patients, while it is generally only one element of a multifactorial ED in the older ones. Vascular factors are predominant among the co-morbidities (156), and hamper the beneficial effects of T therapy since they are more prevalent in the patients not improved with this therapy (179). For that reason combined therapy with T and PDE5-I is often required in such men. PDE5-Is may correct the vascular factors, while T therapy may restore sexual desire, what cannot be done by PDE5-Is. In addition, it recently appeared that T therapy may be required for a PDE5-Is' full efficacy (see below). Other possible explanations for the above discrepancy involve the possibility of too early assessment of the effects of T therapy in certain trials: in a study of 22 hypogonadal ED patients of mean age 58 years treated with injections of T undecanoate, Yassin et Saad (180) observed that improvement of erectile function took longer than 6 weeks in 9 of the 12 markedly improved patients. In addition, the effects of T therapy may depend on the circulating T level that is achieved. This level may depend on the T formulation. In a non randomized prospective study comparing a T gel with injections of T undecanoate, Yassin et Saad (180) observed that mean age 60 years, Saad et al (181) observed on T undecanoate both higher mean T levels (5.3 vs 3.6 ng/ml with the T gel) and higher efficacy as shown by greater increases in the Erectile Function Domain (EFD) of the IIEF.

In an uncontrolled series of 12 men with corporal veno-occlusive dysfunction, considered as one of the most severe aetologies of ED, and low T, who were also treated with T undecanoate, the same authors reported a clinically significant improvement of erectile function associated with a disappearance of the signs of venous leakage at pharmacocavernosometry in 5/12 (179). They speculated on the possibility that veno-occlusive dysfunction of those patients resulted from adipocyte accumulation in penile sub-tunical area of the corpora cavernosa as has been observed in castrated rats. More data are requested to confirm this hypothesis, all the more that pharmaco-cavernosometry is not a totally reproducible investigation (182).

- Another putative explanation of the low success rate of T therapy in older men with ED and low circulating T is that in such patients the low T level may be a consequence rather than the cause of ED (see review in Buvat et al 2006). In two studies by Jannini et al (183) and Carosa et al (184) the low T level increased following successful non-hormonal ED therapies like psychotherapy, intracavernosal injections or PDE5-Is, while in the former study it did not change when such therapies failed. In such cases the reduction in T secretion was likely caused by reduced sexual activity (since this has been shown to stimulate T secretion) and by the stress and depression that often result from ED, through the well known negative impact of the two latter factors on the hypothalamic gonadotropic centers. In an additional study, Carosa et al (185) observed a reduction in the bioavailability of LH in ED patients, that could result from a spacing out of the LHRH pulses via a psychosomatic mechanism since it was also reversible with successful non-hormonal ED therapies.

- Lastly some authors also explain the modest efficacy of T therapy in older men with ED and low total T by the fact that TT may be a poor index of androgenicity. They think that only the bioavailable fractions of T should be taken into account to diagnose hypogonadism after 50 (9). This speculation was never confirmed as concerns the possible impact of T on sexual function. A study found that the success rate of T therapy in the ED patients with low levels of FT or BT was even poorer than that reported in those patients with low levels of TT, especially in the men who had low FT or BT and normal TT levels (155).

2. COMBINATION THERAPY WITH TESTOSTERONE AND PDE5 INHIBITOR IN CASE OF FAILURE OF T THERAPY ALONE

In an uncontrolled study, Greenstein et al (186) treated 48 patients with ED and TD (mean age 60.7y,TT < 4 ng/ml) with a T gel and obtained the unusually high success rate of 64% according to a score of the IIEF-EFD ≥ 26. The authors then combined Sildenafil with the T gel in the patients not improved with T therapy alone, ending in a 100% success rate.

3. COMBINATION THERAPY WITH TESTOSTERONE AND PDE5 INHIBITOR IN CASE OF FAILURE OF PDE5 INHIBITOR THERAPY ALONE

As detailed above, in rodents androgens modulate the expression of both NOS and PDE5, and the presence of androgens is a prerequisite for proper functioning of PDE5-I (9,12). PDE5 expression has been reported to be T-dependent in men too (158).
Several studies suggest that hypogonadism is a risk factor for reduced response to sildenafil in men too (review in Buvat et Bou Jaoudé [187]). Among the most significant ones, the mean TT level of diabetic men with ED was significantly lower in those who did not respond compared with those who responded properly to this PDE5-I (respectively 1.99 vs 5.36 ng/ml) (188). Following radiation therapy for prostate cancer Sildenafil efficacy was also lower in the patients with ED treated with androgen deprivation therapy compared with those without this treatment (189). In a study of 162 men with ED, TD (TT < 3 ng/ml) was one of the 3 significant predictors of poor response to sildenafil (OR 1.89, CI 1.12-3.16) (190). In men with ED and severe TD, Sildenafil failed to increase the erectile response to visual sexual stimulation and this effect was restored following T therapy for 6 months (173). Lastly, in the already mentioned study by Rochira et al where Sildenafil was able to restore the sleep-related erections with the same efficacy as T therapy, the effect of combining Sildenafil with T therapy was greater than the sum of each of these two therapies alone as concerns every parameter of nocturnal erections (176).

*Uncontrolled studies* reported a high prevalence (30 to 40%) of low to low-normal T levels in unselected or diabetic men with ED non responders to sildenafil or tadalafil (mean baseline TT 1.7 to 2.3 ng/ml in the corresponding studies) and a substantial improvement of the response to PDE5-Is in 37.5%-92% of these men following combination of T therapy with PDE5-I, while a short course of T therapy alone had only modest effects (review in [187]). A study suggested that the proportion of such patients improved by the combination with T therapy increased with the duration of T therapy (65% after 10 weeks vs 43% after only 4 weeks) (191).

*Three RPCTs support the speculation that TD hinders the effects of PDE5-Is on erectile function of men too.* In a small study, 20 patients with arteriogenic ED and both serum TT and FT in the lower quartile of normal range, who were non responders to 6 trials with 100 mg sildenafil, were randomized to T or placebo patches combined for 4 weeks while continuing with Sildenafil on demand (174). With respect to placebo, T therapy significantly increased the arterial inflow to cavernous bodies following Sildenafil administration, as well as the scores of the Erectile Function and the Satisfaction Domains of the IIEF. On the other hand Shabsigh et al studied 75 ED patients (mean age 58.5 years) with low to low normal TT (≤ 4 ng/ml), non responders to Sildenafil 100 mg (192). They were randomized to T or placebo gels combined with Sildenafil on demand for 12 weeks. After 4 weeks the mean increases in the scores of the Erectile Function, Orgasmic Function and Overall Satisfaction Domains of the IIEF, as well as the number of patients reporting that their gel improved their response to Sildenafil, were significantly greater in the T group (+ 4.4 vs + 2.1 in the placebo group with concern to the EFD). However the differences were no more significant at weeks 8 and 12, and this may be due to a too small cohort of patients. Lastly Buvat et al randomized 173 men with ED (mean age ≥ 45 years) and either TT ≤ 4 ng/ml or BT ≤ 1 ng/ml, non responders to tadalafil 10 mg once a day for 4 weeks, to receive a placebo gel or a T gel in addition to tadalafil. The EFD of the IIEF and the rate of successful intercourses increased somewhat more in the tadalafil + T gel group than in the tadalafil + placebo gel group, but the difference was statistically significant only in those patients with a T level at baseline below a certain threshold: 3ng/ml for TT, 0.6 ng/ml for BT, and 52 pg/ml for cFT (193).

*Other benefits of combining T therapy to PDE5-Is in men with low T have been reported in uncontrolled studies* (review in [187]): the first one is the improvement in sexual desire, often reduced when T is low, which may lead to withdrawal from PDE5-I therapy due to lack of motivation for sex. Theoretically PDE5-I therapy alone cannot improve sexual desire. However, as mentioned above in a study of 74 men with ED, 6 months of sildenafil, and even more of tadalafil therapy significantly increased the low normal mean serum testosterone level of 3.43 ng/ml to 4.7 ng/ml (184). But it has not been proven that such a small increase is sufficient to have a clinically significant effect on sexual desire, and 2 recent studies were unable to confirm an increase in T following 6 months of Sildenafil and 12 months of tadalafil (in Buvat et Bou Jaoudé [187]). Improvement in other symptoms of hypogonadism like reduced well-being has also been reported following combination therapy (187), but such an improvement, measured with the Aging Male Symptom scale, was also reported with sildenafil alone in a RPCT (194).

*d) significance of testosterone deficiency in erectile dysfunction:* T unquestionably plays a critical role in the control of erectile function of many animal species, including humans. Severe organic hypogonadism impairs every aspect of sexual function in young men, and its negative impact upon sexual function is eliminated by T therapy. However this is a rare finding in the men consulting for ED before the age of 50 years. For example only 0.8% of a consecutive series of 477 men less than 50 years old consulting for ED had a serum T < 2 ng/ml ([156]).

**1. The role of comorbidities:**
Fifteen per cent of the men aged more than 50 years who consult for ED prove to have a serum T repeat-
edly < 3 ng/ml (10.4 nmol/l) (155). The role played by TD in their ED is presently unclear. Only about one third have definite improvement on T therapy with regards to their erectile function. That may suggest that the low T level is not the real cause, or not the only cause of ED in every case. Hypogonadism is too often wrongly diagnosed, based on only one T measurement. A low result indicates a repeat measurement which will give a normal result in 30% of the cases (155). In addition, the majority of the ED patients aged more than 50 years who are found to have a low T level have only a mild or moderate hypogonadism, while the magnitude of the beneficial effect of T therapy on erectile function is inversely related to the baseline T concentration (177). In a consecutive series of 545 ED patients aged more than 50 years, 9% had a T level twice < 3 ng/ml, but only 2.6% (22% of the former) had a marked TD (T level twice < 2 ng/ml or 7 nmol/l) (156). In addition, ED is often multifactorial. In the preceding series, significant vascular factors such as obstruction of the penile arteries or veno-occlusive dysfunction were present in 42% of the patients with ED and TD ((156). In the diabetic men with ED, TD is associated with greater damage of penile arterial function (17). In older men with ED and TD, the prevalence of co-morbidities such as hypertension, hyperlipidemia and LUTS is more than twice higher in those whose erectile function is not improved following T therapy (179).

2. Testosterone deficiency may have itself contributed to the development of these comorbidities

As demonstrated by the frequent and significant association of TD with obesity and metabolic diseases: 58% of men with ED are obese, and in those men obesity is associated with lower levels of TT, BT and FT, as well as with a higher rate of penile arterial insufficiency according to penile CDU investigations (20). Many recent studies have confirmed the highly significant association of LOH with obesity (195-198) or increased waist circumference (199). Likewise, as already mentioned, TD is associated with insulin resistance, T2DM, and the MetS, a precursor state of cardiovascular disease, and with each of its components (15, 25, 200), especially in men with SDs (67). Hypogonadism predicts both T2DM and MetS in longitudinal studies, even in men lean at baseline (15), and in men with prostate cancer, androgen deprivation therapy induces rapidly IR, MetS and serious cardiovascular events (110). More details on these relationships are available in sections II.2.c. and II.2.d. One of the main reasons for the lack of improvement of erectile function following T therapy in the men with ED and TD may be that this treatment comes too late, when TD had already damaged the endothelium and the vascular bed, in part as a consequence of its detrimental effect on insulin resistance and the metabolic balance. A more direct evidence of the critical role of T in the ED of the men with TD is given by the T-dependence of the PDE5-Is' efficacy.

3. It is also possible that in certain cases low T is a consequence of reduced sexual activity or of the stress or the depression associated with ED rather than the cause of ED.

However the 2 uncontrolled studies by Jannini et al (183) and Carosa et al (184) which best support this hypothesis by reporting a significant increase of the T level of men with ED following improvement of erectile function with non hormonal therapies were not confirmed in subsequent studies following 6 months of sildenafil (194) nor 12 months of tadalafil (201). Lastly the association of ED and TD, which are both prevalent conditions does not imply a cause-effect relationship in every case.

2. Hypoactive Sexual Desire

A significant association of TT with the level of sexual desire has been reported in cross-sectional studies of aging urological outpatients (13,167) or of men with ED (12,184), and in a 17-year longitudinal evaluation of aging men (202). In a consecutive series of 1647 men with SD this association was significant only in the youngest age quartile (17-42 years old) (203). Such an association has also been reported with BT (167,202). However other parameters, especially ED (167), age, BMI, cigarette smoking and diabetes (202) interacted with T to determine HSD. In other cross sectional studies such associations were not confirmed, or disappeared after age adjustment (204). In addition the predictive value of low T for HSD was low in individual patients: The prevalence of HSD was of only 50% and 37% in men with TT < 2 and 3ng/ml, and 52 and 43% in those with BT < 1 and 1.2 ng/ml respectively. Two meta-analyses of RCTs (44,178), as well as other RCTs in older men with TD (60), or metabolic diseases (205), demonstrated a significant improvement of sexual desire following T therapy in populations of men with a mean T level < 3.46 ng/ml (12 nmol/l) at baseline. Therefore many studies support the association of low T level with low sexual desire, but suggest a multifactorial origin of this sexual dysfunction. In addition the prevalence of TD seems low in men consulting for isolated HSD (in a consecutive series of 73 patients with HSD and no other SD, TT was normal in every case) (206).
of TD suggesting that T may play a facilitating role in the control of the ejaculatory reflex. However in another consecutive series of 90 men consulting for retarded ejaculation or anorgasmia, only one had TD (206).

VI. ROLE OF TESTOSTERONE DEFICIENCY IN THE OTHER ASPECTS OF AGING

1. EPIDEMIOLOGY OF TESTOSTERONE DEFICIENCY IN AGING MEN:

As specified in section II.1.c, mean serum levels of TT gradually decline from the 40's, while SHBG increases, leading to an even greater decrease in serum BT and FT levels (4,208). However, there is great interindividual variability in T levels in aging men and not all older men will develop TD (209). Depending on what measurements and cut off values are used, the reported prevalence of TD in the aging male varies between 7% to 38.7% (Table VI). Measurements recorded in one longitudinal study revealed that approximately 12% of men aged 50–59 years, 19% of men aged 66–60 years, 28% of men 70–79 years and 49% of men ≥80 years have a low TT level. (94). TD is especially associated with health problems (210) and with obesity (20,195–197,199). In the 3200 aging men of the European Male Aging Study both preceding factors together with age and smoking were the 4 predictors of hypogonadism (198).

It is now recognized that only men who are found to have both low T level and relevant symptoms come within the indications of T therapy. In the MMAS study, 50% of the men with low T levels were asymptomatic (211). Table VII shows the prevalence and incidence of “symptomatic androgen deficiency” (SAD). Follow up over 15 years showed that the SAD was not a stable state, since after 8 years 55% of the men initially diagnosed as SAD had recovered a normal T level (212). The main correlates of SAD are by order of importance visceral obesity (waist circumference), health status and age (199).

The pathogenesis of TD in aging men involves 3 main mechanisms (4): 1. primary testicular changes with a diminished testicular secretory capacity due to decreasing Leydig cell mass and responsiveness to LH, whose serum level is often elevated in that case (208,213,214); 2. altered neuroendocrine regulation of the Leydig cells with apparent failure of the feedback mechanism on LH to fully compensate (213,214,215); 3. independent increase in SHBG binding capacity. Other mechanisms described in section II.2.c. (T and metabolism) may be involved in the many old men with TD who are obese. Further, changes in sensitivity to T leading to androgen resistance have been hypothesized (216,217). Age is associated with a decrease of concentration or down regulation of AR (4,216,217). Controlled trials of T therapy suggested that the threshold level of the effects of T on sexual function may increase with aging (165).

2. CORRELATION BETWEEN TESTOSTERONE LEVELS AND AGING SYMPTOMS

The symptoms of aging and of TD in men are similar (Table VIII). However, aging is also associated with a progressive decline in several other hormones like dehydroepiandrosterone (DHEA), thyroxine, melatonin, pregnenolone, DHT, androstenedione, IGF-1 and growth hormone (GH) (4) and in the efficiency of many essential biochemical regulations (i.e. the NO-cyclic GMP pathway). Thus many of the clinical manifestations may not be due to changes in T level.

The onset of these signs and symptoms varies and depends on many factors including the AR threshold level of the end organs. In hypogonadal men substituted with T pellets, the first symptoms which appear when pellets are exhausted are decreased libido and lack of vigor (162). This was confirmed by Zitmann et al (13) who showed in a population of aging men that the threshold level of circulating T below which the prevalence of a symptom is significantly increased with respect to the overall population differs according to the symptom (figure 2). In their study lack of libido and of vigor were the earliest symptoms manifested. The prevalence of lack of libido and of vigor in the population studied increased when the threshold of TT levels declined from normal to low levels. In addition the study of men on T pellets by Kelleher et al suggested an important inter-individual variability of the T threshold from which the symptoms of hypogonadism appear (162).

a) correlations with changes in body composition

Both aging and androgens have a significant impact on muscle mass and fat distribution. Several studies have confirmed an inverse correlation, independent of age, between abdominal fat mass and FT levels (218-220). These interrelations and their metabolic consequences are discussed in the section II.2.c (T and metabolism). Low FT has also been found to be associated with decreased muscle mass and muscle weakness in aging men (221). Loss of muscle mass seems a major cause of age associated decline in muscle strength (222).

Most studies support a moderate association of low T with physical decline of aging men. Serum T-levels, independent of age, were found to be positively correlated with isometric grip strength, leg extension (223) and overall muscle function (224). In 2 other cross-sectional studies low levels of TT and BT were associated with impaired mobility and low physical performance and muscle strength (225,226). In one of these studies, based on a MMAS sample, elevated levels of TT and BT (as well as of DHEA and DHEA-S) were associated with increased physical performance at a 7 items global physical performance test (but not at grip strength or chair stand tests) (227). But the correlation existed only up to certain critical concentrations (4.51 ng/ml for TT and 1.41 ng/ml for calculated BT). Levels beyond these critical concentrations, as might be achieved through exogenous supplementation, did not appear to confer additional benefits. A study of 20 men on ADT for PCAs found a significant decrease of hand grip strength and manual dexterity with respect to an age matched control group (227). Lastly 2 prospective cohort studies provided conflicting results. Orwoll et al (228) who studied a large cohort of 2587 men more than 65 years old, observed an association of lower T concentrations with reduced physical performance and an increased fall risk. Conversely in the study by Schaap et al, low levels of TT and FT were associated neither with 3 year decline in physical performance nor with 3 years decline in muscle strength (229), nor with an increased incidence of falls during the same period (225), perhaps because their cohort was smaller (constituted of 2 independent samples of 486 and 1071 men of mean age over 70).

In conclusion, and as confirmed by the results of the RPCTs of T therapy (see below), TD certainly contributes to increased fat mass, sarcopenia and decreased muscle strength of elder men, but these are probably multifactorial in origin. The decline in GH with age may also be involved since GH and T administrations have additive effects on these parameters (230,231).

b) Correlations with decrease in bone mineral density

Premature osteoporosis is seen in men with TD associated with Klinefelter syndrome, castration, HPRL, hypothalamic dysfunction and anorexia nervosa (213). Several large scale studies demonstrated that bone density in the radius, spine and hip are correlated with levels of bioavailable T, and even better correlated with bioavailable estradiol (213,232). The correlation between T levels, age and bone mineral density (BMD) have shown mixed results (208,209,213,214,233), but overall, in older men the prevalence of TD is twice higher in those with osteoporosis or rapid bone loss compared with the prevalence in men with normal BMD (234,235). However the prevalence of estradiol deficiency is even higher, and in a large group of 2447 men ≥ 65 years old, those with Total T or E2 deficiency were more likely to be osteoporotic (234). Possible mechanisms explaining the effects of diminished T on bone include reduction in estrogens produced by aromatization of androgens, reduction in calcitonin, and in osteoblast function (213,236,237). The respective responsibilities of the age-related fall in endogenous T and of the decline in endogenous estrogens have not been totally clarified. In a cross-sectional investigation of a large number of older men, though both T and estrogens were strongly related to BMD, both the posi-
tive relationships were independent from each other suggesting that the effect of T on BMD was not only a consequence of its aromatization in E2 (238).

The incidence of hip fractures among men over the age of 65 is 4-5/1000 (208). Many studies have demonstrated the association between minimal trauma hip fracture and low T level (239,240,241). TD is found in up to 20% of men with symptomatic vertebral fractures and 50% of elderly men with hip fractures (235). But data from the Framingham study suggest a predominant role of estrogens since in a cohort of 793 men followed for over 15 years, low T at baseline did not significantly increase risks for subsequent hip fracture while low estrogen did so. However men with low estrogen and T combined had the greatest risk of hip fracture (242).

**In conclusion** TD leads to osteoporosis and to a risk of hip fracture, in a large part, but not exclusively, due to a reduction in estrogens level.

**c) Correlations with decline in cognitive Function**

Correlational studies in young adults reliably implicate spatial cognition as the domain of cognitive function which is the most sensitive to T (243). In several, but not all, of these studies an inverted U-shaped relationship between T and this aspect of cognition was objectified. A large cross-sectional study of 40-80 years old men also found a curvilinear association between T and memory performance and processing capacity/speed, suggesting an optimal hormone level for particular cognitive tasks (244). In another cross-sectional study serum BT, but not TT, levels were associated with a lower risk of anamnestic mild cognitive impairment (245). Several longitudinal studies also suggest that in men the progressive decline of the bioavailable fractions of T with age is associated with the age-related declines in cognitive functions. Age-related decrease in BT has been found to predict decline in visual (246) and verbal (246,247) memories. In the Baltimore Longitudinal Study of Aging (BLSA), after an average follow-up of 10 years a high Free Testosterone Index (FTI) was associated with higher scores of visual and verbal memory, but not of verbal knowledge, general mental status or depressive symptoms (248). In another component of the same study eugonadal men proved to have a reduced rate of decline in visual memory with respect to men with TD, suggesting a possible beneficial effect of high circulating FT concentrations on specific domains of cognitive performance and cognitive decline in older men (94). In a neuroimaging study of a subsample of the BLSA, Positron Emission Tomography found that older men with higher FT had increased blood flow in the hippocampus bilaterally, while hippocampus is known to play a critical role in memory and possibly in spatial cognitive processing (243). However several cross-sectional studies did not confirm the association of age-related cognitive decline with low free or total T after adjustment for salient factors (249,250), or even observed association of high cFT with poorer performance at some cognitive tests (250).

The preceding data raise the issue of a **role of the age-related decline of T in the development of Alzheimer’s disease.** Several, but not all, cross sectional studies have reported lower concentrations of T in men diagnosed with this disease (243,245,251), but such studies may not determine the direction of causality. A prospective longitudinal study of 574 men with a mean age of 66.3 years at baseline, part of the BLSA, observed lower FT levels at 2, 5 and 10 years prior to the diagnosis of Alzheimer’s disease, and this suggests that the reduced T concentrations are unlikely the result of this pathology (252). This observation was not confirmed in another prospective cohort of 376 men, older than the preceding one (mean age 73 years at baseline), which was followed for only 4 years (253). Low FT may be responsible of the high circulating level of gonadotrophins found in Alzheimer’s disease (254). It has been speculated that gonadotrophins may have deleterious effects on brain function (251,255), since their elevated expression has been found to colocalize with neurons vulnerable to Alzheimer’s disease (254). In addition several studies have identified androgens as endogenous regulators of β amyloid protein, whose accumulation, inhibited by T, is widely believed to be the critical initiating step in the pathogenesis of Alzheimer’s disease (251).

**In conclusion** several studies are supporting low T, and, even more, low BT or FT levels, as risk factors for age-related selective losses in cognitive function, or for Alzheimer’s disease, but other studies are conflicting, and presently it is not possible to conclude unequivocally that T physiologically enhances brain and cognitive functions.

**d) Correlations with mood:**

Age-related decline in T levels is associated with a number of non-specific symptoms, including depressive symptoms. The relationship between depressive symptoms and T levels is confounded by numerous factors including medical illness, obesity, smoking, alcohol use, stress, and is thus complex. Studies have not consistently supported an integral role of reduced T levels in major depressive disorder, although T levels may often be reduced in men with treatment-refractory depression, and in older men with dysthymia (256,257). Several cross-sectional studies found especially significant associations of low TT or FT with overt depression in men with ED (OR for depression 1.9, [258]) or with other sexual dysfunctions (66), in middle aged men with long term depression (259), and in men over the age of 70 (2 studies reporting an increased rate of depression in the men with T levels in the lower quartile [260], or lower quintile [261] ) but others did not (262). Seidman et al (263) also reported a significant association between depression and AR gene CAG
repeat length in 1000 men aged 48-79 years. This association was not confirmed in another study of 2 smaller samples of men with median age 75.3 years (262). Lastly a prospective cohort study of 758 men > 50 years old by Shores et al (264) also found that low T levels (≤ 2.5 ng/ml) were associated with an earlier onset by about 2 years and greater incidence at 2 years of depressive illness (adjusted hazard ratio 2.1, CI 1.3-3.2).

In conclusion some studies support the possibility of an association between low T levels and mood but other data are conflicting and more studies are required for confirmation of the association and determination of the direction of the possible causality. There may be vulnerable subpopulations in whom TD contributes to depression but chronic depressive illness may also lead to hypogonadism.

e) Correlation with Metabolic and Cardiovascular Functions

The relationships between TD and these functions have been dealt with in sections III and IV of this chapter.

f) Correlations with Lower Urinary Tract Symptoms (LUTS)

Some uncontrolled studies have reported gradual improvements of the International Prostate Symptoms Score (IPSS) following long term T therapy in men with TD, metabolic syndrome and/or ED (see review in Yassin et al 2008 [265]). This has led to the speculation that lower T levels contribute to the exacerbation of Lower Urinary Tract Symptoms (LUTS) (266,267). In one study T therapy significantly increased bladder capacity and compliance and decreased detrusor pressure at maximal flow (268). Androgen deprivation has been shown in many laboratory studies to inhibit smooth muscle differentiation resulting in poorer relaxation of smooth muscle of the prostatic urethra and bladder (269,270). Other studies have implicated the role of T in maintaining normal autonomic reflex activity in the pelvis and bladder detrusor function through the Rho-kinase/endothelin and nitric oxide pathways (271,272). However no consistent correlation has been found between circulating T levels and LUTS in several studies (265). Therefore RPCTs of T therapy focusing on a beneficial effect on LUTS as primary end-point are required before confirming any possible association of TD with LUTS.

g) Correlations with changes in General Health, Quality of Life

Numerous studies have reported a relationship of lower T levels with poorer general well being and quality of life as reported in the Short-Form SF-12 Health Survey questionnaire, particularly the physical health index (273-275). Lower T levels are predictive of anemia which results in poorer overall health (276,277), especially in type 2 diabetic patients (adjusted OR for anemia 1.7, CI 1.1-2.8 for a TT level < 10 nmol/l, [278]). TD may be involved in frailty, a clinical syndrome characterised by reduced physiologic reserve affecting multiple organ systems and associated with increased risk of falls, fractures, hospitalisation and death (246,279). Frailty is multifactorial with aging, comorbidity, sarcopenia, and endocrine immune dysfunction contributing to the condition. The probable contribution of TD in this syndrome has raised the hope that T therapy could be beneficial to frail men.

3. EFFECTS OF TESTOSTERONE THERAPY IN AGING MEN

The following review has been almost exclusively based on the results of the randomized, placebo-controlled trials of T therapy, and their meta-analyses. The heterogeneity of the RCTs included in the review has to be emphasized. They differed in the serum T level chosen as inclusion criterion, the T preparations that were used, the duration of therapy, which was often short (> 6 months in only a minority of the trials) and the number of patients (8 to 406, but > 40 in only a minority). In addition many studies were insufficiently powered to demonstrate the absence of efficacy.

a) Body Composition and muscle strength

In a meta-analysis of 17 RPCTs of T therapy in middle-aged men by Isidori et al (44), an average of 9 months of T treatment resulted in a significant reduction of 1.6kg (CI: 2.5-0.6, P < 0.001) in total body fat which corresponds to -6.2% (9.2-3.3%) of initial percentage body fat. Active treatment also produced an increase of fat free mass by +1.6kg (CI: 0.6-2.6, P < 0.001) which corresponds to an increase of +2.7% (1.1-4.4) over initial percentage of lean body mass. Overall body weight was unchanged (44). The effects of TRT on muscle strength were heterogeneous, showing a tendency towards improvement only at the leg/knee extension and handgrip of the dominant arm.

In another meta-analysis which included 11 high quality RPCTs of the effects of T therapy on muscle strength of men 65 years old and older, Ottenbacher et al (280) found a mean g-index adjusted for sample size of 0.53, what amounts to a medium treatment effect. The elimination of a single study by Ferrando et al (281) markedly reduced the overall treatment effect (mean g-index 0.23 instead of 0.53). This 6 months study was the only investigation in which T was injected at weekly intervals, and the dosage size of 0.53, what amounts to a medium treatment effect. The elimination of a single study by Ferrando et al (281) markedly reduced the overall treatment effect (mean g-index 0.23 instead of 0.53). This 6 months study was the only investigation in which T was injected at weekly intervals, and the dosage...
In conclusion T therapy consistently results in limited but significant changes in body composition including reduction in fat mass of about 1.6 kg in average and increase in lean mass of also about 1.6 kg. No significant change seems to occur after 6 months. However improvement in muscle strength is less consistent and found in only about half of the studies with a trend to significance in meta-analyses. Improvement in global physical function (timed stair climbing, timed walking) has been reported in a limited number of studies, but does not appear to be convincing.

b) Bone Mineral Density (BMD)

The meta-analysis by Isidori et al (44) included 5 RPCTs of at least 12 months duration of the effects of T therapy on bone of middle-aged and older men. T improved BMD at the lumbar spine by 3.7% (CI 1.0-6.4%) compared to placebo but not at the femoral neck, and produced a consistent reduction in bone resorption markers, with no significant effect on bone formation markers. The highest effect was found with T esters. In one of the largest and longest studies (36 months), the effects of T on lumbar spine were inversely correlated with pretreatment T concentration (284). A further meta-analysis by Tracz et al (285) included 8 RPCTs which enrolled a total of 365 patients. Compared with placebo IM testosterone was associated with an 8% (CI 4%-13%) gain in lumbar BMD and transdermal T had no significant impact. Again T use was associated with a non significant 4% gain in femoral neck BMD. Recently a small additional RPCT confirmed a significant effect on lumbar but not femoral neck BMD (286). Only aromatizable androgens increase BMD (287). Seventy per cent of the bone effects of T seem to result from its transformation into E2.

In conclusion T therapy with aromatizable androgens significantly increases lumbar BMD of older men, but no trials reported the effects of T on fractures, which led Tracz et al (285) to conclude that without bone fracture data, the available trials offer only weak and indirect inferences about the clinical efficacy of T on osteoporosis prevention and treatment in men.

c) Cognitive functions

Fourteen RPCTs have assessed the effect of T therapy on cognitive function of aging men. No meta-analysis of these trials has been published to date. In 6 trials of short duration (12 weeks or less except the 20 weeks trial by Gray et al (165), T therapy was associated with significant improvement of spatial cognition (165,288,289), spatial and verbal memory (289-292), working memory (290) and/or visuospatial skills (293) or constructional abilities (291) either only in the T group, or with respect to the placebo group. Two of these studies included men with mild or moderate Alzheimer’s disease (291,293).

In a study by Cherrier et al (292) association of antazone, an inhibitor of aromatization, cancelled out the effect of T therapy on verbal but not on spatial memory. No significant difference between the T and placebo groups was found in the scores of various cognitive tests administered in 5 other trials of longer duration (either 12 months [294-296], or 5 and 6 months [297,298]. Lastly in one trial a single T ester injection significantly decreased verbal fluency (299) and in a 9 months RPCT of T esters injections, supraphysiological circulating levels of T decreased verbal memory with respect to placebo injections (300).

In conclusion evidence of beneficial effects of T therapy on cognitive functions of elderly men is presently limited. Some short lasting trials support it, but results of studies of longer duration are conflicting. Larger RPCTs of more than 6 months duration are required to confirm their possible clinical significance.

d) Mood:

In a 60 days RPCT in younger men with TD, T therapy led to decreases in anger, irritability, sadness, tiredness and nervousness, and improvements in energy level, friendliness and sense of well-being (301). T therapy has also demonstrated short-term efficacy and tolerability in augmenting antidepressants to alleviate treatment-refractory depression in adult males, but was not effective in treating major depressive disorder in men with TD (256). In older men, 18 RPCTs of T therapy included depression or other mood items in their assessments (no meta-analysis). In most trials these items were only secondary endpoints. No significant improvement was observed in 13 trials (165,288,290,294-297,302-307). Conversely significant improvements of various items were reported in 4 studies: Depression Melancholia Scale (308), Geriatric Depression Scale in a small study of frail, debilitated older men (282), nervousness and insomnia in obese diabetic men (46), and most important greater reduction in Hamilton Depression scale (primary outcome
measure) and higher remission rate (52.9% vs 18.8% in the placebo group) in a 3 months RPCT of only 33 men > 50 years old with subthreshold (or minor) depression and TD (309). In a 6 weeks RPCT of 23 men (median age 50.9 years), remission rate of 53.8% versus 10% on placebo was noted in late onset dysthyemic disorder (263).

**In conclusion** results from multiple RPCTs are conflicting. Most do not support T therapy as a broadly effective antidepressant, but it may be effective in carefully selected populations, or as an adjuvant to antidepressant therapies.

e) **Metabolic and cardiovascular functions:**

Preliminary evidence that T therapy may improve insulin resistance and T2D control in older men has been reviewed in section III. Likewise review of the RCTs reporting a short-term beneficial effect of T therapy in men with CHD may be found in section IV.

f) **Quality of Life**

At least 6 RPCTs have assessed the effects of T therapy on energy and/or fatigue of older men. The beneficial effect of T therapy on these symptoms was significant in 4 of them (46,308,310,311) with respect to the placebo effect or to baseline, and not significant in the 2 others (284,295). Other assessments of well being and quality of life were included, generally as secondary end-points, in at least 13 RPCTs with significant benefits of T therapy in 3 trials (287,310,311), benefits of T therapy limited to only one of the multiple assessed items in 3 trials (121,284,298) and no significant benefit in the 7 other trials (231,296,306,309,312,314).

**In conclusion**, although experienced by many clinicians, the benefits of T therapy on energy, well-being and overall quality of life have not yet been clearly substantiated by RPCTs. However few trials elected these parameters as primary endpoints of the study.

---

**VII. DIAGNOSIS OF TESTOSTERONE DEFICIENCY**

1. **CLINICAL SYMPTOMS AND SCREENING**

a) **Symptoms of testosterone deficiency**

The signs and symptoms which commonly lead to screening for androgen deficiency include loss of libido, erectile dysfunction, depression, lethargy, sleep disturbance, irritability, depressed mood, inability to concentrate, visceral obesity, osteoporosis, loss of muscle strength, regression of secondary sex characteristics, decreased interest in activities, gynecomastia and anemia (Table VI).

Nevertheless, all these signs and symptoms are non specific. As developed earlier, TD is also prevalent in men with insulin resistance; type 2 diabetes, MetS, vascular disease and AIDS (71,325).

Age related hormonal changes in the aging male such as TD usually have an insidious onset with slow progression and do not manifest in all men. There is also great interindividual variability in both clinical manifestations and the intensity of each sign and symptom (326).

The clinical working definition of TD syndrome combines both signs/symptoms of low T levels and biochemical parameters which are low or borderline (2,211,327).

b) Are screeners and inventories valid?

Several questionnaires have been proposed to screen for TD in the ageing men. These include the Androgen Deficiency in Aging Males (ADAM) Questionnaire (328), the Aging Male Symptoms (AMS) Scale (329) and the MMAS questionnaire (330). The validation of the ADAM questionnaires represents an attempt in defining a symptoms complex associated with low bioavailable T levels that is similar to the symptoms complex associated with menopause in women. However, many studies revealed no statistically significant correlation between serum T level and the ADAM questionnaire except for men over age 70 (316,331-333). Similarly the AMS Scales showed inconsistent correlation with T level as some authors found good correlation with T or with the ADAM score (334-336) while for others no association of AMS scores (both total and subscales) were noted with all parameters of T measurement in both Western and Eastern population (211,331,333,337). Beutel et al (333) also demonstrated that the ADAM score but not the AMS score are moderately associated with age and they conclude that, based on their high correlations with depression, both seem to measure symptoms associated with depression rather than with symptoms of TD.

**In conclusion**, as illustrated by Table IX, these questionnaires have a good sensitivity for TD, defined in this table by BT (338). But in practice, they are not useful in the diagnosis of TD because they have very low specificity. Neither of these questionnaires replaces a proper history and clinical examination, and better instruments need to be developed (2). Nevertheless, such tools may be useful for monitoring purposes during T therapy (331,349-341) and may predict the opinion of the investigator upon T therapy results (340,341).

Conversely, in men with sexual dysfunction, the Androtest, a structured interview inventory, as opposed to self-reported questionnaires, appears to be a useful screening test in clinical practice as it shows high sensitivity (76%) and specificity (66%) in detecting biochemically low T (< 10.4 nmol/l) (342). However, as the original validated version is in Italian, adaptation in other languages will need further validation.
2. BIOCHEMICAL DIAGNOSIS (4)

Once a patient presents with symptoms causing clinical suspicion of TD, standardized patterns of diagnostics and therapy should be followed. Underlying causes of TD have been described in section II.2.a. Briefly they are disorders located at the testicular source of testosterone, the Leydig cells (primary TD or hypergonadotropic hypogonadism) or at the central regulation unit, consisting of the hypothalamus and the pituitary gland (secondary TD or hypogonadotropic hypogonadism), the latter secreting luteinizing hormone (LH), which stimulates Leydig cells.

**Symptoms of TD also occur in cases of target organ resistance**, mostly due to inherited alterations of the androgen receptor; in this case, elevated concentrations of both testosterone and LH are found, and the androgen-sensitivity index is elevated, pointing to androgen resistance (see below, pharmacogenetic implications).

For diagnostic purposes in suspected male hypogonadism, assessment of total testosterone, luteinizing hormone (LH), follicle stimulating hormone (FSH), prolactin (be aware of high-dose hook-effects in prolactin assays: use dilution in case of suspected macroprolactinomas) and estradiol is helpful, as well as calculation of free testosterone from total testosterone and sex hormone binding globulin (SHBG), the latter secreting luteinizing hormone (LH), which stimulates Leydig cells.

**Testosterone circulates in the blood of men and women in several forms.** It is bound tightly to sex-hormone binding globulin (SHBG), loosely to albumin, and unbound to proteins (free). In most, but not all, clinical conditions, a measurement of total T is adequate for the evaluation of a patient. It is widely believed that the SHBG-bound T is not readily available to most tissues, whereas albumin-bound and free T are bioavailable. Because SHBG concentrations can be influenced by many factors (e.g., decreased by obesity, testosterone treatment), there are clinical situations in which measured concentrations of total T may not reflect the bioavailable concentrations or the clinical status of the patient. In these circumstances a supplemental test assessing bioavailable or free T will be helpful in clinical decision-making (343). It is important to note that the reference method for measurement of free T, equilibrium dialysis, requires a sensitive, specific, precise, and accurate assay for total T. The current methods of measurement of total T lack the required sensitivity for samples with very low concentrations, as occur in severely testosterone deficient men; this sensitivity limitation can be corrected by newer methods based on mass spectrometry (344). Vermeulen and coworkers (343) could demonstrate that the FT value calculated by TT / SHBG (according to a second degree equation following the mass action law) as determined by immunoassay (cFT) appears to be a rapid, simple and reliable indicator of BT and FT, comparable to FT values obtained by equilibrium dialysis. An easy to use free calculator of calculated FT and BT can be found on www.issam.ch. So, determination of values of T and SHBG might provide a reasonable index of the androgen status. BT is also a rather reliable index, but it should be mentioned that direct FT assays using a T analogue do not yield a reliable estimate of FT (2,343).

# Morley et al 2006 (338)
§ Corona et al 2006 (342)

** Smith et al 200 (300)
*** Heinemann et al 2006 (341)
Determination of androgen receptor genotype and concentrations of serum dihydrotestosterone should be performed in special cases of suspected androgen resistance.

If the clinical picture, the physical exam including genitalia, and patient's history lead to the suspected diagnosis of Kallmann syndrome or Idiopathic Hypogonadotropic Hypogonadism, basal serum levels of the gonadotropins, testosterone and estradiol will yield valuable information, but stimulation tests are mandatory in such cases of suspected secondary TD. Gonadotropin Releasing Hormone (GnRH) (0.1mg) should be given intravenously and, following, LH and FSH concentrations should be assessed after 30 and 45 minutes to demonstrate, whether the hypothalamus or the pituitary gland are affected. The responsiveness of gonadotropins to a GnRH stimulus is sometimes poor or absent which should not immediately be interpreted as disorder at the pituitary level. The gonadotropic cells in the anterior pituitary often require a certain period of "priming" by means of subcutaneous application of GnRH in a pulsatile manner: for a period of 7 days, 5µg GnRH are released every 90 to 120 min using a portable minipump. If the gonadotropin response (rise of LH and FSH levels > 3 IU / l) to a GnRH bolus is normalized then the hypothalamic origin of the hypogonadism is indicated. When there is permanent resistance to GnRH, a pituitary disorder or mutation of the GnRH receptor have to be suspected.

Testing the Leydig Cell response to hCG is helpful in determination of the testicular potential as well as solving the question whether testes are present in cases of primary TD. To this end, human Chorionic Gonadotrophin (hCG) (5000 IU) is given subcutaneously and testosterone concentrations are measured after 2 to 3 days.

3. LOOKING FOR SIGNIFICANT AETIOLOGIES? (2)

The aetiologies of TD are listed in section II.1. Some of them, mainly pituitary tumors, involve serious risks for health, independently of the consequences of low T. This possibility must be systematically remembered in case of secondary TD (normal or low serum LH), and even more of hyperprolactinemia. Measurements of serum LH and prolactin are therefore to be done in case of TD. In such cases pituitary tumors will be searched for with Magnetic Resonance Imaging (MRI). The possibility that hemochromatosis is revealed by TD should also be remembered and if necessary clarified by determining serum iron and ferritin.

4. PRACTICAL ASPECTS (2)

The laboratory reference values of T and FT show a wider range than those for most other hormones, which makes often difficult to establish whether borderline values of T are normal or abnormal. In a patient whose plasma levels of T fall from the upper to the lower range of normal T levels (a drop of as much as 50%), T levels may well be within the reference range but inappropriately low for that particular individual or his particular age. In addition, if the mostly used immunoassays (by chemiluminescence detection) provide fairly accurate measurements between 10 and 35 nmol/L, their accuracy is considerably less below 10 nmol/L. Lastly reference values vary significantly from laboratory to laboratory and from measurement method to method. It is advisable that every laboratory establishes its own 'normal range' of T in men.

There is no generally accepted lower limit of normal. Following Vermeulen's opinion most authors consider the normal range of T levels in young males also valid for elderly men. A pragmatic approach of which T level is low, which T level is very probably sufficient for an optimum androgenic effect, or is in the borderline area where T levels may be sufficient for certain men but insufficient for others due to the inter-individual variability of the sensitivity to T is described in recommendation 8. The corresponding T levels are in agreement with the levels proposed by another recent consensus (11).

Table X: Factors which increase and decrease SHBG in men (and hence respectively decrease and increase the bioavailable fractions of testosterone)
Lastly, because the consequences of lower-than-normal value of T may have great impact, such as T therapy for years, if serum T values are so low that T replacement is considered, the measurement has to be repeated a couple of weeks later, together with an assessment of SHBG, LH and prolactin. It has to be remembered that many physical or psychological stresses of daily living may depress temporarily T secretion.

Recommendations 1-3, 5-8, and 29 (prolactin) contain the guidelines referring to the main clinical and biochemical aspects of TD diagnosis. Figure 5 presents an algorithm for the diagnosis of TD summarizing these guidelines.

VIII. TREATMENT OF TESTOSTERONE DEFICIENCY/ANDROGEN THERAPY

1. INDICATIONS, EXPECTED BENEFITS

- There are two primary indications for testosterone therapy in the adult man. One is for the treatment of men with substantially depressed serum T concentrations due to significant disruption of the hypothalamic-pituitary-gonadal axis, such as following hypophysectomy, or in men with absent or atrophic testes (345). Lifetime treatment with T is indicated in these men. A second, more common indication is for the treatment of men exhibiting signs or symptoms of age-related TD (11).

The most frequently used blood test used to confirm the diagnosis of TD is total T (TT), even though it is recognized TT is an imprecise measure of bioavailable T. Values below 10-12 nmol/L (300-350 ng/dl) for TT have been proposed as consistent with TD (11,345). Free T may be a more useful test, but its use is confounded by the availability of different assays with quite different reference values. Values below 180-225 pmol/l (50-65 pg/ml) for cFT have been proposed as consistent with TD when determined by equilibrium dialysis (11,345). A value less than 50 pmol/L (15 pg/ml) for analog free T as determined by RIA has been reported to correlate with clinical symptoms and biochemical outcomes (346,347).

- A 3-6 month trial of empiric therapy may be considered in men with suggestive symptoms but without definitely diagnostic blood test results, since there is no absolute T concentration that reliably distinguishes who will or will not respond to treatment, due to substantial inter-individual variation in T physiology (13). One study of hypogonadal men undergoing T therapy revealed similar subjective response rates whether total T was <200 ng/dl, 200-300 ng/dl, or greater than 300 ng/dl ("normal"), as long as all men had free T < 15 pg/ml as measured by RIA with T analogue (347).

- Emerging indications for T therapy include ED that is poorly responsive to PDE5 inhibitors (193); decreased bone mineral density (348); and depression resistant to standard anti-depressant medications (349). Although there is inadequate evidence to date to support a formal recommendation for these indications, a growing literature suggests that treatment may be reasonably considered in individual cases based on clinical circumstances. In addition, it seems likely that the indications for T therapy will broaden in the near future based on recent evidence documenting important beneficial relationships between normal serum T and general health outcomes such as diabetes, cardiovascular disease (29), and longevity (100), though some studies are conflicting as concerns CVD and longevity (see sections II.2.d.).

2. RISKS, CONTRA-INDICATIONS

a) Potential risks for the prostate:

Growth of the prostate tissue is testosterone-dependent, which has led to think that T may play a role in prostate pathology and especially prostate cancer (PCa). This speculation was considerably fuelled by the beneficial effects of androgen deprivation in men with recurrent or metastatic PCa, since the initial paper by Huggins et al in 1941 (350). In fact careful review of literature shows that there is no compelling evidence for an association of T levels with prostate diseases.

Most observational studies failed to find correlations between circulating T levels and prostate pathology. No clear correlation with PSA, prostate volume or Benign Prostatic Hyperplasia (BPH) (351,352). Hypogonadism may be associated with reduced total prostate volume (353). But after the 4th decade, age is a more important determinant of prostate size than T, since prostate volume increases regardless of androgen deficiency or replacement (354), and is not associated with T levels (355). Likewise only a small number of the 21 longitudinal studies which examined the possibility that high serum androgen levels are related to increased cancer risk found such an association (356). The pooled analysis of 18 of these studies, involving > 3800 men with cancer and > 6438 men without cancer, found no relationship between the serum levels of 6 different androgens and cancer risk (357). Conversely, case-control studies found correlations of prostate cancer prevalence or severity with low serum T. In hypogonadal men the rate of prostate biopsies positive for cancer was twice higher in those with a T level in the lower tertile compared with those in the highest tertile (358). In other studies low T was associated with high Gleason scores, more advanced stages at presentation, higher recurrence rate following radical prostatectomy, and worse survival (359,360).

Augmentation of serum T levels for replace-
Figure 5: Algorithm for the diagnosis and management of testosterone deficiency (modified after Buvat et al 2006 [2])
ment therapy in men with low or low to normal T does not seem more associated with prostate pathology. Table XI shows a compilation of the results of prostate assessments from 21 RPCTs of T therapy which included such men. The 1173 patients included in the T groups had been treated for a total of 9919 months, while the 750 patients included in the placebo groups had been observed for a total of 7613 months. Mean serum PSA significantly increased in the T groups of 6/21 trials and in 1 of the 21 placebo groups. Mean prostate volume measured with ultrasonography in 6 studies significantly increased on T in 2 studies of 6 and 36 months duration, and increased also on placebo in an additional 36 months study. Mean International Prostate Symptoms Score (IPSS) measured in 6 trials (287,298,30 4,307,361,364), and Urine Flow Rate measured in 2 studies (281,361) did not significantly change during the study in any group. Lastly the rates of prostate cancers were very close in the T group (n = 8, 9.56/1000 patient/years) and the placebo group (n = 7.9, 19/1000 patient/years). There was no clear effect of the trials’ duration on prostate changes. One of these RPCTs, by Marks et al (364), is of special interest. The authors conducted a serial prostate biopsy study in men receiving T therapy for 6 months resulting in an increase of the mean serum TT level from 2.82 ng/ml at baseline to 6.3 ng/ml at 6 month. At 6 months follow-up prostate biopsy, there were no changes in tissue levels of T and DHT, prostate histology, tissue biomarkers or gene expression. Cancer was found in 4 of 19 men in the placebo group and 2 of 21 men in the T treatment group.

Calof et al published in 2005 a meta-analysis of RPCTs of T therapy in men > 45 years old which focused on safety (115). Only 9 of the 19 RPCTs were common to the above compilation. Table XII shows the pooled Odd Ratios for prostate adverse events calculated from this meta-analysis. Although the rate for all prostate events was significantly higher in the T group, there was no significant difference for any individual adverse event, including the rate of PCa (respectively 9.2 and 8.3 per 1000 patient/years in the T and placebo groups).

While the studies included in the Calof et al meta-analysis and in the above compilation were all randomized and placebo-controlled, the significance of their pooling may be limited by their short duration: 3 only lasted more than 12 months (24 to 36 months). Recently a retrospective study left its mark on mind by reporting 20 cases of PCa diagnosed in men receiving T therapy for hypogonadism, including 11 cases detected during the 2 first years of therapy but also 9 detected at later stages, 2½ to 8 years after the start (368). However the methodology was very poor, the authors were unable to find how many total patients had really been followed, and nearly half of these 20 men did not have a digital rectal examination prior to T therapy initiation that was done by primary care physicians. This study above all emphasizes the necessity of systematic and careful screening for prostate cancer before any T therapy. In 11 uncontrolled but prospective studies of T therapy, of 6 months to 10 years duration, a systematic prostate monitoring found only 6 prostate cancers in 965 men followed for 1321 years (0.62%, 4.54/1000 patient-years) (in Shabsigh et al 369).

Since androgen deprivation causes prostate cancer regression, it seems paradoxical that T therapy does not appear to cause more rapid prostate cancer growth in non-castrated men (359). Two primary explanations may explain this paradox. First, as shown by Marks et al (364) 2006), T therapy may fail to increase intra-prostatic T or DHT. A second explanation is based on the Saturation Model proposed by Morgentaler and Traish (360). Studies in humans, animals, and prostate cancer cell lines show a limit to the ability of androgens to stimulate prostate growth, benign or malignant. Whereas there is exquisite sensitivity of prostate cancer to changes in serum T at very low concentrations, at higher concentrations the growth rate appears indifferent to such changes. According to Morgentaler and Traish (360), this would be consistent with maximal binding of androgen to the AR at 2-3 nM/l (0.57-0.86 ng/ml).

Although a history of prostate cancer has been considered an absolute contraindication to T therapy, this point is now under active debate for men who are deemed cured. Review of recent literature finds a total of 110 hypogonadal men to whom T therapy was offered after being submitted to radical prostatectomy 2.5 months to 8 years before (table XIII). The duration of T therapy ranged from 3.3 months to 9 years. No clinical recurrence was observed and only 1 patient had PSA recurrence (after 12 months of transdermal TT, 17 months post-radical prostatectomy). Likewise 31 patients were submitted to T therapy for 6 months to 8.5 years after brachytherapy done 6 to 51 months previously for PCa, and 11 men were submitted to T therapy for 6 to 27 months after radiotherapy for PCa (table XIV). Neither clinical, nor PSA recurrence were observed in these patients. Another series of 13 men who elected an Active Surveillance for their PCa chose to undergo T therapy due to symptomatic hypogonadism (378). Follow-up prostate biopsies were performed in six men, revealing no cancer in two, and possible aggravation in only one patient (change in Gleason score from 6 to 7). Lastly, after 1 year of T therapy, Rhoden and Morgentaler (166) observed no significant differences in PSA and in the risk of developing prostate cancer in men with and without Prostatic Intraepithelial Neoplasia found in previous prostate biopsies, the former being considered to be in a higher risk in developing PCa. These data do not support a high risk of PCa progression or recurrence when T therapy is prescribed in hypogonadal men with a history of "low risk" prostate cancer.

(*) then switched to other types according to preference
the number of reported cases is still small, and the duration of follow-up often short, while PCa recurrence may occur late. **Caution regarding T therapy in such men, as well as a minimum interval since treatment of the cancer, remain essential until RCTs of T therapy have confirmed the safety of TT in such cases.**

**In conclusion,** historically androgen administration has been absolutely contraindicated in men suspected of harboring carcinoma of the prostate. **This is today an area of ongoing research and reevaluation.** There is no compelling evidence that T treatment causes prostate cancer or BPH, or prostate cancer progression from a subclinical to a clinical state in the non castrated man. However there is unequivocal evidence that T suppression can reduce growth and symptoms in men with locally advanced and metastatic prostate cancers. Currently adequately powered and optimally designed long-term prostate disease data are not available to determine if there is an additional risk from T therapy. Hypogonadal men > 45 years old should be counselled on the potential risks and benefits of T therapy before treatment, and carefully monitored for prostate safety during treatment.

**b) Potential cardiovascular risks:**

The belief that T is a risk factor for cardiovascular disease (CVD) is based on the observation that men have both a higher incidence of cardiovascular events and higher T levels than women. However, few, if any, data support a causal relation between higher T levels and CVD. As reported above (sections II.2.c., T and metabolism, and II.2.d., T and cardiovascular health, among 17 prospective longitudinal and over 30 cross-sectional studies only 2 longitudinal studies found a weak association of high T levels with incident or existing CVD in men. Conversely T is low in men with CVD in about half of the cross-sectional studies and low T predicted CVD progression or CV events in 4 of the 17 longitudinal studies. In addition T therapy at physiological dose improves several CV risk factors including visceral obesity, and possibly glycemic balance and insulin resistance, and has negligible effects on lipids and lipoproteins, except the possibility of a slight but significant decrease of both total, LDL and HDL cholesterol on IM injections of T esters, and a favourable decrease in lipoprotein a. Interventional studies suggest mainly beneficial effects of T administration on CV health, including symptomatic and ECG improvements in 4 short RPCTs of T supplementation in men with CHD, and improvement of cardiac condition in 2 RPCTs of T therapy in men with heart failure.

In conclusion **current available evidence suggests that T therapy in men is not associated with an important increase in CV adverse events.** Two meta-analyses of RPCTs of T therapy (45,115) found no significant difference between the T and placebo groups for all incident CV events, nor for each type of event (table IV), except an increase in hematocrit over 50% which was significantly more prevalent in the T group (115), and which might augment the risk of thrombosis (2). However, many of the preceding RPCTs included small numbers of men, often healthy, during short durations, and larger trials, measuring CV endpoints, and enrolling men with CVD for longer durations, are needed to be sure of the CV consequences of T therapy in the medium and long terms. The main practical consequence of these data are that hematocrit or hemoglobin level should be monitored in men receiving T therapy so that appropriate measures may be instituted if polycythemia develops. Conversely monitoring lipids is not required for safety reasons if their level was normal at baseline.

c) **Obstructive Sleep Apnea Syndrome:**

Cautionary statements about T therapy in Obstructive Sleep Apnea Syndrome (OSA) appear frequently in the T therapy literature and guidelines, despite lack of convincing evidence that T therapy causes and/or aggravates this syndrome. Also, there is a lack of consistency in the findings connecting T therapy to OSA. Despite the warnings in the package inserts, it is evident that the link between T therapy and OSA is weak, biased by methodological issues in many of the studies, and most studies involved small numbers of men (379).

d) **Infertility:**

All delivery methods for T therapy share as common shortcoming some suppression of the hypothalamic-pituitary-gonadal axis if this axis was previously at least partly functional. This suppression results from a negative feedback mechanism causing decreased intratesticular secretion of T and spermatogenesis. This negative impact on fertility is transient and disappears some months after discontinuation of T therapy. Agents that stimulate the endogenous production of T such as Human Chorionic Gonadotropin or in the mild cases anti-estrogens like clomiphene (380) would theoretically avoid this effect. In young men with hypogonadotropic hypogonadism, long-term T therapy does not compromise forthcoming responsiveness to LH and FSH when they will require fertility (381), and may even in some cases be followed by recovery of pulsatile secretion of gonadotropins with T secretion and spermatogenesis (382). However, a recent report indicates that prior androgen therapy is independently associated with a decrease in the likelihood of achieving conception (383).

e) **Risks linked to aromatisation of testosterone**

Known breast cancer is a classical contra-indication to T therapy. Some flare-ups of missed breast cancers with positive estradiol receptors have been
reported in men shortly after starting T therapy (384). Other cases of this cancer which is very rare in men have also been observed after long-term T therapy (385). Likewise rare cases of increase in a prolactinoma size have been reported in men whose hyperprolactinemia had not been adequately suppressed by dopamine-agonists at the time of starting TT, or even had been so (386). The most frequent consequence of aromatisation of the administered T is gynecomastia.

f) **Contraindications and restrictions for** use of testosterone therapy are summarized in recommendations 18 to 20.

3. **INITIATION, FOLLOW-UP**

Once it has been decided to initiate T treatment, it is usually recommended to start with a short acting formulation, mainly to check tolerance and early side effects, especially polycythemia, and then, possibly, follow with long-acting T, this remaining the choice of the patient and the practitioner.

At initiation of T treatment, individual assessment of comorbidities (as possible causes of symptoms) and potential risks versus benefits of T is particularly important (11).

After initiation of T treatment, patients should be monitored for prostate disease at 3–6 months during the first year, and at least annually thereafter (11).

Should the patient’s prostate cancer risk be sufficiently high (suspicious finding on DRE, increased PSA, or as calculated using a combination of risk factors noted above), transrectal ultrasound-guided biopsies of the prostate are indicated, as in any other patients at risk.

Severe lower urinary tract symptoms (LUTS) evident by a high (>21) IPSS Score due to BPH represents a relative contraindication (although there are no compelling data to suggest that T treatment exacerbates LUTS or promotes acute urinary retention). After successful treatment of lower urinary tract obstruction, this contraindication is no longer applicable.

Hematocrit or Hemoglobin should be measured before starting T treatment and at least every year.

4. **AVAILABLE PREPARATIONS**

There are many T compounds in the market to be used in T therapy. They differ in their formulations, the route of administration, the dose and interval to be used (pharmacokinetics) and also in their safety profiles. The most common available preparations are listed in the **Table XV**.

a) **Oral Formulations**

The oral route is the easiest one to replace T, but the ingested hormone is almost completely inactivated by its first pass through the liver: it is therefore difficult to achieve sustained blood levels with oral formulations and most of them are weakly active (eg. Mesterolone) (1). The 17 alpha alkylated derivatives of T (specially methylT and fluoxymesterone) are more active but due to the potential hepatotoxicity (eg. hepatocellular adenoma, cholestasis, jaundice and hemorrhagic liver cysts), these formulations should no more be

</table>
clinically used (1,388). The only active and safe oral formulation is the T Undecanoate (TU), in oleic acid or in a mixture of castor oil and propylene glycol laureate (T undecanoate caps), encapsulated in soft gelatin. However its absorption is variable and it must be administered with dietary fat, to promote an adequate absorption. Eighty percent of men showed normal plasma T levels with the dose of 120-240 mg/day (389). Oral TU has the advantages of flexible dosage, self-administration and immediate decrease in T serum levels after interruption of treatment.

b) Buccal Formulation

Transbuccal administration provides the absorption of T through the oral mucosa avoiding intestinal pass and liver inactivation. It is presented as a biopellet to be pressed on the gum above the incisor tooth: a buccal film is achieved and should be put between the lower gum and the cheek (390). Men treated with buccal formulation (Striant®) 30 mg twice a day and compared to a group of patients given 5 mg of T gel formulation daily showed no differences in mean T serum levels (391) and its effect in sexual functioning were comparable when giving injectable T enanthate (392).

c) Transdermal Formulations

Transdermal preparations are available either as skin patches or as hydroalcoholic gel and are designed to deliver 5 to 10 mg of T per day (2). They should be used daily and normally provide uniform T serum levels during the treatment. Their efficacy and safety are well demonstrated (390). The patches can be scrotal and non scrotal, and these can be without or with enhancers in order to increase the skin absorption (393). Dose adjustment should be considered since the skin absorption can vary between men. Skin irritation is a common side effect with the patches but uncommon with the gel. Some men – and this is different between cultures - also complain of lack of spontaneity and even shame in using both scrotal and non-scrotal patches. There were some reports of men being dissatisfied in shaving the scrotal skin and difficulties to place and keep in place the patches all time. Patient's compliance with T gel seems much better than with T patches (390). After 5 minutes the gel dries and swimming or having a shower 4 to 6 hours after does not affect T serum levels. Since gel achieves a steady-state level within few days, timing of application is not an issue. Transdermal formulations also have the advantages of flexible dosage, self-administration and immediate decrease in T serum levels after interruption of treatment.

d) Subcutaneous Formulations

Subdermal pellet implants of T are used since 1940 (162). There are many reports showing their benefits but also their complications (eg. infection, extrusion). They need a specialist to be implanted and have a prolonged period of action (around 6 months).

e) Intramuscular Formulations

The intramuscular injection of T administered in oily depot is a route very often used. These formulations can be divided in short and long acting.

- The more frequently used short acting formulations – they have very similar pharmacokinetics - are T Enanthate (TE) and T Cypionate (TC), and must be injected 200 to 250 mg in general in intervals of 2 to 4 weeks. The T propionate has a much shorter half-life and 50 mg should be injected every 2 to 3 days (390). Other formulations containing an association of T esters can be found in some countries (Table XV). The short acting T formulations induce serum peak levels of T 2 to 3 days after injection, with in general a transient supraphysiological level, followed by an exponential decline to subphysiological levels in 10 to 14 days – the serum levels are in general subnormal before the next injection (1). These highs and lows of T may be unpleasant for some men and produce fluctuations in patients' mood, sexual desire and activity, and energy level. (2). They have the advantage of being the most cost-effective formulations and the disadvantage of painful injections and the need of more frequent medical visits.

- The long acting formulation available (T Undecanoate) shows more favorable kinetics than the short acting ones: a first injection of 1,000 mg of TU is followed by a second injection 6 weeks after (loading dose) and then an injection every 12 weeks. It does not reach supra - or subphysiological levels, keeping serum levels physiological within the normal range for 12 weeks of treatment period (Figure 6). Thus, the side effects due to the serum fluctuation levels of T are not observed with this formulation.

There are several studies showing the high efficacy and safety of intramuscular TU (394-396). It must be injected slowly - at least one minute - deeply into the gluteal muscle. TU is generally well tolerated and very few patients relate irritation or pain at the site of injection (390). It has the advantage of requiring only one injection every 3 months.

f) Alternatives to testosterone

1. Oral Clomiphene and other Antiestrogens:

Estrogens exert a negative feedback on gonadotrophin secretion (see Figure 4). Anti-estrogens class 1, due to their antagonistic effects on Estrogen Receptor (ER) in the hypothalamus and pituitary, have the potential to increase serum T levels in men with hypogonadotropic (secondary) hypogonadism by restoring physiological endogenous testosterone secretion, while maintaining testicular volume and, potentially, spermatogenesis. In addition, some anti-estrogens, as tamoxifen, do not act as antagonist in all the tissues, but maintain some estrogenic activity (selective estrogen receptor modulator, SERM) in some tissues as the epididymis (397) and maybe...
the bone. In fact following administration of other SERMs, as raloxifene and toremifene, an increased bone mineral density in GnRH agonist-treated men has been demonstrated in men treated with GnRH agonist and therefore hypogonadal (398). Shabsigh et al (399) reported positive results in terms of T rise with clomiphene citrate (25 mg daily) in a study on 36 men with T deficiency (less than 3 ng/ml), thus confirming previous experiences of Guay et al (380,400) in subjects with ED. However, an improvement of sexual symptoms was described by Guay et al.(380) in ED subjects only after prolonged therapy (four months). A recent study indicates that clomiphene is able to restore normal T and LH levels and to improve sperm motility and erectile function in most (70%) of male patients with prolactinomas and persistent hypogonadism under usual dopaminergic therapy (401). Because an increased estrogen-mediated negative feedback on hypothalamus-pituitary gland has been hypothesized as a possible cause of the obesity-induced T deficiency (see Figure 4), it is conceivable that anti-estrogens may help in restoring T levels in such a common condition. However, only few data are available for clomiphene in the so-called late-onset hypogonadism (402). Also tamoxifen, in a retrospective study in subjects with infertility, was able to increase T and gonadotrophins (403). In conclusion, there are preliminary evidences of some beneficial effect of antiestrogens in restoring testicular function in specific subgroup of ED subjects (secondary hypogonadism/TD). However, long-term double blind, placebo-controlled studies are needed to verify their activity in male subjects with sexual dysfunction and, more important, their safety.

2. HUMAN CHORIONIC GONADOTROPIN (hCG):

Human chorionic gonadotropin (hCG) is purified from the urine of pregnant women and shows the same biological activity as LH, but with a longer half-life. One injection of 5000 units stimulates T secretion for 3 to 5 days on condition that the Leydig cells are responsive. It is mainly used in the condition of hypogonadotrophic (secondary) hypogonadism when fertility is required, in combination with FSH or human menopausal gonadotropins. It is usually administered intramuscularly three times a week at a dose of 1000-2000 units, or twice a week at a dose of 5000 units. T levels should be monitored after 1-2 months of therapy, the day before the next injection. If hCG alone is not sufficient in restoring sperm production, FSH could be added. Responsiveness to hCG is influenced by several factors including testis volume, and the time of onset of hypogonadism (prepubertal versus postpubertal). Side effects of hCG per se are limited, but due to the expected rise in T plasma levels, monitoring would be the same as for T substitution. Once pregnancy has been achieved, patients usually go back on T therapy, due to the higher patient compliance (404).

3. FUTURE ANDROGEN THERAPIES: SELECTIVE ANDROGEN RECEPTOR MODULATORS (SARMs) (REVIEW IN BHASIN ET JASUJA 2009, 405)

Selective androgen receptor modulators (SARMs) are a new class of AR ligands that might change the future of androgen therapy dramatically. The discovery and development of SARMs provides the opportunity to design molecules that exert androgenic activities variable from one tissue to
another to elicit the specific desired activity. An ideal SARM for the treatment of primary or secondary TD would be orally active, with a pharmacokinetic profile consistent with once a day administration, capable or incapable of stimulating the prostate, seminal vesicles, and other sex accessory tissues at doses equipotent to those needed to provide increases in muscle mass and strength along with fat-free mass, support bone growth, and maintain/restore erectile function, libido, virilization, and male habitus. Unlike testosterone, these SARMs are not substrates for 5α-reductase activity. Other activities that are considered undesirable should be diminished or eliminated, such as potential liver toxicity, blood pressure effects and fluid retention, induction of gynecomastia, infertility and overstimulation of erythropoiesis. With improved pharmacokinetic characteristics and tissue-selective pharmacological activities, SARMs can be expected to extend the clinical applications of androgens to osteoporosis, muscle wasting, male contraception and diseases of the prostate. Mechanistic studies with currently available SARMs are able to define the contributions of differential tissue distribution, tissue-specific expression of 5α-reductase, ligand-specific regulation of gene expression and AR interactions with tissue-specific coactivators to their observed tissue selectivity.

Research into SARMs has made dramatic progress over the past decade, and several lead compounds with various chemical structures and in vivo tissue selectivity have been identified and developed, with some proceeding to clinical trials. Most of the discovery and development efforts continue to be devoted to nonsteroidal AR agonists as anabolic SARMs. Meanwhile, there is growing interest in the search for non-steroidal AR antagonists and peptide antagonist as tissue-selective anti-androgens. The mechanism of tissue selectivity of SARMs remains unclear, although tissue-specific expression of 5α-reductase appears to have a role for many of the SARMs that are identified currently. It is not clear if other mechanisms related to SARM action contribute to the observed tissue selectivity in vivo. Future mechanism-based drug design will rely on further investigations of the mechanisms of action of known SARMs, including co-regulator recruitment during the genomic actions of ARs, signaling pathways involved in the non-genomic effects of ARs, and potential tissue-specific distribution.

Clinically, SARMs with improved pharmacokinetic characteristics and tissue selectivity might expand the therapeutic applications of AR ligands to include androgen replacement therapy, muscle wasting, osteoporosis, male contraception, BPH and prostate cancer.

Of the mechanisms that have been proposed to achieve tissue selectivity of AR ligands, the most definitive evidence exists for the role of 5α-reductase. The tissue-specific expression of 5α-reductase makes it a unique contributor to tissue selectivity. Specific inhibition of the type 2 enzyme by finasteride blocks the conversion of T to DHT in the prostate, and T exhibits partial agonist activity in the regrowth of this tissue in castrated rats. Therefore, for SARMs replacing testosterone, which should have relatively low intrinsic activity and/or potency and do not interact with 5α-reductase, tissue selectivity might be caused simply by their partial agonist activity in the prostate. Most SARMs with verified tissue selectivity appear to be partial agonists in the prostate, which indicates that their tissue selectivity is related, at least partially, to the tissue-specific expression of 5α-reductase. If tissue selectivity can be achieved by lack of interaction with 5α-reductase, it might also be achieved by tissue-specific metabolism of the ligands by 5α-reductase. Several approaches might make use of the potential tissue-specific conversion to develop SARMs, including inactive parent compounds that are activated by type 2 5α-reductase in the prostate to form anti-androgens, or AR agonists that are inactivated by type 2 5α-reductase in the prostate, and, finally, AR agonists that are converted to anti-androgens only by type 2 5α-reductase in the prostate. The feasibility of these approaches might be limited by the chemical structures of 5α-reductase substrates. However, the common interaction of T as substrate and ligand of 5α-reductase and AR, respectively, indicate that this might be exploited as another unique therapeutic application of SARMs. The focus will thus be on non-steroidal AR-agonists. Current investigations focus on substances like quinolinone analogs, aryl propionamide analogs, hydantoins analogs, and tetrahydro-quinoline analogs.

4. Practical aspects:

Guidelines referring to the main indications of T therapy in Sexual Medicine, as well as to the main available preparations may be found in recommendations 10 to 17. The algorithm of figure 7 sketches the broad outline of TD treatment.

---

**B. ESTRADIOL, ESTRADIOL/TESTOSTERONE RATIO, ESTRADIOL RECEP'TIVITY (406)**

---

**I. PHYSIOLOGICAL REMINDER:**

The testosterone/estradiol ratio represents aromatase activity since low testosterone levels may result from lower production or higher metabolism to estradiol by the enzyme aromatase. Also conditions of insulin resistance or hyperglycaemia most likely result in reduced androgen synthesis by mitigating Leydig cell

Figure 7: Algorithm for the treatment of the Testosterone Deficiency Syndrome
response to gonadotrophins; but, in addition, also the central regulatory unit seems to be attenuated by the aromatization product of testosterone: estradiol (aromatase is mainly located in fat tissue and, thus, obesity might trigger hypogonadism also by inhibition of gonadotrophin release via the activated hypothalamic estrogen receptors).

Aromatase belongs to the cytochrome P450 family and forms an electron-transfer complex with its partner, NADPH-cytochrome P450 reductase. Because of the membrane-bound character and heme-binding instability, no crystal structure of aromatase has been reported so far. Hence, aromatase polymorphism may play a pivotal role in facilitating the effects also of testosterone as a variable degrader and modulator of this steroid.

II. CARDIOVASCULAR EFFECTS OF ESTROGENS:

Protective roles of estrogens against cardiovascular disease has been appreciated for many years until the equivocal results of cardiovascular outcomes in clinical trials on hormone replacement therapy were reported. Although new ongoing trials aim to resolve these discrepancies, it is obvious that cardiovascular effects of estrogens are complex and diverse also in men.

To understand further effects of estrogens, the detailed knowledge on the specific role of both classical estrogen receptor (ER) subtypes and G protein-coupled receptor are of importance. The pattern of ER-alpha and ER-beta expression in various tissues, the genomic and non-genomic estrogens versus subtype selective ER-alpha and ER-beta stimulation on isolated tissues and in different knockout animal models are of pivotal importance. As ER-alpha and ER-beta are expressed differentially, the pattern depends on tissue, sex and diseased condition. However, a clear role for each ERs have to be finalised with focus on mechanisms and by exploring the potential of ERs-selective agonists for clinical utility.

III. ESTROGENS AND THE PROSTATE:

Special attention should be paid to prostate tissue: both androgens and estrogens play a marked role in the prostate and are critical for normal prostate growth and development. The role of androgens in the prostate and in prostate disease is well known, however, the role for estrogens in the prostate and in prostate disease is complex and is still only just beginning to be appreciated.

Our understanding of the role and action of estrogens in the prostate has advanced significantly recently due to important discoveries, including the discovery of a second estrogen receptor subtype (ER-beta), the detection of aromatase in the prostate, and the identification of rapid nongenomic estrogen signaling. We now know that estrogens are essential for normal tissue homeostasis within the prostate and that too little or too much leads to perturbation of the glands growth and the emergence of disease. We are also beginning to recognize the importance and differential roles of the estrogen receptors ER-alpha and ER-beta. Specifically, the activation of ER-alpha leads to aberrant proliferation, inflammation, and the development of premalignant lesions, while, in contrast, the activation of ER-beta is critical in prostatic stromal-epithelial cell signaling and mediating antiproliferative effects that balance the proliferative action of androgens on the epithelium.

These data have established the importance and complexity of estrogen action. We now know that estrogens have the capacity to exert both beneficial and adverse effects in the prostate via ER-beta and ER-alpha, respectively. Based on this, the selective targeting of estrogen action may form the basis of new therapies for prostate disease.

C. OTHER HORMONES

I. PROLACTIN

1. PHYSIOLOGICAL ROLE

Prolactin (PRL) is a 23 kDa-polypeptide secreted by pituitary lactotroph cells. Circulating forms of prolactin include, beside the usually predominant monomer form (23 kDa), high molecular forms such as macroprolactin (>100 kDa), a biologically inactive complex of PRL and IgG. PRL secretion is mainly inhibited by dopamine (DA), via D2 receptors, and stimulated by serotonin and thyrotropin-releasing hormone (TRH), the three-aminoacid peptide, which stimulates also thyrotropin (TSH) secretion (review in Sobrinho, 407).

In mammals, the main physiological role of PRL is, during gestation, to prepare the breast for milk production, and, during puerperium, to stimulate lactation. During breast-feeding, PRL secretion is maintained elevated by suckling, via a peripheral nervous loop. It is likely that PRL is also involved in regulation of a variety of brain functions, overall directed to organize and coordinate behavioural and neuroendocrine adaptations during pregnancy and lactation. In addition, PRL inhibits ovulation, by blocking the pulsatile secretion of GnRH, therefore providing to breast-feeding women a natural method of contraception (2, 408). According to these important actions of PRL, knocking out PRL gene in mouse resulted in female infertility.
In contrast to the importance of PRL in female reproduction, the physiological role of this hormone in males is still obscure. Gene deletion of PRL or of its receptor does not alter male reproductive fitness, although this receptor is expressed in the brain, testis, male accessory glands and even in the penis. Several studies have shown that PRL increases following male orgasm (review in Kruger et al [409]), hypothesizing a negative feedback control of this PRL surge on sexual motivation, contributing, therefore, to the post-orgasmic refractory period. However, it is noteworthy that the post-orgasmic rise in PRL is relatively modest and similar in men and women, who are less prone to post-orgasmic refractoriness and satiety. In addition PRL increases during other emotional, stressful, or disturbing conditions (including venipuncture) or following stimulation of the nipple or areola (2,410).

It has been demonstrated that a low PRL response to a serotonergic challenge could be considered a mirror of a blunted central serotoninergic function (411). Recent data indicate that also circulating prolactin, in the normal physiologic range, could mirror the central serotoninergic tone. In fact, among males consulting for sexual dysfunction, hypoprolactinemia (i.e. prolactin levels in the lowest quartile) is associated with particular psychobiological features, often considered as reflecting a low serotoninergic signalling. These include a higher prevalence of premature ejaculation and anxiety symptoms along with MetS and arteriogenic ED (412).

2. HYPERPROLACTINEMIA: PATHOPHYSIOLOGICAL ASPECTS

Although the physiological role of PRL in males is still poorly understood, the association between hyperprolactinemia (HPRL) and derangements in both the reproductive and sexual behaviors is better defined. The prevalence of mild HPRL (PRL >420 mU/L or 20 ng/ml) in male subjects with sexual dysfunction is quite variable, ranging from more than 13% to less than 2% (2,408). In these subjects, severe HPRL (SHPRL, PRL > 735 mU/L or 35 ng/ml) is a relatively rare event (less than 1%; 2,408). Milder forms of HPRL (MHPRL) do not play a significant role in the pathogenesis of male SD. Conversely, SHPRL has a negative impact on sexual function, impairing sexual desire - as well as erectile function - and T production (2,408). It has been demonstrated that in subjects with SD, a severely reduced libido is associated with a 10-fold increase in the prevalence of SHPRL (408). A PRL-induced hypogonadism, which is frequent but not constant, and results from a PRL-dependent decrease of LH secretion, could explain, at least partially, this association (2,408). PRL may also play a direct role in the control of male sexual desire. Among hypogonadal subjects with HPRL, prolactin-lowering drugs are able to restore both T levels and libido (408), while TT alone is not as effective (2,410).

The relationship between HPRL and erectile function is under debate. Some authors have suggested a possible pathogenetic link between severe ED and SHPRL (2,408). In a consecutive series of 51 men with SHPRL and prolactinoma compared to 51 age-matched normal controls, 96.7% of the former vs 13.7% of the latter (p<0.0001) had a reduction of the nocturnal erections although only 50% of the patients complained about sexual disturbances (413). The number of nocturnal erections correlated with the PRL levels. Following treatment with cabergoline, NPT normalized in 60% of patients who had normalized PRL levels and in 8% of patients who did not. However, in a series of 2146 men with SD, Corona et al. did not confirm a significant association between SHPRL and severe ED after adjustment for confounders (408).

Among patients with MHPRL, repeat blood sampling revealed normal PRL values in almost one half of cases, most probably due to venipuncture stress. On the other hand, the same study (408) confirmed that in patients with SHPRL, false positive cases could derive also from the presence of a macroprolactin (9.4%). SHPRL underlined an organic problem in the hypothalamic-pituitary region in 2/3 and a drug-induced condition in almost 1/3 of cases, being, therefore, a condition to be carefully addressed. Several medications can induce HPRL via a number of neuroendocrine mechanisms, including an impairment of dopaminergic transmission or an increase in serotoninergic or opioidergic transmission. Estrogens directly stimulate PRL synthesis (review in Molitch [414]). The use of selective serotonin reuptake inhibitors has been associated with a mild HPRL and a decreased sexual desire (415). SSRI-associated hypoactive sexual desire was still present after adjusting for PRL levels, therefore suggesting a PRL-independent effect of this class of anti-depressant on libido (415). Table XVI summarizes the main causes of HPRL.

3. CLINICAL ASPECTS

a) Sexual dysfunctions of hyperprolactinemic men:

A compilation of over 300 hyperprolactinemic men found sexual dysfunctions in 88%, including ED in almost every case (410). The most typical pattern associated ED with hypoactive sexual desire (HSD). As reported above, nocturnal erections are reduced in most men with SHPRL (408,413). Measuring systematically PRL in over 2100 men with mixed SDs, Corona et al (408) found no association between ED and HPRL, but 92% of the studied population complained about ED which may have reduced

      VII) CALCIUM CHANNEL BLOCKERS:
         - Verapamil
      VIII) HORMONES
         - Estrogens
         - Antiandrogens
      IX) ANTICONVULSIVANTS:
         - Phenytoin
the chance of such an association. In their series SHPRL but not MHPRL was significantly associated with HSD. However HSD was absent in one third of men with SHPRL. Gynecomastia was not associated with HPRL. Retarded ejaculation and anorgasmia have also been observed, mostly associated with ED (410), but sometimes isolated (416). In the above series of mixed SDs, retarded ejaculation was associated with HPRL, but no more after adjustment for the use of hyperprolactinemic drugs (417). Some cases of retrograde ejaculation cured by dopamine-agonist therapy have also been reported (418).

b) Prevalence of hyperprolactinemia in men with erectile dysfunction:

Routine determinations of serum PRL found HPRL in 1 to 5% of ED patients. Compiling the 10 largest series of literature led to a prevalence of SHPRL at 0.62% and of pituitary adenomas at 0.38% among 8700 ED patients (2). In addition 1.5% of these patients had MHPRL. Though low, these figures are somewhat higher than the prevalence in the general population (SHPRL in 0.27%, and pituitary tumors in 0.03% among over 13000 Asian men) (419,420).

Prevalence of hyperprolactinemia in men with other sexual dysfunctions: It is also very low. No SHPRL was found in consecutive series of men consulting for HSD without associated ED (n=53), non drug-induced anorgasmia/retarded ejaculation (n=74), and premature ejaculation (n=124) (410).

4. DIAGNOSIS

a) Routine or selective prolactin measurement?

Although SD may be for a long time the only symptom of male HPRL, a curable cause which may be linked to a life-threatening pituitary adenoma, the very low prevalence of SHPRL can hardly justify routine PRL measurement, especially in ED patients. Restricting it to those men with low T would have led to miss 6 of 12 SHPRLs and 3 of 7 pituitary tumors found in 1800 ED patients (156). Likewise sexual desire may be normal in many ED patients with HPRL (410,421). Combining both criteria would be more efficient. Reassessing the results of 1370 consecutive ED patients, Buvat (410) found that by restricting the measurements to those men with HSD or serum T < 4 ng/ml (low + low normal values), they would have saved over 50% of the measurements while missing only one of 10 SHPRLs, and none of 6 pituitary tumors. PRL should also be measured in case of isolated HSD, and retarded or absent orgasm.

b) Measuring serum prolactin:

Blood must be sampled fasting, preferably following a 20 min rest to reduce the stress linked to venipuncture. In case of result > 20 ng/ml (400 mUI/l), the test should be repeated after discontinuation of any drug likely to increase PRL (table XVI), if possible 20 min after insertion of a catheter. This would eliminate almost 50% of MHPRLs found at first assay (408). If not already checked, serum T and TSH should be measured in the same time.

c) Screening for macroprolactins:

In case of non drug-induced SHPRL associated with a normal T and/or a normal sexual function, it is recommended to screen for these biologically inactive variants of PRL with high molecular weight, which constitute "false HPRLs". This may be done by means of PRL chromatography or, in a cheaper way, precipitation with polyethylene glycol. Macroprolactinemas account for 10 to 22% of all HPRLs (2) and are found in about 1% of the general population (419). Exceptional macroprolactinemas associated with biologic activity or with a pituitary adenoma have been reported (2,408,422).

d) Looking for significant etiologies:

Drug-induced HPRL accounts for 17% (423) to 26% (408) of HPRLs in men with SD (table XVI). Secondary HPRL may also result from hypothyroidism (significant association with high serum TSH [408], renal insufficiency and cirrhosis, and to any process disturbing the hypothalamic-pituitary dopaminergic transmission (including different types of hypothalamic and pituitary tumors). Primary HPRL may be idiopathic, but in most men it is associated with a PRL-secreting pituitary adenoma (prolactinoma). Macroprolactinomas (> 10 mm diameter), as other types of hypothalamic or pituitary tumors, are likely to result in tumorous complications: visual disturbances, or even blindness, due to compression of the optic chiasma, and hypopituitarism, which may become life-threatening if decompensated (figure 8).

Any non drug-induced HPRL must therefore benefit from a scan or better a MRI of the hypothalamic-pituitary area, especially in case of SHPRL. In a compilation of 8700 ED patients by Buvat et al (2), 67% (31/46) of those with SHPRL harboured a pituitary tumor. Macroprolactinomas are the most prevalent in these men (413). Some microprolactinomas (diameter < 10 mm) have also been reported in men with SD and MHPRL (408,421).

e) Additional investigations to be done in case of macroprolactinoma:

Campimetry and assessment of the main pituitary...
functions to detect a possible hypopituitarism are recommended and will be better achieved by an endocrinologist. De Rosa et al (413) found 10 hyperthyroidisms and 3 hypoadrenalisms among 41 men with macroprolactinomas.

5. TREATMENT OF SEXUAL DYSFUNCTIONS OF HYPERPROLACTINEMIC MEN

Dopamine-agonist agents (mainly bromocriptine and more conveniently cabergolide which often requires a single administration per week) should be the first choice treatment in case of SHPRL. In most cases these prolactin-lowering agents normalize every aspect of sexual function, in addition to the serum PRL and T levels. They may also shrink the associated prolactinomas, or at least prevent their growth (408,410,424). Conversely, the success rate of these agents does not exceed the placebo effect in the MHPRL-associated SDs (2).

Transphenoidal removal may also be proposed in case of prolactinoma. It may definitely cure both the tumor and the HPRL (425), and protect against any further tumorous complication. However dopamine-agonist therapy is more often chosen as first line treatment at least in case of microprolactinoma, since tumorous extension or complications seldom occur with this therapy (2,424). In case of macroprolactinoma, hypogonadism may persist despite the return to a normal PRL level. Such patients require the combination of T therapy with dopamine-agonist therapy. T therapy alone might stimulate the growth of the pituitary tumor through the aromatization of T into estradiol (2).

II. GROWTH HORMONE

1. PHYSIOLOGICAL ROLE:

Growth hormone (GH) is a 191-amino acid polypeptide synthesized and secreted, under control of growth-hormone releasing hormone (GHRH, positive) and somatostatin (SRIF, negative) of somatotroph cells in the anterior pituitary (426). Its secretion is also positively regulated by the 28-amino acid peptide ghrelin, synthesized primarily in peripheral tissues, as stomach. The primary role of GH is to promote linear bone growth, through the promotion of insulin-like growth factor 1 (IGF-1) synthesis in the liver and other peripheral tissues. GH also has general metabolic effects that result in a positive protein balance. It increases lipolysis, which causes the release of free fatty acid from adipose tissue. Carbohydrate metabolism is also affected, through the stimulation of neoglucogenesis. The availability of this alternative fuel allows for the utilization of the spared proteins for growth. The GH receptor is a monomeric 620-amino acid protein of the class I cytokine-hematopoietin receptor superfamily, homologous with the receptors of PRL, interleukins 2-7, erythropoietin, and colony-stimulating factor. Each GH molecule binds to two receptors, forming a dimer that is directly translocated to the nucleus or primes a JAK2-dependent cascade of intracellular phosphorylation, where signal-transducing activators of transcriptional proteins (STATs) play a major role. This hormone is used clinically to treat children’s growth disorders and adult growth hormone deficiency. A number of factors are known to affect GH secretion, such as age, gender, diet, exercise, stress, and other hormones, as well as sex steroids. In particular, androgen stimulates, while estrogen inhibits, GH release.

2. GONADAL AND SEXUAL FUNCTIONS IN MEN WITH EXCESSIVE OR DEFICIENT GH SECRETION:

- GH excess (acromegaly): The most common disease of GH excess is a pituitary tumour composed of somatotroph cells of the anterior pituitary, casing a syndrome known as acromegaly. Acromegaly is a relatively rare condition, with an estimated prevalence of 20-60 cases per million. Measurement of the serum concentration of GH or of its induced protein IGF-1 has become a pivotal criterion in both the diagnosis of the disease and the establishment of cure after appropriate (surgical and/or medical) treatment. The pituitary adenoma may become large enough to cause headaches, impair vision by pressure on the optic nerves, or cause deficiency of other pituitary hormones by displacement. Secondary hypogonadism is a relatively common feature of acromegaly (427-429). Prolonged GH excess thickens the bones of the jaw, fingers and toes. Accompanying problems can include muscle weakness, insulin resistance and pressure on nerves, casing carpal tunnel syndrome. Cardiomyopathy and an increased mortality rate due to cardiovascular events are common. Although impotence and decreased libido is often reported as a symptom of acromegaly in textbooks (426), it is still unclear if it is due to the excess of GH or to the compression by the GH-producing tumour of the neighbouring gonadotrophin producing cells. An excess of PRL, caused by mixed hyperproduction of GH and PRL or by compression of the pituitary stalk, is a common feature of acromegaly, which can partially contribute to the sexual dysfunction. Moreover, due to the similarity of GH and PRL receptors, GH excess induces PRL-like effects and can induce galactorrhea. Patients with acromegaly have also prostate enlargement (429), which can be partially normalized upon disease control by surgery or medical therapy (427,428). It has been demonstrated that in acromegalic subjects, adequate surgical and or medical therapy can also partially revert hypogonadism, although an irreversible hypogonadism has been described in those with larger adenomas (427-429). In none of these studies (427-429) was acromegaly-related sexual dysfunction was in-
vestigated. In subjects with acquired GH deficiency in adulthood, GH supplementation increases prostate size, an effect that was further potentiated by androgen supplementation in those who were also hypogonadal (430). These findings suggest a direct relationship between GH/IGF-1 axis and prostate size, at least in the youngest subjects.

- GD deficiency: Because in the aging male a progressive reduction of GH release and IGF-1 synthesis has been described (review in Sherlock et Toogood [431]), the effect of GH, with and without T supplementation, has been tested in controlled trials. Only a small, short-term (one month) controlled trial in older individuals that were not GH or T-deficient assessed sexual function. Neither GH nor T affected the number of sexual intercourses or mood (432).

3. POSSIBLE EFFECTS OF GH ON THE PENILE MECHANISMS OF ERECTION?

It has been suggested that GH can induce peripheral vasodilation by increasing endothelial nitric oxide (NO) synthesis or activity through an IGF-1 induced effect (433) or through a post-translational phosphorylation of eNOS (434). In addition it has been demonstrated that GH supplementation enhances NOS-containing nerve fiber regeneration in both the intracavernosal and dorsal nerves after experimental unilateral cavernous nerve neurotomy in the rat (435). In isolated human penile strips GH can induce a dose-dependent relaxation, along with an increase in cGMP (436). However, all these effects were obtained at a relatively high concentration of GH. A modest, but significant, increase in cavernosal concentrations of GH has been described during the physiological process of erection in men (436,437). Such an increase is, however, at least 3 orders of magnitude lower than those required to induce a 30% relaxation on “in vitro” human strips (436). In a study of ambulatory men no correlation was found between peripheral GH levels and all the dimensions of the AMS questionnaire, including sexual function (438). In a small series of patients with organic, but not psychogenic ED, peripheral GH levels were found lower than in age-matched controls (439). In the same study cavernous GH level, in both organic and psychogenic ED, was not different from the peripheral one (439).

4. CONCLUSIONS:

Prevalence of ED and decreased libido is increased in acromegalic patients (426). However it is still a matter of debate whether GH has a direct role in inducing these disorders or if the cause of reported male sexual problems is the accompanying TD or PRL increase. Hence, due to the low prevalence of acromegaly in the general population, GH or IGF-1 determinations are not recommended as first line examination in male subjects with sexual dysfunction. Further studies on GH and erection are strongly encouraged.

III. MELANOCORTINS: ALPHA MSH AND OTHER PRO-OPIO-MELANOCORTIN DERIVATIVES

Melanocortins (MC) are a family of peptides, including adrenocorticotropic hormone (ACTH) and α-, β- and γ-melanocyte-stimulating hormones (MSH), derived from the cleavage of a large precursor peptide: pro-opiomelanocortin (POMC). Both α-MSH and β-MSH interacts with specific MC receptors (MCRs), MCR3 and MCR4, within the hypothalamus and the limbic system, and, in the experimental animal, mediate a typical behaviour syndrome including grooming, stretchings and yawnings, spontaneous penile erection and ejaculation and increased sexual receptivity. Two synthetic analogs of α-MSH have been developed for human use. The first called melanotan (afamelanotide, formerly CUV1647) is on track for registration for its photoprotective properties and the second is called bremelanotide (formerly PT-141), and developed by Palatin Technologies (440). Bremelanotide is a cyclic heptapeptide under development for its erectogenic properties. Preliminary studies indicate that, following intranasal or subcutaneous administration, bremelanotide resulted in healthy men and in men with ED in a statistically significant erectile response (see in Miner and Seftel (440) and Hellstrom (441) for reviews). In a recent randomized, double-blind, placebo controlled study in ED men, a favorable response with bremelanotide has been reported in 33.5% of subjects, as compared to 8.5% in the placebo group (442). Patient’s satisfaction with intercourse was also greater in the treated group. However, in all the studies drug-related adverse effect were present, as nausea, yawning and flushing, which, somehow, limited the attractiveness towards this treatment. There are also concerns regarding a possible increase in blood pressure.

IV. OXYTOCIN

Debackere and colleagues (443) in the 60’s originally postulated that oxytocin (OT) could be released in the male circulatory system during sexual activity. In fact, using a cross-circulation technique, they found that a manual stimulation, per rectum, of seminal vesicles, prompted a milk-ejection response in the female partner. Further studies demonstrated that a surge of OT happens during male sexual activity, peaking during or after orgasm. This evidence in humans matches data from many other species. In addition, because pharmacological administration of OT increases the number of ejaculated spermatozoa in different animal species, including human, a physiological role for oxytocin during ejaculation has been hypothesized. OT receptors are abundantly expressed in the human male genital tract. However conclusive data on effects of OT on human ejaculation are still lacking (444,445).
Brain OT plays an important role in the regulation of male sexual behaviour, facilitating erection and orgasm in different experimental animals through an action on paraventricular nuclei of the hypothalamus (446). Intranasal administration of OT makes human men more trusting and reduces anxiety and psychosocial stress (446). However compelling evidence showing that OT facilitates pair bonding in humans as it does in animals is still lacking. In addition, in a double blind, placebo controlled study, a specific effect of intranasal OT on appetitive, consummatory and refractory sexual behaviour was not found (447), even though an anecdotal report indicates that intranasal OT can facilitate orgasm in an otherwise anorgasmic male (448).

V. DEHYDROEPIANDROSTERONE (DHEA) (review in 2,449)

1. BIOSYNTHESIS OF ADRENAL ANDROGENS

DHEA is synthesized in the zona reticularis of the adrenal gland, and is sulfated via sulfotransferase into DHEA-Sulfate (DHEA-S), which is thought to be the storage form of DHEA. The majority opinion is that there is free interconversion between DHEA and DHEA-S. The production follows an age-dependent pattern: decreasing with age. While serum DHEA-S concentration does not vary throughout the day, DHEA secretion follows a diurnal pattern similar to that of cortisol.

2. MECHANISMS OF ACTION OF DHEA:

DHEA is considered as a prohormone, which is converted peripherally to other sex steroids (especially T and E₂), and the steroid produced depends on the particular 17-hydroxylase enzymes predominating in that particular tissue.

Recently, a putative receptor specific for DHEA has been identified on endothelial cell plasma membranes that structurally related steroids failed to compete for binding, which has been shown to acutely increase NO release from intact vascular endothelial cells. These effects may be both genomic and nongenomic, and are independent of other steroid hormone receptors. These findings have possible implications for DHEA as an antiatherogenic compound, as DHEA independently inhibited human vascular smooth muscle cell proliferation in vitro, and in vivo (450), possibly by regulating cell cycle relevant proteins through a cytoplasmic steroid-hormone-independent pathway (451), especially Gi/o protein-mediated and ERK ½ dependent, (452). Iwasaki et al (in 2) demonstrated that both DHEA and DHEA-S had possible anti-inflammatory and immunomodulatory effects by inhibiting proinflammatory cytokine-induced transcription, an effect that neither estradiol or testosterone could duplicate.

3. PATHOPHYSIOLOGY OF DHEA DEFICIENCY

Primary adrenal insufficiency manifests symptoms of androgen deficiency through a lack of DHEA as well as a variety of non-endocrine medical conditions. The age-related decline in DHEA levels may correlate with many age-related phenomena such as diabetes, insulin resistance, hypertension, atherosclerosis, coronary artery disease, decreased bone mineral density, cancer and dementia. Depression and other mood disorders, eating disorders and chronic stress states have also been reported. In the MMAS, DHEAS was the only hormone which showed a strong (negative) correlation to the prevalence of ED among 17 investigated hormones including T and estradiol. Exogenous corticosteroids can decrease adrenal DHEA synthesis as adrenolytic drugs, like mitotane, and inhibitors of corticosteroid synthesis, like ketoconazole, can reduce adrenal production of DHEA.

4. MEASUREMENT OF DHEA

Measuring DHEA blood levels is generally not recommended because of its circadian secretion during the day and its short terminal half-life of approximately 4.5 hours. The measurement of DHEA-S is preferred because of more stable levels in the blood due to its longer half-life of approximately 24 hours. The measurement of DHEA-S can be performed at any time during the day.

5. DHEA REPLACEMENT IN ADRENAL INSUFFICIENCY

Adrenal insufficiency has been traditionally treated with glucocorticoids alone or with mineralocorticoids, but treating the concurrent androgen deficiency with DHEA has not yet reached standard of care, despite the obvious decrease in quality of life including decreased vitality, increased fatigue, reduced physical function, and sexual dysfunction. RCTs of DHEA replacement in adrenal insufficiency have given conflicting results: DHEA improved overall well-being, mood, and sexual functioning in the majority of the studies, which mainly included women. Insulin sensitivity and lipid profiles have benefited. However, other studies did not confirm these effects.

6. DHEA THERAPY IN HEALTHY AGING SUBJECTS

DHEA improved overall sense of well-being compared with placebo in an earlier study of a mixed cohort of men and women which used a questionable methodology. But other studies failed to show benefit in aging men. Regarding improvement in sexual function, the effects of DHEA administration have been conflicting, demonstrating benefits in older women, but none in aging men (2,453). A randomized, placebo-controlled trial in 40 ED patients claimed improvement on 50 mg DHEA administered for 6 months, but
objective data were missing in this paper. A recent review of the effects of endogenous and exogenous DHEA on cardiovascular disease risks reiterates the inconsistencies regarding the metabolic effects of DHEA supplementation, and suggests that positive effects have not been consistently shown.

7. OTHER PROPOSED USES FOR DHEA THERAPY

Beneficial effects on mood have been observed while using DHEA as treatment for depression and dysthymia, but only minor and transient improvements in cognitive performance were observed in Alzheimer’s Disease. In terms of bone health, the beneficial effects of DHEA supplementation are felt to be minor though proven in elder women in a 12 months RPCT (453). DHEA supplementation has been shown to reduce the frequency of flares and decrease steroid dose requirements in systemic lupus erythematosus. The potential for immunoregulatory effects of DHEA has been reinforced by the presence of specific binding found in murine T cells. Specific binding of DHEA on muscle cells suggests the possibility of DHEA therapy in muscular disorders.

8. CONCLUSIONS

DHEAS is the most abundant circulating sex steroid which is converted to other steroid sex hormones, and also may have a direct action on its own cell membrane receptor. DHEA deficiency has been correlated with symptoms of androgen deficiency and its supplementation has been shown to be beneficial to patients with primary and secondary adrenal insufficiency. However, studies looking at the effects of DHEA supplementation on other conditions have been inconsistent to date. The new data on DHEA has shed some important information, but we have a long way to go before we feel that we understand the complete physiology of DHEA and its therapeutic implications (454).

VI. THYROID HORMONES

1. PHYSIOLOGICAL ROLE:

The thyroid gland produces, under TSH control, two major active hormones, thyroxine (T4) and tri-iodothyronine (T3), which circulate in human blood tightly bound to carrier proteins, including thyroxine binding globulin (TBG). Free fractions of thyroid hormones are the biologically active hormones (FT4 and FT3), which regulate protein, fat and carbohydrate metabolism. Hence, there are no organs or tissues even partially unaffected by thyroid diseases. For instance, both hypothyroidism and hyperthyroidism result in clear alterations in the cardiovascular and mental state. However, the association between thyroid diseases and SD in men has not been systematically studied until recently.

2. HYPERTHYROIDISM AND SEXUAL FUNCTION:

In a consecutive series of 755 men presenting with SD, a two-fold greater prevalence of hyperthyroidism was evident among the men with premature ejaculation (PE) (455). According to this finding, Carani et al (456) in a small multicentre, prospective study, demonstrated that most (50%) hyperthyroid patients have PE, a prevalence that was substantially reduced (15%) by treating the underlying disease, with a consequent doubling of ejaculatory latency. A recent study in a Turkish population essentially confirms an association between the hyperthyroid state and premature ejaculation, which was substantially ameliorated by therapy of the thyroid disease (457). However Waldinger et al (458) did not find any relationship between PE and thyroid dysfunction in a cohort of 620 men with life-long PE, what logically suggests that the association with hyperthyroidism is restricted to the acquired type of PE.

3. HYPOTHYROIDISM AND SEXUAL FUNCTION:

In Carani’s study (456) it was also shown that medical treatment of the opposite state, hypothyroidism, resulted in a two-fold decrease in ejaculatory latency and a reduction in delayed ejaculation. Hence, the view that thyroid hormones regulate the ejaculatory reflex is gaining credence. Carani’s study also suggests that low sexual desire and ED may be related to hypothyroidism and can be normalized by thyroid hormones therapy (456). The underlying pathogenetic mechanisms are not completely clarified. Although it is possible that a hypothyroidism-induced PRL rise could mediate these negative effects on male sexuality, a direct role of thyroid hormones on reproductive tissues has also been postulated. A role for hyperthyroidism-induced anxiety was also envisaged (455,457). A recent study (459), in a limited number of ED patients, indicated that ED is extremely common in males with thyroid dysfunction. Treatment of the latter restored erectile function. Hence, more studies are needed to clarify the role of thyroid hormones on male sexual response.

VII. EPIDEMIOLOGY AND MANAGEMENT OF SEXUAL DYSFUNCTIONS IN THE DIABETIC MAN

Numerous researchers have attempted to understand and to quantify “normal” sexual behaviors. A systematic approach to male sexual (dys)function, specifically on sexual desire disorder, arousal difficulties and orgasms disorders must involve diabetes mellitus as a pivotal pathological entity.
1. EPIDEMIOLOGY OF SEXUAL DYSFUNCTIONS IN RELATION TO DIABETES MELLITUS

The prevalence of erectile dysfunction (ED) in men with diabetes mellitus (both type 1 and 2) is widespread and was largely investigated in a very elaborate and representative cross-sectional study of 9,868 Italian men. The age range was 20 to 69 years. The overall prevalence of ED was 35.8%, and increased with age, it was 4.6% in men in their 20’s and 45.5% in men older than 60 years. Of paramount importance is that independent factors of influence within the background setting of disturbed glucose control were duration and control of diabetes, obesity, complications of diabetes and cigarette smoking (460).

2. DIABETES-RELATED SEXUAL DYSFUNCTIONS IN MEN

Sexual dysfunction is any problem that regularly interferes with a person’s sexual performance. Men with diabetes are more likely than nondiabetics to experience sexual dysfunction. Sexual problems that may affect diabetic men include erectile dysfunction, ejaculation problems, and low levels of testosterone. Sexual dysfunction in people with diabetes often involves damage to blood vessels (diabetic angiopathy) or nerves (diabetic neuropathy). This damage often results from poorly controlled glucose. Other common factors that contribute to sexual dysfunction include obesity, fatigue, depression, medications, urinary tract infections, yeast infections and overactive bladder. Signs and symptoms vary according to the type of dysfunction the patient is presenting with. Diagnosis begins with a medical history and physical examination. Diagnosis should include also urine tests, nerve tests depending on the patient’s gender and type of dysfunction involved.

Diabetes is known to cause multiple medical (461), psychological (462), and sexual (463) dysfunctions. Impaired sexual function in men is a well-documented complication of diabetes. Several studies have shown that men with diabetes are at increased risk for erectile dysfunction, that it occurs at an earlier age (464–467), and that it is related to longer duration of diabetes, poor metabolic control, and the presence and number of diabetic complications. The debate about the etiology of sexual dysfunction of patients with diabetes is, however, still ongoing. Because patients with diabetes are at risk for vascular and neurological complications and psychological problems, they are at risk for both organogenic and psychogenic sexual dysfunction (463). Therefore, attempts to clarify the etiology of sexual dysfunction have proposed neurological, vascular, endocrine, and psychological factors; medication use; or a combination of both (465–467). It has been hypothesized that the etiology of sexual dysfunction in men with diabetes is linked with somatic factors (463).

Changes in sexual functioning are common as people age. Having diabetes, however, can result in earlier onset and increased severity of sexual problems. Diabetic men are more likely than nondiabetics to experience sexual dysfunction. Depending on the cause of sexual dysfunction, its onset may be sudden and temporary, or gradual and permanent. Many people with diabetes also suffer from high blood pressure, obesity, dyslipidemia, general fatigue, infections, hormonal conditions, bladder problems or depression, all of which can also contribute to sexual problems. Patients experiencing sexual difficulties must be encouraged to discuss these issues openly with their partner, and then seek appropriate treatment.

3. TYPES OF SEXUAL DYSFUNCTIONS IN DIABETES MELLITUS

a) Erectile dysfunction (ED) Men with diabetes are three times more likely to experience ED than those without diabetes (460). In addition, men with diabetes and ED may experience the problem 10 to 15 years earlier in life than nondiabetics. It is not uncommon for a man seeking treatment for erectile dysfunction to learn that he has diabetes. ED such serves also as a portal men’s health.

b) Male hypogonadism: Beginning in middle age, this condition is common in men, but more common in diabetic men. Recent research suggests that hypogonadism may also be associated with insulin resistance, the progression of type 2 diabetes and possibly heart disease (468-470).

c) Retrograde ejaculation: This is typically caused by failure of the urethral sphincters due to damage of the autonomic nerve system. Men experiencing this problem may notice that a small amount of semen is discharged during ejaculation, which may cause fertility problems (469,470).

d) Premature ejaculation: Factors that may contribute to this common condition include diabetes, cardiovascular disease, nerve damage, urethritis, or even hypogonadism (469,470).

e) Retarded or absent ejaculation: This difficulty occurs even in the absence of ED and libido issues. Risk factors for delayed ejaculation include diabetes, high blood pressure, nerve disease, prostate problems, and use of medications, like beta blockers and SSRI antidepressants (469,470).

4. MANAGEMENT OF SEXUAL DYSFUNCTIONS IN DIABETIC MEN

Risk factor modification by controlling the blood glucose levels is the essential and first step. Decreasing glucose concentrations will correct certain metabolic abnormalities, but the use of insulin sensitizers will further increase blood flow by decreasing insulin resistance. A second step is the treatment of the re-
lated factors, such as hypertension, obesity and any diabetic complication (470). The treatment of diabetic ED should begin with a review of potential risk factors and it must involve the partner and the relationship. In 9,496 adults with diabetes the incidence of modifiable risk factors was higher in the population with diabetes versus controls: hypertension (56% vs 22%), hyperlipidemia (41% vs 20%), obesity (78% vs 57%) (471).

Hypertension is significantly associated with abnormal glucose metabolism and the overall risk of cardiovascular events (11). Especially the use of angiotensin converting enzyme inhibitors or AT-1 blockers has been shown to increase blood flow in diabetic men (470).

Treatment of hypogonadism accompanying insulin resistance may correct many of the symptoms of androgen deficiency, and also improve erectile dysfunction, depending, of course, on how many other medical co-factors are present, especially how far vascular damage has advanced (470,471).

Phosphodiesterase inhibitors are a symptomatically working very efficient tool to help patients with ED, also including men with diabetes. Diabetic men often have clinical or subclinical neuropathy and their production of nN0 will be decreased. This is why the results of these agents are not as positive in men with diabetes mellitus as with other risk factors for ED. According to a Cochrane Review, sufficient evidence exists that PDE-5 inhibitors form a care that improves erectile dysfunction in diabetic men, but neither vardenafil, tadalafil nor sildenafil have been steadily proven to be most beneficial in diabetes mellitus induced ED (472).

Other therapies of ED and sexual dysfunctions in men with diabetes may be administered according to the indications, guidelines and patient-related individual experience as well as preference. These may include intraurethral alprostadil, penile self injection therapy, vacuum constriction devices and penile prosthesis. Testosterone therapy may be indicated as a monotherapy or in combination with other ED therapies (470).

D. RECOMMENDATIONS

I. DIAGNOSIS OF TESTOSTERONE DEFICIENCY

1. DEFINITION OF TESTOSTERONE DEFICIENCY (TD). (GRADE B)

- Testosterone Deficiency is a clinical AND biochemical syndrome, frequently associated with age and comorbidities, and characterized by a deficiency in testosterone and relevant symptoms.

- It may affect the function of multiple organ systems and result in significant detriment in the quality of life, including alterations in sexual function.

2. CLINICAL DIAGNOSIS. (GRADE A TO C)

- The clinical manifestations of Testosterone Deficiency are variable.
  - Sexual dysfunction, in particular Hypoactive Sexual Desire (GrA), Erectile Dysfunction (GrB), Delayed Ejaculation (GrC), are prominent and often the presenting symptoms.
  - Visceral obesity is often associated, and muscle mass and very likely bone mineral density are diminished (GrA).
  - Diminished strength, alterations in spatial cognition and mood may be associated (GrC).
  - The physical examination is, frequently, unhelpful. But small testicular size, alterations in testicular consistency and hair distribution, gynecomastia, and small prostate size can be detected.
  - Not all the manifestations need to be evident simultaneously and their intensity shows marked inter-individual variability.

3. TESTOSTERONE DEFICIENCY AND METABOLIC DISEASES: SCREENING. (GRADE B)

- Patients with clinical conditions associated with insulin resistance (obesity, type 2 diabetes, metabolic syndrome) should be screened for TD since it is often co-morbid.

- In these clinical conditions, it is important to measure Sex Hormone Binding Globulin – SHBG - to estimate calculated Free Testosterone – cFT, which is very well correlated to the value of FT measured by the reference assay, equilibrium dialysis.

4. TD AND METABOLIC DISEASES: POSSIBLE BENEFITS OF TREATMENT. (GRADE A)

- Visceral obesity should be appropriately managed because it is significantly associated with subsequent vascular events.

- Visceral obesity seems to be both the cause and the consequence of testosterone deficiency.

- In subjects with TD Testosterone Therapy improves body composition by moderately decreasing fat mass and increasing lean body mass. Preliminary data indicate a positive effect.
of T therapy on glycaemic control. However, such secondary benefits require further confirmation by large scale studies.

5. TESTOSTERONE AND CARDIOVASCULAR DISEASES. (GRADE C)
- Cardiovascular disease is often associated with low testosterone. All men with testosterone deficiency, as well as all men over 40 years of age or those younger with a strong family history should have their cardiovascular risk factors assessed and addressed.
- Routine testosterone measurement is not advised in men with cardiovascular disease without symptoms of TD like hypoactive sexual desire, ED, visceral obesity or diabetes, until randomised controlled trials of T therapy have confirmed its utility.

6. QUESTIONNAIRES. (GRADE B)
- A number of questionnaires have been proposed to help towards screening for or diagnosing TD.
- Many are sensitive but not specific.
- In subjects with sexual dysfunctions, structured interviews as Androtest demonstrate enough sensitivity and specificity to raise the suspicion of testosterone deficiency.
- However the diagnosis of TD should not be based exclusively on questionnaires or structured interviews.

7. BIOCHEMICAL DIAGNOSIS. (GRADE C)
- In patients with Erectile Dysfunction, and/or Hypoactive Sexual Desire, and/or Retarded Ejaculation, these investigations are recommended:
  - serum sample for Total Testosterone (TT) determination.
  - In case of a low level we recommend:
    - to repeat the TT determination
    - together with SHBG (to calculate free T [FT]),
    - and serum LH, and prolactin measurements.

8. THRESHOLD LEVELS FOR THE BIOCHEMICAL DIAGNOSIS OF TD. (GRADE C)
- There are no generally accepted lower limits of normal total testosterone. There is, however, general agreement that:
  - TT > 12 nmol/l (3.5 ng/ml or 350 ng/dl) does not usually require substitution.
  - Based on the data of young hypogonadal men, men with TT < 8 nmol/l (2.3 ng/ml or 230 ng/dl) usually benefit from testosterone treatment.
  - Between these levels :
    - measuring FT by equilibrium dialysis or calculating it from TT and SHBG levels may be helpful. A lower limit of 225 pmol/l (65 pg/ml) is accepted by many.
    - A Testosterone Therapy test may be envisaged for 3-6 months. Beyond that time, T therapy would be continued only in case of substantial benefit.
  - Clinical judgment should be exercised for men who have symptoms and are above these levels.

9. OTHER HORMONAL ALTERATIONS. (GRADE C)
- It is recognized that significant alterations in other endocrine systems occur in association with aging but the significance of these changes is not well understood, particularly in relation to sexual function.
- Generally, determinations of Estradiol, Cortisol, DHEA or DHEA-S, Melatonin, GH and Insulin-like Growth Factor-1 are not indicated unless the corresponding endocrine disorders are suspected based on the clinical signs and symptoms.

II. TESTOSTERONE THERAPY

10. INDICATION FOR TESTOSTERONE THERAPY. (GRADE C)
- A clear indication
  - a clinical picture
  - together with biochemical evidence of hypoandrogenism should exist prior to initiation of androgen therapy.

11. AGE AND TESTOSTERONE THERAPY. (GRADE C)
- In the absence of definite contraindications, age is not a limiting factor to initiate Testosterone Therapy in men with TD.

12. INDICATION OF TESTOSTERONE THERAPY IN MEN WITH SEXUAL DYSFUNCTION. (GRADE A TO C)
- Men with TD and:
  - Hypoactive Sexual Desire (GrA),
  - Erectile Dysfunction (GrB),
Retarded Ejaculation (GrC) are candidates for Testosterone Therapy.

Absence of an appropriate response after adequate testosterone treatment for 3-6 months (GrC) calls for further investigations to rule out associated co-morbidities (GrA).

13. COMBINATION THERAPY WITH TESTOSTERONE AND PHOSPHODIESTERASE TYPE V INHIBITORS. (GRADE B)

- Evidence is emerging suggesting a therapeutic synergism with the combined use of Testosterone and PDE5-Is in men with Erectile Dysfunction and low testosterone. These observations are preliminary and need additional studies.

- However, combination therapy can be considered in TD men who have not improved with T alone.

- In addition it is recommended to measure testosterone in case of PDE5-I failure if not previously done.

14. TESTOSTERONE COMMERCIAL FORMULATIONS. (GRADE A AND C)

- Current commercially available preparations of T (with the exception of the 17α-alkylated ones) are safe and effective (GrA).

- The treating physician should have sufficient knowledge and adequate understanding of the advantages and drawbacks of each preparation.

- The patient should be given the opportunity to actively participate in the choice of testosterone formulation (GrC).

15. SERUM TESTOSTERONE LEVELS TO BE ACHIEVED WITH TESTOSTERONE THERAPY. (GRADE C)

- The purpose of testosterone treatment is to bring and maintain serum testosterone levels within the physiological range. Supraphysiological levels are to be avoided.

- No evidence exists for the need to maintain a circadian rhythm of serum testosterone levels.

16. OTHER FORMS OF ANDROGEN THERAPY. (GRADE B)

- The use of other androgens such as:
  - Dehydroepiandrosterone (DHEA)
  - Dihydrotestosterone

  has not been proven to be effective specifically in male sexual dysfunctions.

- Anti-estrogens may raise endogenous testosterone on condition of intact hypothalamic-pituitary gonadotrophic centers. No data are presently available regarding their long-term safety in men.

17. ANDROGEN ABUSE OR MISUSE. (GRADE C)

- Testosterone Therapy should be used only when specific indications exist, and to achieve serum levels of testosterone in the physiological range.

- Its (ab)use for performance enhancement may expose to serious complications, and is to be strictly condemned.

III. CONTRA-INDICATIONS AND CAUTIONS FOR USE

18. PROSTATE SAFETY. (GRADE C)

- Historically androgen administration has been absolutely contraindicated in men suspected of, or with a history of prostate cancer.

- This is an area of ongoing research and reevaluation. There is no compelling evidence that T treatment causes prostate cancer or prostate cancer progression in the non castrated man (L1).

- Testosterone Therapy is contra-indicated in men with clinical evidence of prostate cancer until more evidence on safety is available.

- Men with TD >45 years old should be informed before treatment on the benefits of T therapy, the limits of knowledge concerning prostate safety, and the fact present data are reassuring.

19. TESTOSTERONE THERAPY AFTER TREATMENT FOR PROSTATE CANCER. (GRADE C)

Testosterone Therapy after treatment for prostate cancer

- Men successfully treated for prostate cancer and suffering from confirmed, symptomatic TD are candidates for TRT, after a prudent interval (depending on the type of cancer treatment), if there is no evidence of residual cancer.

- The risks and benefits must be clearly understood by the patient and the follow-up must be particularly careful.

- Safety data are limited, but early reports are reassuring. However, the clinician must exercise caution together with adequate knowledge of the advantages and drawbacks of androgen therapy in this situation.

20. BREAST CANCER. (GRADE A)

- Testosterone Therapy is contra-indicated in men with breast cancer.
21. CAUTIONS IN THE USE OF TESTOSTERONE THERAPY. (GRADE B AND C)

- Men with:
  - Significant erythrosis (hematocrit > 52%) (GrC)
  - Severe symptoms of Bladder Outlet Obstruction (GrC)
  - Should not be started on Testosterone Therapy without prior improvement of the co-morbid condition.

- Follow-up of such men should be especially careful, as that of men with:
  - Severe Obstructive Sleep Apnea Syndrome though no scientific evidence exists in favor (or against) a causal relationship between testosterone and this syndrome (GrC).
  - Severe congestive heart failure, due to the risk of fluid retention in case of overdosing (GrB).

22. TESTOSTERONE THERAPY AND FERTILITY. (GRADE C)

- Candidates for Testosterone Therapy should be informed that this therapy may temporarily suppress spermatogenesis. In case of desired fertility, alternative therapies such as gonadotrophins or anti-estrogen may be useful.

- In men with hypogonadotrophic TD, long-term testosterone supplementation does not preclude forthcoming responsiveness to gonadotrophins, but may prolong the time required to obtain pregnancy.

23. MONITORING: LIVER. (GRADE A)

- Currently available preparations are largely free of hepatic toxicity. Liver function studies are not required prior to onset of therapy.

- Despite the lack of evidence, most manufacturers (for regulatory purposes) include warnings about hepatic risks in their product insert.

24. MONITORING: LIPIDS AND GLYCAEMIA. (GRADE A)

- Monitoring lipids and glycemia is not required for safety, but may be so for monitoring efficacy of other aspects of treatment.

25. MONITORING: PROSTATE. (GRADE A AND C)

- In men > 40 years old, PSA is mandatory:
  - as baseline parameter of prostate health prior to Testosterone Therapy, then 3, 6, 12 months later and then every year if no significant change.
  - Digital Rectal Examination is also required at baseline and, at least, every year (GrC).

- Transrectal Ultra-Sound guided prostate biopsies are indicated only for changes or abnormalities in the DRE or PSA (absolute value or velocity from the second year) (GrA).

26. TESTOSTERONE THERAPY AND CARDIOVASCULAR HEALTH. (GRADE B)

- Testosterone Therapy is not associated with markedly increased cardiovascular risk until 36 months of use, and replacement can be advocated on conventional established clinical grounds. However the possibility of T therapy induced polycythemia should be considered.

- Preliminary evidence suggests the possibility of beneficial effects of Testosterone Therapy on cardiovascular function. The body of evidence supports the need for long term placebo controlled randomised trials of testosterone replacement in hypogonadal men with regard to morbidity and mortality.

27. MONITORING: HEMATOCRIT. (GRADE C)

- Polycythemia (hematocrit > 52%) may develop during Testosterone Therapy (L1). Periodic hematological assessment is indicated:
  - Before treatment
  - 3, 6, 12 months after the start
  - Then annually if no significant change

- Dose adjustments, change of preparation, phlebotomy, or discontinuation of treatment may be necessary.

28. MONITORING: MOOD. (GRADE B)

- Testosterone Therapy results in variable improvements in mood and well being.

- The development of negative behavioral patterns (aggressiveness, hypersexuality) during treatment has been associated with T Therapy. There is no evidence of such effects in the recent literature.
V. OTHER HORMONES LIKELY TO PLAY A ROLE IN MALE SEXUAL DYSFUNCTIONS

29. PROLACTIN. (GRADE C)
   - Hyperprolactinemia is an uncommon cause of Erectile Dysfunction.
   - However, determination of serum prolactin is recommended in cases associated with Hypoactive Sexual Desire, and when biochemical TD has been documented, because it can be associated with serious and treatable diseases.

30. THYROID HORMONES. (GRADE B AND C)
   - Associations between hyperthyroidism and premature ejaculation (GrB), and between hypothyroidism and retarded/delayed ejaculation, and hypoactive sexual desire (GrC) have been reported.
   - An increased prevalence of both hyper- and hypothyroidism has been reported in men with Erectile Dysfunction (GrC).
   - Thyroid hormones disorders should be suspected in ejaculatory disorders. Thyroid hormone measurement is not indicated in other sexual dysfunctions, unless based on the presence of corresponding clinical signs and symptoms of thyroid diseases (GrC).

CONCLUSIONS

PRIAPISM RECOMMENDATIONS

RECOMMENDATIONS FOR FUTURE RESEARCH IN PRIAPISM
Priapism describes a persistent erection arising from dysfunction of the mechanisms regulating penile tumescence, rigidity and flaccidity. A correct diagnosis of priapism is a matter of urgency requiring identification of the underlying hemodynamics. Committee 15 to the International Consultation on Sexual Medicine (ICSM 2009) was charged with developing an evidence-based guideline on priapism. Committee 15 sought to define the types of priapism, and address pathophysiology, epidemiology and effective management of priapism.

Previous scientific organizations including the American Urological Association Guidelines Committee 2003 (www.auanet.org) and the International Society for Sexual Medicine Standards Committee 2006 (www.issm.info) have noted that the literature was comprised mainly of small case series and individual case reports, and included inconsistent definitions and methods with little long-term outcome data. Some recent case series have included detailed methodology: duration of priapism, etiology of priapism and erectile function outcomes. Recommendations in this report are based on best practices as defined by prior AUA guidelines and ISSM standards, contemporary case series, and bench research. Using the International Consultation of Urologic Diseases modification of Oxford Centre for Evidence Based Medicine Guidelines, the level of evidence for recommendations cited in this review are Level 3 / 4, grade C (www.cebm.net).

The basic science supporting current concepts in the pathophysiology of priapism, and clinical research supporting the most effective treatment strategies are summarized in this review. Suggestions for future research are made. These recommendations were presented in a public forum and have been amended following debate and comments from the International Consultation on Sexual Medicine – Paris, July 10-13, 2009.

I. DEFINING PRIAPISM

Priapism is a full or partial erection which continues more than 4 hours beyond sexual stimulation and orgasm or is unrelated to sexual stimulation.

1. ISCHEMIC PRIAPISM (VENO-OCCCLUSIVE, LOW-FLOW)

Ischemic priapism is a persistent erection marked by rigidity of the corpora cavernosa, and little or no cavernous arterial inflow. In ischemic priapism there are time dependent changes in the corporal metabolic environment with progressive hypoxia, hypercarbia, and acidosis. The patient typically complains of penile pain and the examination reveals a rigid erection. The condition is analogous to a muscle compartment syndrome, with well documented histologic changes occurring to the corporal smooth muscle by 12 hours. Interventions beyond 48 - 72 hours of onset may help relieve erection and pain, but have little benefit in preserving potency. Histologically by 12 hours corporal specimens show interstial edema, progressing to destruction of sinusoidal endothelium, exposure of the basement membrane, and thrombocyte adherence at 24 hours. At 48 hours thrombi can be found in the sinusoidal spaces and smooth muscle necrosis with fibroblast like cell transformation is evident.[1]

Ischemic priapism is an emergency. When left untreated resolution may take days and erectile dysfunction invariably results.

2. STUTTERING PRIAPISM (INTERMITTENT)

Stuttering priapism characterizes a pattern of recurrence. The term has historically described recurrent unwanted and painful erections in men with sickle cell disease.[2] Patients typically awaken with an erection that persists for several hours. Unfortunately males with sickle cell disease (SCD) may experience stuttering priapism from childhood; in these patients the pattern of stuttering may increase in
frequency and duration leading up to a full episode of unrelenting ischemic priapism. Unfortunately any patient who has experienced an episode of ischemic priapism is also at risk for stuttering priapism.

3. NON-ISCHEMIC PRIAPISM (ARTERIAL, HIGH-FLOW)

Non-ischemic priapism is a persistent erection caused by un-regulated cavernous arterial inflow. Typically the corpora are tumescent but not rigid and the penis is not painful. A history of blunt trauma to the penis or an iatrogenic needle injury is common. Whatever the mechanism of injury, the result is a disruption of the cavernous arterial anatomy creating an arterio-venous fistula. The cavernous environment does not become ischemic and cavernous blood gases do not show hypoxia, hypercarbia or acidosis. This type of priapism once properly diagnosed, may not require emergent intervention. Beyond the acute trauma patients do not complain of pain. Normal erectile function has been reported after recovery from the initial event, despite persistence of non-sexual partial erection.

II. HISTORY OF PRIAPISM

The term priapism has its historical origin in reference to the Greek god Priapus, who was worshiped as a god of fertility and protector of horticulture. Priapus is memorialised in sculptures for his giant phallus. The first recorded account of priapism in English medical literature is recorded in the Lancet and attributed to Tripe in 1845.[3] In 1914 Frank Hinman Senior published a landmark article describing the natural history of priapism.[4] In 1960 his son Frank Hinman Jr. proposed that venous stasis, increased blood viscosity and ischemia were responsible for priapism and emphasized that failure to correct these abnormalities in the penile environment was essentially responsible for treatment failures.[5]

Advances in our understanding of the physiology of erection and the pathophysiology of erectile dysfunction further substantiated the early hypothesis that prolonged veno-occlusion within the corporal bodies is analogous to a compartment syndrome. In 1983 Hauri demonstrated the radiologic differences between veno-occlusive and arterial priapism.[6]

Frank Hinman Sr. in 1914 first described ‘acute transitory attacks of priapism’ as opposed to persistence or rapid recurrence of a single episode. The actual term of stuttering priapism is attributed to Emond et al 1980 in observations of patients with sickle cell disease in a Jamaican clinic.[7] Stuttering priapism episodes were seen to increase in frequency and length leading up to major, unrelenting events of ischemic priapism. Attempts to manage these same sickle cell patients with stuttering ischemic priapism resulted in the early recommendations for hormonal suppression of nocturnal erections and stuttering priapism with estrogen.[2]

Nonischemic priapism is a rare condition, occurring far less commonly than ischemic priapism. It is invariably associated with antecedent perineal or penile trauma. It was first described in the English literature in a 1960 report by Burt et al.[8]

III. EPIDEMIOLOGY AND PATHOPHYSIOLOGY OF PRIAPISM

1. ETIOLOGY OF ISCHEMIC PRIAPISM (VENO-OCCulsive, LOW-FLOW)

Ischemic priapism accounts for more than 95% of all priapism episodes. The erection of ischemic priapism may begin with sexual stimulation, with or without the administration of pharmacologic agents. Once an erection persists beyond 4 hours, and is not relieved by cessation of sexual stimulation or orgasm, the physiologic phenomena of ischemic priapism have begun. Erections lasting up to four hours are by consensus defined as ‘prolonged’; all manufacturers of erection facilitating pharmacotherapies (oral, injectable and intraurethral) recommend that the patient seek out emergent medical consultation for prolonged erection.

In 1986 Pohl et al reported on 230 cases. The etiology of priapism was identified as idiopathic in the majority, 21% of cases were associated with alcohol or drug use/abuse, 12% with perineal trauma and 11% with sickle cell disease.[9] This and other reports on the etiology of priapism are greatly influenced by the prevalence of sickle cell disease. The life-time probability of a man with sickle cell disease developing ischemic priapism ranges from 29-42%.[7] Although the etiology of veno-occlusive priapism is predominated by sickle cell disease, there is a wide variety of associations in the literature from urinary retention to insect bites.[10]

a) Sickle Cell Disease

Blood dyscrasias are a risk factor for ischemic priapism. The mechanism of SCD priapism has been presumed to be stagnation of blood within the sinusoids of the corpora cavernosa during physiologic erection and sickled erythrocytes obstructing venous outflow from the corporal bodies.[11] In Nelson and Winter’s series of cases they noted that sickle cell disease (SCD) was the primary etiology of ischemic priapism in 23% of adult cases and 63% of pediatric cases.[12] Sickle cell hemoglobinopathy accounts for at least a third of all cases of priapism and indeed prevalence of ischemic priapism will vary significantly with the population of males in a community with SCD. From Emond et al’s 1980 observational study comes the most commonly quoted prevalence: among 104 men attending an outpatient sickle cell clinic in Kingston, Jamaica the prevalence of priapism among men with homozygous sickle cell (SS) disease was 42%.[7]

Tarry and Duckett (1987) found a 6.4% incidence of priapism in an outpatient clinic for children with sickle cell diseases.[13] Adeyoju et al (2002) in an international multicenter observational study of sickle cell disease, cited mean age of onset at 11 years with one quarter ischemic priapism cases presenting during prepubertal years, and rare first time presentation by third decade of life.[14] Based on the World Health Organization global prevalence map of sickle cell disease Aliyu (2008) estimates that 20-25 million individuals worldwide have homozygous SCD; 12-15 million in sub-Saharan Africa, 5-10 million in India and 3 million in other world regions; 70,000 patients with SCD live in the United States.[15]

Contemporary science has identified the molecular pathophysiology behind many of the complications of sickle cell. The sickle cell genetic mutation is the result of a single amino acid substitution in the beta-globin subunit of haemoglobin. The clinical features are seen in homozygous SCD patients: chronic hemolysis, vascular occlusion, tissue ischemia and end-organ damage. HbS polymerizes when deoxygenated, injuring the sickle erythrocyte, activating a cascade of hemolysis and vaso-occlusion. Membrane damage results in dense sickling of red cells, causing adhesive interactions among sickle cells, endothelial cells and leukocytes. Hemolysis releases hemoglobin into the plasma. Free Hbg reacts with nitric oxide (NO) to produce methemoglobin and nitrate. This is a scavenging reaction; the vasodilator NO is oxidized to inert nitrate. Sickled erythrocytes release arginase I into blood plasma, which converts L-arginine into ornithine, effectively removing substrate for NO synthesis. Oxidant radicals further reduce NO bioavailability. The combined effects of NO scavenging and arginine catabolism result in a state of NO resistance and insufficiency termed: hemolysis-associated endothelial dysfunction.[15-18]

Hemolysis and reduced nitric oxide availability are currently thought to be responsible for SCD pulmonary hypertension, leg ulcers, priapism and stroke. Increased blood viscosity is thought responsible for painful crises, osteonecrosis and acute chest syndrome. SCD patients with priapism have a fivefold greater risk of developing pulmonary hypertension. SCD priapism is also associated with reduced haemoglobin levels and increased haemolytic markers: reticulocyte count, bilirubin, LDH and aspartate aminotransferase.[19] Cerebral vascular accidents are more frequent, close to episodes of full blown priapism; the ASPEN syndrome (priapism, exchange transfusion and neurological events) describes cerebral vascular accidents in SCD patients who have received exchange transfusions.[20] Sickle cell trait is considered a benign condition; a few complications have been associated with extreme physical
b) Iatrogenic Priapism: Complication of Treating ED

Injection of intracavernous vasoactive medications for ED is the cause of priapism that many Urologists will encounter; prolonged erection is more commonly reported than priapism. In a review of worldwide reports on intracavernous injection (ICI) programs Junemann et al (1990) noted that diagnostic injection resulted in 5.3% of men getting ischemic priapism and 0.4% of men reported priapism after injecting at home. In papaverine based ICI programs reports of prolonged erections and priapism are poorly differentiated, and range from 0 – 35%. In worldwide clinical trials of the Alprostadil Study Group, prolonged erection (defined as 4-6 hours) was 5% and priapism (> 6 hours) was described in 1% of subjects. In papaverine / phentolamine / alprostadil ICI programs prolonged erections have been reported in 5% - 35 of patients.

c. Oral Phosphodiesterase type 5 Inhibitors

Generally all PDE5 inhibitors have similar side effects related directly to their mode of action, tissue content of substrate, and pharmacologic selectivity for type 5 inhibition versus other phosphodiesterase enzymes: headache, flushing, dyspepsia, rhinitis, light sensitivity and myalgia. Morales et al (1998) analyzed data from 4274 men who received double-blind treatment with sildenafil or placebo for up to six months, and 2199 who received long-term open-label sildenafil for up to one year. No cases of priapism (erection lasting longer than 4 hours) were reported. In a study of 130 patients with sickle cell disease Adeyoju et al (2002) reported that 46 (35%) had a history of stuttering priapism.

3. ETIOLOGY AND PATHOPHYSIOLOGY

3.1. Non-ischemic Priapism

Priapism caused by unregulated cavernous arterial inflow. The epidemiology data on non-ischemic priapism is almost exclusively derived from small case series or individual case reports. Non-ischemic priapism is much rarer than ischemic priapism and the etiology is largely at-
tributed to trauma. Injuries most commonly reported are to the crura or corporal bodies; the forces may be blunt or penetrating resulting in laceration of the cavernous artery or one of its branches within the corpora. The mechanisms include: straddle injury, coital trauma, kicks to the penis or perineum, pelvic fractures, birth canal trauma to the newborn male, needle lacerations, complications of penile diagnostics, and vascular erosions complicating metastatic infiltration of the corpora.[40-44] Although blunt trauma is the most commonly reported etiology, high-flow priapism has been described following surgical interventions: cold-knife urethrotomy, Nesbitt corporalplasty, deep dorsal vein arterialization.[45,46] Any mechanism which lacerates a cavernous artery or arteriole can produce unregulated pooling of blood in sinusoidal space with consequent erection.

Contemporary reports suggest that high flow priapism may have a unique sub-variety. Several authors have noted that following either aggressive medical management of ischemic priapism with aspiration and intracavernous alpha adrenergic injections or surgical shunting that priapism may rapidly recur with conversion from ischemia to high flow. High-flow priapism has been reported following medical and surgical management of ischemic priapism.[47-49] Color Doppler ultrasound in these cases reveals formation of an arteriolar-sinusoidal fistula as in typical high flow priapism or on rare occasion a high flow hemodynamic state of the cavernous arteries with no evident fistula formation. The committee proposes that this subtype of high flow priapism be suspected in cases where rapid recurrence, persistence of priapism with partial penile rigidity or stuttering priapism not associated with pain is evident. This non-fistula type of arterial priapism is the result of dysregulation of cavernous inflows. Non-fistula arterial priapism is a rare complication of medical or surgical management of ischemic priapism.[50-52]

Non-ischemic priapism is typically delayed in onset compared to the trauma; especially if the injury was the result of blunt forces.[53] Sustained partial erection may develop within 24 hours. It is believed that the hemodynamics of a nocturnal erection disrupt the clot and the damaged artery/arteriole ruptures; the unregulated arterial inflow creates a sinusoidal fistula. As healing progresses with clearing of clot and necrotic smooth muscle tissue, the fistula forms a pseudocapsule. Formation of a pseudocapsule at the site of fistula may take several months.

4. PRIAPISM IN CHILDREN

Priapism in children and adolescents is most commonly related to SCD. The literature suggests that the prevalence of priapism in pediatric sickle cell clinics is 2-6%. [40] The majority of SCD priapism is ischemic. In the newborn period fetal hemoglobin predominates, not hemoglobin S.[44] SCD phenotypes related to ischemic or occlusive crises are unlikely to be evident while fetal hemoglobin persists. Newborn priapism is an extremely rare phenomenon with only limited case reports and rare application of contemporary diagnostic modalities. Erection is frequently elicited in males during the newborn period. In newborn males simple tactile stimulation such as diaper changing, bathing, urethral catheterization may result in erection; the erection quickly subsides following cessation of stimulation. Fewer than 20 cases of newborn priapism have been reported in the literature; rarely has etiology been defined: polycythemia, blood transfusion and birth canal trauma.[54-57] The majority of cases have been conservatively managed with spontaneous resolution reported from hours to days. Minimally invasive diagnostics (color Doppler ultrasound, see Evaluation below) should be performed.[58-59] In pediatric patients who develop priapism following trauma an effort should be made to localize the arteriolar-sinusoidal fistula, Hatzichristou et al 2002 have reported that direct manual compression will soften the erection. They note that this non-invasive therapy likely works in children and not adult males, because the perineum has considerably less subcutaneous fat and crural bodies may be more easily compressed.[60]

IV. THE MOLECULAR BASIS OF ISCHEMIC AND STUTTERING PRIAPISM:

Advances in our understanding of the molecular basis of priapism have drawn significantly from both in vitro and in vivo experimental studies using animal models. There is emerging data on the true inciting mechanisms involved in ischemic priapism. Ischemic priapism consists of an imbalance of vasoconstrictive and vasorelaxatory mechanisms predisposing the penis to hypoxia and acidosis. In vitro studies have demonstrated that when corporal smooth muscle strips and cultured corporal smooth muscle cells are exposed to hypoxic conditions significant apoptosis results, and alpha-adrenergic stimulation fails to induce corporal smooth muscle contraction.[61-64] Extended periods of severe anoxia significantly impair corporal smooth muscle contractility and causes smooth muscle cell death and ultimate fibrosis of the corpora cavernosa. In experimental animal models of ischemic priapism, lipid peroxidation, an indicator of injury induced by reactive oxygen species (ROS), and increased hemoxygenase expression occurs in the penis during and after ischemic priapism.[65,66]

Additional pathophysiologic mechanisms involved in the progression of ischemia-induced fibrosis are the upregulation of hypoxia-induced growth factors. An example of one such pleiotropic cytokine is transforming growth factor beta (TGF-β). TGF-β is a cytokine which is vital to tissue repair. However,
excess amounts may induce tissue damage and scarring and upregulation of TGF-β occurs during hypoxia and in response to oxidative stress.[66,67] It is hypothesized that TGF-β may be involved in the progression of the corporal tissue to overt fibrosis.[68,69]

There are several genetically engineered animal models displaying priapic behavior and these too have provided important insights. Transgenic mouse models of sickle cell disease manifest priapism, supporting their use in studies to elucidate the pathogenic mechanisms of sickle cell disease-associated priapism in humans.[70,71] There have been two major discoveries in elucidation of the molecular mechanism of ischemic priapism. Mi et al have shown that transgenic sickle cell mice corpora cavernosa have enhanced smooth muscle relaxation to electrical field stimulation (Mi 2008).[72] Transgenic sickle cell mice and mice lacking endothelial nitric oxide synthase (eNOS) gene expression display supraphysiologic erections and spontaneously phasic priapic activity in vivo.[73,74] Observations of the abnormal erectile responses in these mice were fundamental in spurring ahead recent investigations establishing aberrant nitric oxide (NO) and adenosine regulation in the penis as a mechanism of ischemic priapism especially as it relates to sickle cell disease.

Endothelial cells actively regulate basal vascular tone and vascular reactivity, by responding to mechanical forces and neurohumoral mediators with the release of a variety of relaxing and contracting factors. In the penis, the vascular endothelium is a source of vasorelaxing factors such as NO and adenosine as well as vasoconstrictor factors such as RhoA/Rho-kinase. Recent evidence suggests that in states of priapism there may be aberrant NO and adenosine signaling thus identifying a potential role for NO/cGMP as well as adenosine and RhoA/Rho-kinase signaling in the pathophysiology of ischemic priapism.[72,75,76] eNOS-/- mutant mice have an exaggerated erectile response to cavernous nerve stimulation and have phenotypic changes in erectile function consistent with priapism.[76,77] Mice lacking the eNOS gene manifest a priapism phenotype through mechanisms involving defective phosphodiesterase type 5 (PDE5) regulatory function in the penis, resulting from altered endothelial nitric oxide/cGMP signaling in the organ.[77,78] Supporting this hypothesis, PDE5 expression is significantly reduced in corpora cavernosa smooth muscle cells (CCSMC) grown under anoxic and hypoxic cell culture conditions.[78] Chronic endothelial-NO deficiency in eNOS-/- mutant mice also influences other signaling molecules in the penis, in particular the RhoA/Rho-kinase system which is known to exert significant contractile effects in the penis.[73] In priapism contexts, the cyclic nucleotide cGMP is produced in low steady state amounts under the influence of priapism-related destruction of the vascular endothelium and thus reduced endothelial nitric oxide activity; this situation thereby downregulates the set point of PDE type-5 function, secondary to altered cGMP-dependent feedback control mechanisms.[76,77,79] Under these conditions, when NO is neuronally produced in response to an erectogenic stimulus or during sleep-related erectile activity, cGMP production surges in a manner that leads to excessive erectile tissue relaxation because of basally insufficient functional PDE type-5 to degrade the cyclic nucleotide. Additionally, reduced Rho-kinase activity in concert with PDE5 dysregulation may contribute to the susceptibility of corporal tissue to excessive relaxation via two distinct molecular mechanisms (enhanced vasorelaxation by uninhibited cGMP and less contractile effects of Rho-kinase). Transgenic sickle cell mice also have significant reductions in penile NO/cGMP signaling leading to deficient PDE5 expression/activity as well as reduced RhoA/Rho-kinase expression from which they manifest enhanced erectile responses and recurrent priapism.[76] Another potential cause of enhanced corporal smooth muscle relaxation in sickle cell disease-associated priapism is elevated penile adenosine levels thus causing the corpora cavernosa to be in chronically vasodilated state.[72] Taken together, these data suggest that ischemic priapism and most importantly stuttering priapism is a direct result of NO imbalance resulting in aberrant molecular signaling, PDE5 dysregulation, adenosine overproduction, and reductions in Rho-kinase activity, translating into enhanced corporal smooth muscle relaxation and inhibition of vasoconstriction in the penis.

V. EVALUATION AND DIAGNOSIS OF PRIAPISM

1. HISTORY

In order to initiate appropriate management, the physician must determine whether the underlying priapism hemodynamics are ischemic or nonischemic. Emergency management of ischemic priapism is recommended. Ischemia should be suspected if the patient has progressive penile pain, associated with the duration of erection; has used known drug associated with priapism; has sickle cell disease or another blood dyscrasia; has a known neurologic condition especially those affecting the spinal cord. Stuttering priapism history is one of recurrent episodes of prolonged erections, usually non-resolving morning erections or sexually stimulated erections. Nonischemic priapism should be suspected when: there is no pain, there is a history of coital trauma, or blunt trauma to the penis. The onset of post-traumatic high flow priapism in adults and children may be delayed by hours to days following the initial injury.
2. PHYSICAL EXAMINATION

Inspection and palpation of the penis is recommended. In ischemic priapism the cavernous bodies are rigid and the penis is tender to palpation. In high flow priapism the cavernous bodies are tumescent not rigid. Depending on the time since trauma there may be ecchymosis of the penis or perineum. Although malignancies are rare etiologies of priapism, examination of the abdomen, testicles, perineum, rectum and prostate will help identify a cancer primary. If physical examination reveals the penis is nontender, tumesced or partially erect - nonischemic priapism is suspected. In children and adults with high flow priapism depending on the location of trauma and time since the traumatic event there may be residual bruising and some tenderness to palpation.

3. LABORATORY TESTING

Evaluation should include a CBC, WBC with blood cell differential, platelet count and coagulation profile to assess anemia, to rule out infection, to detect hematologic abnormalities and to insure that the patient can safely tolerate surgical interventions should initial medical management fail. A sickle cell prep and haemoglobin electrophoresis should be requested. Other hematologic abnormalities may cause priapism and should be sought if etiology is unknown: leukaemia, platelet abnormalities, thalassemia. An elevated reticulocyte count is non-specific and may be elevated in both priapism due SCD and thalassemia. Urine and plasma toxicology should be done if recreational narcotic or prescription psychoactive drugs are suspected from psycho-social history. A corporal blood gas by aspiration is recommended in the emergency evaluation of priapism. The corporal blood aspirate is essential to differentiate ischemic from nonischemic priapism.

4. PENILE IMAGING

Color duplex Doppler ultrasonography (CDU) of the penis and perineum is recommended in the evaluation of priapism, if this technology is available. CDU is an adjunct to the corporal aspirate in differentiating ischemic from nonischemic priapism (Figure 1). Patients with ischemic priapism will have no blood flow in the cavernous arteries; the return of the cavernous artery waveform will accompany successful detu-
mescence. Patients with nonischemic priapism have normal to high blood flow velocities detectable in the cavernous arteries. CDU may also localize the site of trauma in high flow priapism.[23] Examination of the entire penile shaft and perineum is recommended; this can be done with the patient supine, but frog legged (Figure 2). Penile arteriography should be reserved for the management of high flow priapism, when embolization is undertaken; arteriography is too invasive as a diagnostic procedure to differentiate ischemic from nonischemic priapism.[81] Penile blood gas assessments become confusing following interventions. Color Doppler ultrasound should always be considered in the evaluation of a full or partial erection following treatments for ischemic priapism. The differential diagnosis includes: resolved ischemia with penile edema, persistent ischemia, conversion to high flow priapism. Lue 2002 has reported on the use of intracavernous pressure monitoring during interventions for priapism, to predict resolution or recurrence.[11] Intracavernous pressure monitoring technology is generally available in operating rooms and not in the clinic.

There have recently been reports on the use of magnetic resonance imaging in priapism. Kirkam et al 2008 noted that there are three possible roles for MRI to help in the assessment of priapism; the first would be in the imaging of a well established arterio-l-sinusoidal fistula.[82] The authors acknowledge a limitation of MRI is resolution; MRI can not demonstrate small vessels as clearly as high-frequency Doppler sonography or angiography. The second would be in ischemic priapism to demonstrate the presence and extent of tissue thrombus and corporal smooth muscle infarction. Ralph (2009) used MRI in the prospective management of 50 patients with refractory ischemic priapism failing medical / surgical management (24-720 hours).[83] Patients underwent MRI to characterize the extent of smooth muscle necrosis prior to placement of penile prosthesis. The third role for MRI would be in the imaging of corporal metastasis causing priapism.

VI. MEDICAL TREATMENTS

1. ISCHEMIC PRIAPISM

Historically, first aide was applied by the patient or recommended by a health practitioner unfamiliar with the hemodynamics of priapism; these interventions included: ejaculation, ice packs, cold baths, cold water enemas. Each of these remedies was thought to end erection by inducing vasoconstriction. Some historical reports advised voiding and exercise. Oral sympathomimetic drugs such as terbutaline, pseudoephedrine and etileferine have been reported superior to placebo in reversing prolonged erection (< 4 hours) initiated by intracavernous injection therapies with efficacies of 28 – 36%.[84]

The recommended treatment of ischemic priapism is the decompression of the corpora cavernosa by corporal aspiration. Aspiration will immediately soften the erection and relieve pain. Aspiration alone may relieve priapism in 36% of cases. The AUA Guidelines Panel (2003) advised that there was not sufficient data to conclude that aspiration followed by saline intracorporal irrigation was any more effective than aspiration alone.[80] However, Ateyah (2005) reported that a combination of blood aspiration and cold saline irrigation effectively terminated priapism in 66% of cases compared to aspiration alone 24%.[85] In view of the limited data on the efficacy of cold saline in relieving ischemic priapism, the committee’s recommendation is that penile blood aspiration be performed in the initial treatment of ischemic priapism.

Aspiration followed by the intracavernous injection of sympathomimetic drugs is the standard of care in the medical treatment of ischemic priapism.[80] Sympathomimetic pharmacotherapeutics (phenylephrine, etilephrine, ephedrine, epinephrine, norepinephrine, metaraminol) cause cavernous smooth muscle contraction. In the laboratory normal smooth muscle preparations from humans shows concentration dependent contractions upon exposure to phenylephrine, if the corporal environment is well oxygenated and has a normal pH.[61,86] Broderick and Harkaway (1994) described time dependent changes in the corporal environment beginning within 6 hours of prolonged erection.[62] Animal models of ischemic priapism have demonstrated impairment in smooth muscle contraction with progressive acidosis, hypoxia and glucopenia.[61,64,86,87] Corpus cavernosum specimens form patients presenting with pro-
Figure 2
longed priapism show no contractions to high dose phenylephrine in vitro. AUA Guidelines 2003 noted significantly higher resolution of priapism following sympathomimetic injection with or without irrigation (43 to 81%) compared to aspiration with or without irrigation (24 to 36%).[80] Phenylephrine is a selective alpha-1 adrenergic receptor agonist without beta mediated ionotropic and chronotropic cardiac effects; it is the agent of choice by consensus recommendation.[80,88] There are no comparative trials of sympathomimetics in the management of priapism. Case reports vary in efficacy from 43 – 81%, with time dependent efficacies for each agent reported. Phenylephrine is usually diluted in normal saline with a concentration of 100-500 mcg/ml and given in 1 ml dosages every 3 - 5 minutes. Dosing should be intermittent over the course of an hour.[80] There are no comparative dosing regimens available, nor are there dose tolerating studies to report. It is this committee’s recommendation that phenylephrine be concentrated as 200 mcg/mL in saline and be administered intermittently as 0.5 mL to 1.0 mL doses every 5-10 minutes to a maximum dosage of 1 mg (up to 10 separate injections of 0.5 mL [100 mcg] or 5 separate injections of 1 mL [200 mcg] ). Extremes of age and existing cardiovascular diseases should be taken into consideration during intracavernous sympathomimetic dosing. Serial or continuous monitoring of blood pressure and pulse should be performed during and immediately following intracavernous injection of sympathomimetic drugs. Potential side-effects of intracavernous sympathomimetics include headache, dizziness, hypertension, reflex bradycardia, tachycardia, and irregular cardiac rhythms. Davila (2007) reported subarachnoid hemorrhage in a case of sickle cell disease ischemic priapism.[89] The patient was a 24 year old African American male who reported sudden and severe headache immediately following phenylephrine intracorporal dosing of 500 mcg/mL repeated every three minutes for 4 mL.

Sickle cell disease and hematological malignancies are rare but important causes of ischemic priapism. Classically, treatment of hematologically-induced ischemic priapism involved analgesics, hydration, oxygen, bicarbonate and blood transfusion. However, systemic therapy alone is not effective management of SCD priapism.[90] A recent report suggested that blood transfusion may have no effective role in the treatment of sickle cell-induced priapism.[20] Reports from hematology centers suggest high success rates using penile aspiration/irrigation and intracavernous sympathomimetics for this type of priapism.[91]

2. STUTTERING PRIAPISM

Various factors need to be considered when treating stuttering priapism. Although an episode may last < 4 hours, increasing frequency or duration of stuttering episodes may herald a major ischemic priapism. Multiple frequent visits to the ER to resolve the priapism are disruptive to the patient's life and embarrassing. If attacks follow sexual activity, patients may become sexually avoidant.[14,39] Safety and efficacy of various treatments are poorly characterized in the literature. The side effects of recommended medications should be understood by the patient. Patients on chronic medical therapy to decrease the frequency of stuttering episodes may significantly benefit from performing a single sympathomimetic intracorporal injection at home as part of a personal treatment algorithm.[92,93] Multiple treatment options have been described: oral and injectable alpha adrenergic agonists, terbutaline, digoxin, anti-sickling agent hydroxycabamide, oestrogens, GnRH analogues, antiandrogens, baclofen, gabapentin and recently phophodiesterase type-5 inhibitors.[39] Etilefrine is an alpha agonist available as oral or injectable in some countries. Maximum oral dosing is 100 mg in 24 hours.[94] Okpala (2002) followed 18 men (17 SCD patients and one with sickle trait) all with history of stuttering priapism. Patients were given etilefrine in escalating dosages from 25 mg at bedtime to a maximum of 100mg each day. Stuttering episodes were reduced in frequency and duration in 72%. In children a very small series of six SCD children were followed with dosing twice daily with 0.25 mg/kg of etilefrine.[95] The experience of multiple investigators using oral alpha adrenergic dosing in the management of SCD stuttering ischemic priapism suggests that oral alpha adrenergics at limited daily dosing should be considered in the management of stuttering priapism; drug therapy is typically initiated at bedtime.

a) Hormonal Therapies

The primary action of systemic hormonal therapy in stuttering priapism is the suppression of the androgenic effects on penile erection. Attempts to treat stuttering priapism with hormones have exploited known regulators of male sexual function by targeting the pituitary gland (GnRh agonists), suppressing pituitary function through feedback inhibition (diethylstilbestrol), blocking androgen receptors (antiandrogens) and reducing testicular and adrenal synthesis (ketonazole). In the only randomized placebo-controlled trial, a synthetic oestrogen, diethylstilbestrol, (DES) caused termination of the stuttering episodes in all patients subjected to treatment.[96] However, in more than 50% of patients (5 out of 9) recurrence occurred after treatment cessation. Similar results are described by others in case reports.[95,97] Long-term estrogen therapy is not recommended due to the potential cardiovascular side-effects. GnRH analogues, goserelin acetate and leuprolide acetate, have been described in case reports.[97, 88] Chronic dosing with GnRH analogues in combination with as needed penile injection of alpha adrenergics have been reported in the management of ischemic stuttering priapism.[99]
Discontinuation of GnRH analogues typically leads to stuttering resumption. Anti-androgens carry their actions by direct suppression of the penile androgen receptors. These agents including, lutamide, bicalutamide and clomadinone, have been able to cause considerable relief of stuttering priapism in a number of case reports.[100-102]

**b) Baclofen**

Studies in both rats and humans suggest that baclofen inhibits penile erection and ejaculation, through GABA receptor activity. In rats stimulation of GABAB beta-receptors in the lumbosacral spinal cord inhibits erection in rats.[103-105] Denys et al 1998 reported on nine men with multiple sclerosis or spinal cord injuries who were treated for 44 months with intrathecal baclofen for muscle spasticity; 8 of 9 reported decreased erectile function which reversed upon cessation of baclofen.[106] Rourke et al 2002 first reported on the use of orally nightly baclofen 40 mg in the management of recurrent priapism in patients with neurological lesions.[107] D’Aleo et al 2009 are the first to report on the use of an intrathecal pump dosing baclofen 180 mcg daily for the management of skeletal muscle spasm and recurrent priapism in a patient with spinal cord injury; the patient was refractory to treatment with oral dosing of 75 mg/day, but responded to a test dosage of 25 mcg intrathecally.[108] The neurologic literature generally fails to categorize these erectile events as ischemic or non-ischemic. Triggering events may be tactile nonsexual stimulation causing repeated—reflexogenic erections. Better characterization of these unwanted reflexogenic erections is needed to characterize hemodynamics, inciting events, duration and impact on erectile function. In non-neurogenic patients baclofen daily dosing is associated with drowsiness, nausea, complaints of fatigue, and ED. Recurrent reflexogenic erections are clearly an unwanted condition associated with muscle spasticity in men with spinal cord lesions and neurologic disease, but it remains to be demonstrated that the duration and hemodynamics of such erectile events are similar to ischemic stuttering priapism in SCD.

c) **Phosphodiesterase Type 5 Inhibitors in the Management of Ischemic Priapism: A Counter-Intuitive Treatment Strategy**

Bialecki and Bridges (2002) first reported on sildenail having a paradoxical effect in controlling stuttering priapism in three patients with SCD.[109] Although this proposal would immediately seem illogical based on the knowledge that PDE5 inhibitors exert erectogenic effects, there is a scientific basis for using these agents to treat priapism. In a small case series, Burnett and colleagues have shown that daily sildenail or tadalail therapy reduces ischemic priapism episodes in men with stuttering priapism.[110] Accordingly, when used in long-term dosing regimen unassociated with erection stimulatory conditions, PDE5 inhibitor therapy alleviates recurrent priapism episodes in men with sickle cell disease-associated priapism and idiopathic priapism without affecting normal erectile capacity.[71,111] The working theory is that surges of cGMP go unchecked because of downregulated levels of PDE type 5; this results in stimuli like nocturnal erection resulting in unchecked corporal smooth muscle relaxation. In initial series, the short-acting PDE5 inhibitor sildenail citrate was given in a dose of 25 mg oral daily dosage, with escalation to 50 mg daily. Subsequently these investigators have reported on tadalail at 5 to 10 mg oral dosing taken three times weekly. Multi-center, randomized, double-blind, placebo controlled clinical trials are under. PDE5 Inhibitors should be started under conditions of complete penile flaccidity, not during a stuttering episode. Efficacy is seen after a week or more of dosing.

### VII. SURGICAL MANAGEMENT OF ISCHEMIC PRIAPISM

Surgical management of ischemic priapism is indicated after repeated penile aspirations and injections of sympathomimetic injections have failed or if such an attempt has resulted in significant cardiovascular side effects. The previous International Consultation 2004 recommended corporal aspiration and alpha-adrenergic agonists for at least one hour prior to surgery.[88] Early surgical intervention is ideal in patients with malignant or poorly controlled hypertension or for men who are using monoamine oxidase inhibitor medications that have contraindications to alpha agonist administration. A comprehensive discussion which includes baseline erectile function, duration of priapism, risks and benefits of the surgery, and erectile dysfunction should be held with the patient/guardian and an informed consent form signed by the patient/guardian.

1. **SHUNTING**

The ISSM Standards Committee (expert opinion) have stated that shunting is to be considered for priapism events lasting ≤ 72 hours. Consideration should be given to foregoing shunting in priapism events lasting longer, in particular where cavernous thrombosis is evident and no blood can be aspirated from the corporal bodies.[88,112] It is generally accepted that the longer an episode of ischemic priapism lasts the greater the likelihood of compromised erectile function will be in the future. Previous reviews have concluded that priapism lasting longer than 24 hours was associated with a 90% erectile dysfunction rate.[113] Evidence based recommendations based on erectile function outcomes are few. One recent study does document erectile function outcomes by contemporary standards (International Index of Erectile Function). Bennett and Mulhall
(2008) carefully documented 39 cases of sickle cell disease priapism presenting to their emergency room over eight years; men were routinely interviewed for erectile function status within four weeks of priapism/interventions.[114] Of the 39 African American men followed, 73% acknowledged prior episodes of stuttering; 85% had previously been diagnosed with SCD; only 5% had been counseled or were aware that priapism was a complication of SCD. A standard protocol of aspiration and phenylephrine was performed; shunting for failure of medical management was performed in 28%. In those patients where priapism was reversed, spontaneous erections (with or without use of sildenafil) were reported in 100% of men with priapism reversed < 12 hours; 78% reversed by 12 – 24 hours; 44% reversed by 24 – 36 hours. No patient reported spontaneous erections after priapism duration of > 36 hours.

The objective of shunt surgery is oxygenation of the corpus cavernosal smooth muscle (CCSM). The technical goal of shunting in ischemic priapism is to re-establish outflow from the cavernous bodies by creating a communication to the glans, or corpus spongiosum or directly to a vein (Figures 3,4,5). Shunt procedures are subdivided into 4 groups:[115]

- Percutaneous distal shunts (Winter[116], Ebbehoj[117], Lue[118])
- Open distal shunt (Al-Ghorab[119,120], Burnett[121])
- Open proximal shunt (Quackles[122], Sacher[123])
- Saphenous vein (Grayhack[124]), Superficial or Deep Dorsal Vein (Barry[125])

One of the factors involved in the success of shunts is shunt patency. Patency of a shunt can be verified in the operating room and recovery room in a number of ways.[126,127] While open shunt procedures are likely to result in higher shunt patency rates, there is no data comparing percutaneous and open distal shunts; the surgeon must be guided by familiarity with various techniques. In cases where a distal shunt fails, a proximal shunt is indicated. This decision to proceed more aggressively (open distal shunting, proximal shunt or a vein shunt) may be made in the operating room after the completion of the initial percutaneous shunt, if oxygenated blood is not present within the corporal bodies, intracavernous pressures do not fall, the penis does fails to detumesce and refill with compression, or color Doppler ultrasound shows no cavernous artery inflow. Shunt outcome should be immediately assessed by:

- Visualization of bright red blood in corporal aspirate
- A corporal blood gas
- Color Doppler ultrasound
- Measurement of intracavernosal pressure
- Penile compression maneuver (squeeze and release)

The most commonly performed proximal shunt is the unilateral shunt, described by Quackles in 1964 (Figure 6). Proximal corpus cavernosum to spongiosum (CC – CS) shunt procedures require a trans-scrotal or perineal approach.[122] There is no data comparing bilateral (Sacher[123]) and unilateral CC - CS shunts. Typically, bilateral shunts are staggered; right side and left side are separated by a distance of at least 1cm in an effort to minimize the risk of urethral stricture at the point of CC - CS communication. In cases where proximal shunt fails, some have advocated performing a saphenous vein bypass or deep dorsal vein procedure (Figure 7). A wedge of tunica albuginea is removed and the vein is anastamosed end to side of CC. There are no comparative trials of vein shunting for ischemic priapism. Authors site a significant risk of saphenofemoral vein thrombus and pulmonary embolism with vein shunting.[128]

2. IMMEDIATE IMPLANTATION OF PENILE PROSTHESIS

Some authorities have suggested performing immediate penile prosthesis implantation for ischemic priapism. The time point at which this becomes a reasonable option is unclear. However, any discussion pertaining to early prosthesis insertion should be documented and include a comprehensive review of the theoretic advantages and actual risks (infection, mechanical malfunction, urethral injury, device erosion). The natural history of untreated ischemic priapism or priapism refractory to interventions is severe fibrosis, penile length loss and erectile dysfunction. The advantages of early penile implantation are preservation of penile length, and technically easier implant insertion. Ralph (2009) reported on 50 patients with ischemic priapism. All patients failed conservative management with the instillation of alpha-adrenergic agents [200 mcg phenylephrine repeated to a maximum dosage of 1500 mcg].

Unsuccessful shunts were performed in 13/50 cases.[83] Mean duration of priapism was 209 hours (range 24 – 720 hours). All patients had evidence of cavernous smooth muscle necrosis on MRI and all 50 underwent insertion of penile prosthesis in the acute setting of refractory ischemic priapism. Revision rates were significant, 12/50 patients. The infection rate of 6% was also notably high, and likely related to multiple factors including ischemic tissues and preceding penile interventions.
VIII. INTERVENTIONAL ANGIOGRAPHY IN THE MANAGEMENT OF ARTERIAL (NON-ISCHEMIC, HIGH-FLOW) PRIAPISM

It is very important to stress that non-ischemic priapism is not an emergency and spontaneous resolution may result, without any significant adverse effects on erectile function. There are no comparative outcome studies of intervention versus conservative management in high-flow priapism; there are sufficient case descriptions especially in children to recommend initial watchful waiting. Thus, observation is primarily recommended for this type of priapism. Conservative measures include: ice applied to the perineum and site-specific compression. In view of the current literature, the committee concludes that cavernous aspiration/irrigation and intracavernous sympathomimetics have no role in the treatment of non-ischemic priapism.

Patients demanding immediate relief can be offered selective arterial embolization. The pathognomonic arteriographic finding is an arterial-lacunar fistula; a characteristic intracavernosal cone-shaped blush of contrast is seen at the site of the cavernous artery or arteriole laceration (Figure 2). Permanent (e.g., coils, acrylic glue) and temporary (e.g., autologous clot) embolization techniques have been described. The success rate of treatment of high-flow priapism with selective embolization is quite high, 89% regardless of the embolization material used. Similar results have been reported by others. However, it should be noted that a single treatment of embolization carries a recurrence rate of 30-40%. The most notable side-effect of arterial embolization is erectile dysfunction. Although it was previously reported that non-permanent embolization material cause less erectile dysfunction that permanent ones (5 vs 39%), more recent reports employing a standardized assessment tool (IIEF) in long-term evaluation of post-embolization erectile function describe similar rates of dysfunction, ranging between 15 and 20%. Other reported adverse effects include penile gangrene, gluteal ischemia, purulent cavernositis and abscess of perineum.

Several reports describe combined ultrasound compression with selective arterial embolization to increase success rate in the treatment of non-ischemic. Puppo (1985) compared perineal duplex ultrasound and concomitantly preformed selective internal pudendal arteriography showing excellent sensitivity in detecting the arterial-lacunar fistula on ultrasound that is seen angiographically (12 of 12 cases). If the follow-up clinical examination is equivocal for recurrence of high-flow priapism, a perineal duplex Doppler ultrasound can determine the need for repeat arteriography and embolization.

IX. SURGICAL MANAGEMENT OF ARTERIAL (NON-ISCHEMIC, HIGH-FLOW) PRIAPISM

Arterial priapism is not a urologic emergency. Non-ischemic priapism is painless, there have been reports of partial erection persisting for years. Any intervention must follow a comprehensive discussion with the patient regarding risks and benefits of any of the procedures advocated by the clinician. In cases of long-standing arterial priapism where a

Table 5: Surgical Management of Ischemic Priapism.

- Document accurately baseline erectile function, duration of priapism, history of stuttering and prior interventions.
- Ensure an adequate trial of corporal aspiration and alpha-agonist administration.
- Obtain informed consent.
- Commence with a distal percutaneous shunt.
- Define the patency of the shunt prior to sending patient to recovery room.
- Conduct serial postoperative examination to demonstrate shunt patency.
- Perform an open distal shunt technique or proceed to proximal shunting, if erection persists.
- After shunting follow up with patient on erectile function outcomes and therapies.
- Consider penile prosthesis at the time of presentation:
  - If patient has failed aspiration and sympathomimetic intracavernous injection
  - If patient has failed distal and proximal shunting
  - If ischemia has been present for > 36 hours
- Consider an MRI prior to surgery or corporal biopsy at time of implant to document corporal smooth muscle necrosis.
pseudocapsule around the fistula has developed, surgical ligation has been reported to be successful. Formation of a pseudocapsule may take weeks to months following trauma. Corporal exploration prior to the formation of a pseudocapsule may result in ligation of cavernous artery rather than selective ligation of the fistula. Currently this intervention is reserved for patients: who do not wish to pursue expectant management; or who are poor candidates for angio-embolization or refuse the procedure; or where technology is not available; or when angioembolization has failed.[112,137,138] The surgical approach is transcorporal. Intra-operative Doppler ultrasound guidance is recommended.

CONCLUSIONS
Prompt diagnosis and appropriate management of priapism are necessary to spare patients ineffective interventions and maximize erectile function outcomes. Future research is needed to understand corporal smooth muscle pathology associated with genetic and acquired conditions that result in ischemic priapism. Documenting erectile function outcomes based on duration of ischemic priapism, time to interventions, and types of interventions is needed to establish evidence-based guidance. Better documentation of onset of high-flow priapism in relation to time of injury, and response to conservative management versus angiographic or surgical interventions is needed to establish evidence-based guidance.

Table 6: Surgical Management of HIGH-FLOW Priapism.

- Arterial priapism is not emergency and may be managed conservatively.
- Diagnosis is best made by penile/perineal duplex Doppler ultrasound.
- Angioembolization represents first-line intervention.
- Where angioembolization fails or is contraindicated surgical ligation is reasonable.
- Document pre-operative erectile function/dysfunction
- Obtain informed consent prior to surgical intervention.
Ischemic priapism associated with sickle cell disease requires intracavernous treatment. A hematologist may provide concurrent systemic therapies but the best resolution rates are achieved with therapies directed at the penis.

Oral therapy is not recommended for the treatment of acute ischemic priapism.

Shunt surgery should be considered for all cases of veno-occlusive priapism failing aspiration and intracavernous injection of sympathomimetics. Patients should be counseled that erectile function outcomes decline significantly when priapism has lasted greater than 24 - 36 hours and that complete ED is anticipated if priapism persists for greater than 36 hours.

A distal cavernoglanular shunt should be the first choice of shunting procedures because it is technically easier to perform than proximal shunting.

Percutaneous distal shunting is less invasive than open distal shunting and may be considered first. There are a number of distal shunting procedures and the surgeon should be familiar with these procedures and their complications. Open distal shunting should be considered if percutaneous shunting fails. There are no comparative trials of safety, efficacy or erectile function outcomes for percutaneous versus open distal shunting techniques.

If distal shunting fails, then proximal shunting is recommended. Proximal shunting establishes a communication between the corpora cavernosa and spongiosa at the base of the penis. The surgeon must be aware of the unique anatomic relationship between the corpus spongiosum and urethra. Shunting may also be accomplished with vein grafting to the corpora cavernosa. Venous shunts have increased the risk of thromboembolism.

Following pharmacologic or surgical reversal of ischemic priapism, penile tumescence rather than complete flaccidity may be evident. A phenomenon of conversion to high-flow has been described. In cases where the examination may be equivocal, Color Doppler ultrasonography or cavernous blood gas are recommended (if this technology is available) to demonstrate restoration of cavernous flows.

In men presenting with ischemic priapism of duration > 36 hours or failing interventions, severe erectile dysfunction is inevitable. Consideration may be given to implantation of a penile prosthesis for unresolved ischemic priapism. Complications related to immediate implantation of penile prosthesis for unresolved ischemic priapism are significantly high, but delayed placement of penile prosthesis is technically challenging due to corporal fibrosis, and outcomes may be compromised due to penile shortening. The patient must be fully informed of the risks of immediate implantation. The surgeon must be familiar with the additional technical concerns posed by weaknesses in the tunica albuginea from prior shunting procedures.

STUTTERING ISCHEMIC PRIAPISM

The goals of managing a patient with stuttering ischemic priapism are: prevention of future episodes, preservation of erectile function, and balancing the risks versus benefits of various treatment options.

A trial of daily oral sympathomimetic therapy (alpha adrenergic) may be used in the management of patients (adults and children) with stuttering ischemic priapism associated with hemoglobinopathies. Dosing efficacy should be monitored for frequency and duration of stuttering episodes, blood pressure and normal erectile capacity.

A trial of daily oral PDE5 inhibitor therapy may be used in the management of patients (adults and children) with stuttering ischemic priapism associated with hemoglobinopathies. Dosing should be initiated under conditions of complete penile flaccidity. Dosing efficacy should be monitored for frequency and severity of stuttering episodes, and PDE5 inhibitor side effects and normal erectile capacity.

A trial of gonadotropin-releasing hormone (GnRH) agonists or antiandrogens may be used in the management of adult patients with stuttering priapism. Hormonal agents should not be used in patients who have not achieved full sexual maturation and adult stature. Chronic GnRH or antiandrogen dosing in adult males may affect libido, may affect fertility, cause gynecomastia, cause hot flushes, promote osteoporosis, and worsen sexual function.

Intracavernous injection of phenylephrine (by the adult patient or parent) should be considered as an adjunct to daily systemic therapies in patients with stuttering ischemic priapism. When administered at home for prolonged morning erections, an injection of a intracavernous sympathomimetic may overt a full blown episode of ischemic priapism.

NON-ISCHEMIC PRIAPISM (HIGH-FLOW, ARTERIAL)

Aspiration with or without injection of sympathomimetic agents is not recommended as treatment for high-flow priapism.

Color Doppler ultrasonography (if this technology is available) of the penis and perineum is recommended in the evaluation of priapism, when the history or examination suggests penile trauma.

The initial management of nonischemic priapism may be observation. Immediate invasive interventions (embolization or surgery) can be performed at the request of the patient, but should be preceded...
by a thorough discussion of chances for spontaneous resolution, risks of treatment-related erectile dysfunction and lack of significant consequences expected from delaying interventions.

Penile arteriography is invasive and should not be used as diagnostic procedure to differentiate ischemic from non-ischemic priapism. Penile arteriography should be reserved for the management of high-flow priapism, when embolization is elected.

Selective arterial embolization is recommended for the management of non-ischemic priapism in patients who request treatment. The embolization with either temporary or permanent materials may cause ED. Overall success rates with embolization are high, although a single treatment carries a recurrence rate of 30-40%. There are no comparative outcome studies of selective pudendal catheterization and embolization techniques.

There are no comparative trials of embolization versus surgery in the management of high-flow priapism; the decision to pursue one technique or the other must be based on availability of technology and skills of the physicians. Surgery requires either ligation of a cavernous artery or intra-operative identification of the fistula and excision of the arteriolar-sinusoidal pseudocapsule. Ligation of a cavernous artery may result in ED. Excision of a pseudocapsule and selective ligation of the fistula is more likely to preserve erectile function.

Color Doppler ultrasound guidance is recommended for the intra-operative management of high-flow priapism.

RECOMMENDATIONS FOR FUTURE RESEARCH IN PRIAPISM

BASIC SCIENCE

Future research should include animal models to study the pathophysiology of ischemic priapism. These models should examine the clinical observation that interventions for ischemic priapism may result in a phenomenon of conversion to high flow. Specific questions need to be addressed: Is cavernous arterial dysregulation a normal post-ischemic response? When do post-ischemic high flows resolve? Future research should characterize the molecular dysregulations in stuttering ischemic priapism.

CLINICAL RESEARCH

Sickle cell patients should receive education on priapism and its management. Recent studies suggest that only 5% of sickle cell disease patients recalled learning that priapism was a complication of SCD.

Case-based reports of priapism should document: pre-priapism erectile function by patient and partner; duration of priapism with respect to initiation of each intervention; history of stuttering priapism; recovery of erectile function.

Future reports should make use of standardized erectile function questionnaires.

Consideration should be given to multi-center, randomized, double-blind, placebo controlled clinical trials for the prevention of stuttering priapism in high risk patients (sickle cell disease).

Comparator trials are needed in: daily dosing of oral alpha-adrenergic agents versus phosphodiesterase type 5 inhibitors for stuttering priapism; distal shunting techniques; delayed management versus immediate interventions for high flow priapism.

In patients with refractory ischemic priapism studies should examine outcomes and complication rates for immediate versus delayed prosthetic implants (patient/partner satisfaction, rates of infection, tunica perforation, erosion, and revision).

A. PEYRONIE’S DISEASE

INTRODUCTION

Peyronie’s disease is both a physically and psychologically devastating problem for the affected male. Currently it is considered a wound healing disorder that presents with a fibrous inelastic scar of the tunica albuginea which is currently believed to occur in the genetically susceptible individual following some form of trauma to the penis. In the flaccid state, a palpable scar develops which in the erect state causes a variety of deformities, including curvature, shortening, narrowing, and hinge effect. In the early phase there is oftentimes an inflammatory component which causes pain. This inflammatory pain tends to resolve with time, but because of the deformity, intercourse may be compromised or impossible. Peyronie’s disease is also frequently associated with erectile dysfunction, and a variety of other comorbid disorders, including diabetes, hypertension, dyslipidemia, and low testosterone. Peyronie’s disease was named after François Gigot de la Peyronie, who first described this disorder and offered treatment recommendations in 1743. In spite of over 265 years passing since de la Peyronie’s description, we still do not fully understand the etiopathophysiology nor is there a recognized, reliable, and effective nonsurgical treatment for this disorder. As a result, Peyronie’s disease remains a treatment dilemma for the practicing physician.

I. EVALUATION OF PATIENTS WITH PEYRONIE’S DISEASE

1. INTRODUCTION

One of the most important aspects in the management of patients with Peyronie’s disease is the initial assessment and counseling. It is imperative that the patient receives information about the etiology, natural history of the disease, treatment options and understands the prognosis so that real expectations can be met with subsequent greater patient satisfaction. The quality of life of both the patient and partner may be significantly affected, with an increased risk of depression, low self-esteem and relationship difficulties being common [1].

The incidence of 3.2% in the Cologne questionnaire study of 8000 men highlights the increase in the number of patients presenting with Peyronie’s disease [2]. In this study the prevalence increased from 1.5% for 30-39 year-old men to 6.5% for men over 70. Several studies have suggested that younger men may present with more advanced disease. In one study, men less than 40 years of age were more likely to present with multiple plaques, more complex curvatures and were more likely to be diabetic [3]. Overall, approximately 30% of patients will have diabetes which has been found to be associated with advanced curvatures and vasculogenic erectile dysfunction [4,5]. Two thirds of patients with Peyronie’s Disease are likely to have risk factors for arterial disease and therefore worsening long term erectile function [5].

Peyronie’s disease is a progressive disorder with nearly half of men having disease progression if left untreated. In a recent study by Mulhall et al. 246 men diagnosed with Peyronie’s disease and followed for one year without treatment demonstrated that 12% improved, 40% remained stable, and 48% worsened [6].

In most cases, Peyronie’s disease may be divided into an acute inflammatory phase and a chronic phase. During the former, there may be penile pain and curvature progression although the pain typically resolves spontaneously within 6 -18 months from onset in most patients [6].
2. PATIENT EVALUATION

The diagnosis of Peyronie's Disease is usually apparent from the patient history and penile examination. The main points to gather from the history are whether the disease is still active, the nature of the curvature and the presence of erectile dysfunction (Table 1). This data collection can be facilitated by utilizing a disease-specific questionnaire (Table 2) [7].

Patients with a short disease duration (< 12 months), penile pain or a recent change in penile deformity are still likely to have active inflammatory disease and therefore are not surgical candidates and would be more likely to benefit from medical therapy.

Penile pain may be persistent in the inflammatory stage of the disease but is usually only present during erection. The pain is not usually severe in nature but may interfere with sexual function although spontaneous improvement usually occurs as the inflammation settles within 6 months and almost all men will experience pain resolution by 18 months (94% of 246 men treated conservatively) [6,9].

Table 1
Salient features to assess in Peyronie’s Disease.

- Duration of disease
- Penile Pain
- Stability – acute vs. chronic
- Presence of Plaque or induration
- Penile deformity – angle, direction, indentation, waisting, hinge-effect
- Penile length
- Erectile function
- Normal, ED (psychogenic, structural, vascular)
- ED risk factors

781
All the patients have either a well defined plaque or an area of induration that is palpable on physical examination, even though patients may be unaware of it [8]. The plaque is located on the dorsal surface of the penis in two thirds of patients with a corresponding dorsal penile deformity [9]. Lateral and ventral sited plaques are not as common but result in more coital difficulties as there is a greater deviation from the natural coital angle. Multiple plaques located on opposite sides of the penis or plaques appearing in the septum may cause penile shortening with or without a penile deformity [10]. The consistency of the plaque, be it soft, tender, calcified or ossified should be noted as this may act as a guide to management. Calcification may occur at initial presentation or develop over time. It appears that calcification is not a manifestation of a more mature plaque as previously thought. Rather it may represent a different genetic subtype of PD [11].

An assessment of the curvature on erection is best made by an intracavernosal injection of a vasoactive agent. This is more accurate than a home photograph or a vacuum assisted erection test as the latter often underestimates the degree of curvature, either because the erection is not full or the full extent of the curvature is masked by the subcutaneous tissue engorgement [12]. This also allows complex curvatures to be assessed and will aid in the decision for the type of treatment best suited to the individual.

The severe emotional distress that occurs is, in part, due to the deformity, but mainly due to the penile shortening that occurs in almost all patients. It is imperative therefore that the stretched penile length is measured preoperatively so that the patients realize that the length loss postoperatively is mainly due to the disease itself and not to the surgical correction [13, 14]. Clinical depression is remarkably common. In a series of 92 men who completed the CES –D validated questionnaire, 48% were clinically depressed and severely so in 22% of these patients [15].

Erectile dysfunction associated with Peyronie’s Disease has been reported in up to 58% of men [2,5]. It is not uncommon for unsuspected Peyronie’s Disease to be diagnosed at the time of investigation of their erectile dysfunction [16,17]. It is clear, therefore, that erectile dysfunction in Peyronie’s Disease is common and may precede the onset of the deformity. It is usually due to one of 4 factors [1,8]:

a) Psychological (Performance anxiety)

The physical abnormality of the penis can cause anxiety or depression which may be severe enough to interfere with the ability to obtain or maintain an erection.

b) Deformity preventing coitus

The penile deformity may be so severe that penetration is made difficult or even impossible. This is more likely to occur if the deformity is in a ventral or lateral direction, or when a dorsal curvature exceeds 60 degrees. The pain that is sometimes experienced in Peyronie’s Disease may also interfere with the erectile capacity.

c) Flail penis

There are a small group of patients with extensive Peyronie’s Disease who also have circumferential plaques with cavernosal fibrosis. Tumescence is reduced or absent from this segment, and if extensive may result in an unstable penis or hinge effect.

d) Impaired erection

It is often difficult to decipher the cause of the impaired erectile capacity. It may be due to concomitant vascular disease that occurs in 54% of patients with Peyronie’s Disease [5] or to site specific venoocclusive dysfunction through an emissary vein that passes through the Peyronie’s plaque into the dorsal vein of the penis and cannot be compressed between the tunical layers [18]. Patients may present with only a flaccid distal portion of the penis or a soft glans penis, the proximal segment being normal. There is controversy as to the mechanism of this, be it arterial, venous or fibrotic in nature but certainly a significant symptom of advanced organic disease [8]. A detailed history of any arterial risk factors for erectile dysfunction should be noted and an assessment of erectile function best made by the validated International Index of Erectile Function-5 (IIEF-5) questionnaire [19]. A PD specific questionnaire is in development and should aid in the assessment of the man with PD and may prove useful in evaluating quality of life-related changes following treatment.

3. INVESTIGATIONS IN PEYRONIE’S DISEASE

Ultrasound is used to identify the site and consistency of the plaque and is a useful tool in the clinical trial setting to assess penile vascular blood-flow parameters. It can also determine the extent of plaque calcification as those men with extensive calcification have historically been noted to not respond well to non-surgical therapies. Extensive calcification appears to be a primary indication for surgical correction as these plaques do not respond to medical therapy. It is a minimally-invasive technique that is more accurate than x-ray, CT scan, or MRI [20]. A vascular assessment should be performed in all patients with erectile dysfunction as well as those undergoing surgery and is best done using duplex ultrasound [21]. The results of this investigation can often show vascular disease in patients who report normal potency which may influence the subsequent management [22].
Many patients have little in the way of symptoms, and reassurance, particularly that the palpable lump is not cancer and that the pain will resolve, may be all that is necessary.

II. Peyronie’s Disease: Epidemiology-Pathology-Mechanisms

1. Epidemiology: Prevalence and Co-morbidities

The misconceptions regarding the prevalence of Peyronie’s disease (PD) in men and the associated co-morbidities have recently been documented in the USA by a mail survey of primary-care physicians and urologists in Illinois and Wisconsin [23]. Although the sample size was relatively small and the response rates were around 44%, the 250 replies showed that 63% and 48% of the primary care physicians and 41% and 37% of the urologists thought respectively that the prevalence is less than 1% and that PD is not frequently associated with erectile dysfunction.

This confusion among clinicians probably stems from the inadequacy of the initial epidemiological studies, but even in the last decade the same concerns regarding the PD intervention trials stated in a recent PubMed search [24] apply to the more current studies on the true prevalence of PD. Both this article and some previous reviews of the last 4 years [25-29] coincide in asserting a 3-9% prevalence, much higher than what was assumed, with an average onset at 50-60 years of age.

However, as it often occurs in sexual dysfunction related topics, the number of reviews exceeds the paucity of original studies. Table 3 shows that in the last decade only five studies evaluating the prevalence of PD could be identified in five countries. Altogether they detected or enrolled 313 cases, and the total screened population was 8,697 subjects. This would give an average prevalence of 3.6%, which agrees with two large studies in Brazil [30] and Germany [2], with 3.7% and 3.2%, respectively. However, the only study in the USA [31] reported a 8.9% prevalence, even higher than a previous study in Italy with 7.1% [32], and remarkably different from the most recent report, from India, with 2% prevalence [33].

The mean age in these studies was older than 55 years, and penile curvature was present in over 80% of patients whereas painful erection was reported by over half of them in Germany and India, features that are common to all the studies. The question remains why despite a similar presentation, the reported prevalence for PD may differ so considerably, from 2% to 9%, and it may be speculated that this may reflect, at least in part, the impact on different social views on self-reporting versus the methodology employed for clinical detection, or even the diversity of sexual practices.

Epidemiological studies that focus on the primary clinical features and co-morbidities found in PD patients but do not investigate prevalence in the general population are more abundant. Eleven such reports were identified from six countries, and all were based on clinical examination (Table 4). As in the prevalence studies, diagnosis was based on plaque detection, although in a couple of cases they considered either plaque or penile curvature. Overall the studies on Table 4 covered 2,180 patients, with the two largest ones in terms of total population of PD and non-PD patients in Egypt [34,38] and three other studies were conducted in the USA [3,36-37]. Patients were in general 55 years of age or older, and only 10-15% were younger than 40 years of age. [34,38,42] also shown in Table 3 [2,31].

As in one of the prevalence studies already discussed [33] three other reports [3,37,41], identified a history of penile trauma, but surprisingly in view of the prevalent hypothesis of this event being a main factor in the development of PD, only 5 to 13% of patients older than 40 years of age report or remember a traumatic event associated with the onset of PD. The number was higher in younger patients, but disclosed by only 18% of those [3]. Four studies on Table 4 revealed a significant association with erectile dysfunction (ED) in comparison with the non-PD population [35,38,39,41], consistent with two other studies in Table 3 [2,31]. However, the primary suspected culprit for the ED, namely corporal veno-occlusive dysfunction (CVOD), could be found as associated with PD only in the 30-39 years of age patients when using Doppler in a carefully designed study [36]. This opens up the intriguing question of what type of ED is actually more prevalent in the older PD patients than in the non-PD counterparts.

The association with Dupuytren’s disease was only investigated since 1999 in two studies, where it was shown to be highly significant in the older population [3], and affecting 39% of PD patients versus only 1.2% in the controls [42]. Strikingly, PD was significantly associated with a family history of Dupuytren’s but not of PD [42]. However, Dupuytren’s was not seen in patients younger than 40 years of age [3]. An earlier study noted that 20% of PD patients presented with Dupuytren’s [40].

Epidemiological studies were also conducted on diabetes as a co-morbidity and although six studies on Table 3 and 4 [3,5,31,34,37,43], found PD to be significantly associated with diabetes, however three other studies [32,41,42] failed to show this association. One of these reports [3] indicated that diabetes occurred in 50% of PD patients younger than 40 years of age and in 18% of patients over this
age, which is obviously much higher than even the high PD prevalence (8.9%) detected in the general population screened by this group in another study [31]. A 20.3% prevalence of PD in diabetic patients was confirmed by another group [43]. When diabetic patients with PD were compared with PD patients with no risk factors (4) they had a significantly higher severity of PD as shown by penile curvature. Some of these reports provided data supporting a significant association of PD with obesity [34,38,43], hypertension [3,5,36,41], hyperlipidemia [3,5,33,34,37,38], smoking [32,34,37,38,42,43], and pelvic surgical interventions [42]. Interestingly, the more comprehensive study in terms of the multiplicity of the investigated co-morbidities [42], identified by multivariate logistic analysis, TURP and Dupuytren’s contracture as by far having the highest odds ratios (205-207), as compared to the others ranging from 3 to 14.

ETIOLOGY AND HISTOPATHOLOGY

The etiology of PD has been discussed in a number of recent reviews [24-29,44-46] but there is little critical assessment of the interpretations and significance of a very small number of related experimental or observational papers. A widely accepted hypothesis on the etiology of the PD plaque is that it originates from trauma or microtrauma to the erect penis during different types of sexual activities with or without partners [47]. It is based on essentially three types of evidence. On one side, the seminal demonstration of fibrin staining or immunodetection in tissue sections of the PD plaque [47-51], corroborated in human penile sections and an animal model of PD [52], which suggest that fibrin is the remnant of fibrinogen extravasation into the tunica albuginea during a traumatic episode, leading to an abnormal healing process and therefore to a “scar” that would evolve into a palpable plaque. The second is the demonstration that injection of fibrin into the tunica albuginea of the rat elicits a PD-like plaque resembling in certain aspects the histology and evolution of the human PD [52,53]. The third is essentially clinical, i.e., the already discussed epidemiological association of PD with a history of sexually elicited trauma to the erect penis or other forms of invasive interventions, mainly surgical, in the pelvis that may affect the homeostasis of penile tissues.

2. ETIOLOGY AND HISTOPATHOLOGY

The etiology of PD has been discussed in a number of recent reviews [24-29,44-46] but there is little critical assessment of the interpretations and significance of a very small number of related experimental or observational papers. A widely accepted hypothesis on the etiology of the PD plaque is that it originates from trauma or microtrauma to the erect penis during different types of sexual activities with or without partners [47]. It is based on essentially three types of evidence. On one side, the seminal demonstration of fibrin staining or immunodetection in tissue sections of the PD plaque [47-51], corroborated in human penile sections and an animal model of PD [52], which suggest that fibrin is the remnant of fibrinogen extravasation into the tunica albuginea during a traumatic episode, leading to an abnormal healing process and therefore to a “scar” that would evolve into a palpable plaque. The second is the demonstration that injection of fibrin into the tunica albuginea of the rat elicits a PD-like plaque resembling in certain aspects the histology and evolution of the human PD [52,53]. The third is essentially clinical, i.e., the already discussed epidemiological association of PD with a history of sexually elicited trauma to the erect penis or other forms of invasive interventions, mainly surgical, in the pelvis that may affect the homeostasis of penile tissues.
However, three findings weaken this hypothesis. One is the fact that despite the epidemiological association the majority of patients do not have recollection of a traumatic episode during sexual activity [31]. Conversely, the second is the demonstration that a very strenuous torsion of the erect penis practiced by some ethnic groups [54], was not associated with a higher incidence of PD. Obviously, it may be argued that a microtrauma not perceived, or easily forgotten by the patient, may be sufficient to elicit the initial scar, and that only certain types of trauma would damage the complicated interaction between the tunica albuginea and the surrounding well vascularized tissues so as to allow the infiltration of the tunica by blood. Ethnic differences may also play a role in the resistance to develop PD. The third concern is that so far there is no demonstration in animal models that penile trauma causes a PD-like lesion, since surgical injury only induces a transient fibrotic process that behaves as an acute reaction that later regresses [55].

Whatever the interpretation of the etiological role of penile trauma, the association of PD with Dupuytren’s disease and a family history for this condition suggests that a genetic or immune-related process may determine predisposition to this localized fibrosis by modulating the reaction after trauma or microtrauma. This hypothesis has been entertained but so far there is no evidence, simply because no systematic research effort has been conducted in this respect, other than sporadic studies. One of the latest (from 1997) [56] stated: “Our results support the hypothesis that there is some involvement of the immune system in the pathogenesis of Peyronie’s disease, although the available data still appear to be insufficient to formulate a definite pathogenetic hypothesis.” This holds true today, as shown in other subsequent studies [57,58]. The same applies to genetic predisposition, often mentioned in reviews but where no studies that we are aware of have been conducted during the last decade, other than two looking into polymorphisms in the TGFβ1 and alpha-1-antitrypsin gene that were not conclusive [59,60]. As a rule of thumb applicable to other research fields, if a finding has not been followed up by the same group or others in a period of 5 years, its significance is not strong. Similarly, no bacteriological association could be identified [61].

As in other aspects of Peyronie’s disease, no firm conclusion can be achieved on its etiology, other than an assuming that penile trauma or microtrauma is a triggering factor in many cases, and that unknown autoimmune or genetic predisposition may favor the development of the plaque by counteracting processes that would naturally regress it. It may be speculated that patients who present both with PD and Dupuytren’s disease would be the most adequate for a comparison of potential biomarkers or gene associations against patients of either condition alone, and against the non-PD population. In this respect, the current availability of proteomic tools may allow for a better characterization of potential biomarkers than in previous studies [62].

As to the pathology of the PD plaque, this is much better known because there are three lines of evidence on PD plaque histology in comparison to normal tunica albuginea. One is the early literature on the histochemistry, and more recently using immunohistochemistry and other assays, of the human PD plaque [48,50,63-71], showing that the main pathological process is tissue fibrosis, namely the excessive deposition of collagen and extracellular matrix with disorganization of collagen fibers and loss and disorganization of elastic fibers, combined in most cases with fibrin accumulation and different degrees of inflammation. Perhaps the most characteristic feature is the appearance of myofibroblasts, cells sharing the fibroblast/smooth muscle phenotypes that are not normally present in the tunica albuginea [71-74]. Progression is characterized by an increase in fibrosis, and in some calcification and ossification [11,75] where osteoblasts may be identified, that leads to a substantial hardening of the plaque, as seen in at least 15% of patients [20]. Spontaneous regression is a rare event [5,42].

The other evidence stems from the four animal models of Peyronie’s disease where a PD-like plaque develops either by pharmacological intervention, or spontaneously in the tunica albuginea of the rat or mouse: a) the most widely used TGFβ1-induced model [63,72,76-83], where this pro-fibrotic factor or a derived peptide is injected only once into the rat tunica and a plaque resembling the human one is found around 45 days later; TGFβ1 is produced in the human PD plaque and is the main profibrotic factor in multiple tissues [84]; a variation of this rat model, based on successive injections of an adenoviral construct expressing a constitutively active TGFβ1 protein which induces a measurable penile curvature and calcification [85]; c) the fibrin-induced rat model, where a single fibrin injection mimics the extravasation of fibrinogen, initiating an acute inflammation followed by a faster development of the PD-like plaque (about 30 days) [50,52,53]; and d) the tight skin (Tsk) mouse model, where a spontaneous PD-like plaque develops with fibrosis, penile bending, and areas of chondroid metaplasia with heterotypic ossification [86].

The third line of evidence is focused on the identification of the myofibroblast as the key cell in the development of the human and rat plaques, based on the culture of these cells and further in vitro characterization, in comparison to their counterparts obtained from the normal tunica albuginea [44,45,72-74,81-83,87-95]. Myofibroblasts are a common feature in most tissue fibrosis and in abnormal wound healing [96], and their persistence by the inhibition of
programmed cell death leads to scar formation, and this is likely the case in the PD plaque [51]. Several publications from two research groups have shown that myofibroblasts are responsible for the excessive collagen deposition in the plaque and possibly may cause penile bending by their well known contractility, but in addition that they are potentially tumorigenic or acquire this trait upon culture [11,93].

Moreover, these cultures contain pluripotent stem cells expressing specific markers, and are able to form myofibroblasts, smooth muscle cells, and osteoblasts, but not adipocytes, and in a paracrine fashion modulate in dual cell culture the differentiation of a multipotent cell line into osteoblasts and myofibroblasts [11,97]. The presence of stem cells in the normal tunica albuginea may explain the fibrotic and osteogenic progression of the PD plaque upon the release of cytokines following microtrauma to the penis which would stimulate this cell lineage commitment.

3. CELLULAR AND MOLECULAR MECHANISMS

Thanks to the analysis of the human PD plaque and of their cell cultures by a variety of cellular and molecular biology approaches, including DNA microarrays, in comparison to the similar information obtained in animal models, a preliminary picture of the molecular mechanisms operating in the initiation, development, progression, and pharmacological inhibition of plaque formation, or its occasional spontaneous regression, has emerged. It is remarkably similar in many aspects to fibrotic processes in other organs, and specifically in the penile corpora cavernosa in erectile dysfunction [98]. The main features of a rather plausible interpretation, that needs confirmation in certain aspects, are as follows:

Fibrinogen or other blood proteins extravasated into the tunica albuginea accumulate in the PD plaque by a putative inhibition of the fibrinolytic and proteolytic systems [48,50] by so far unknown mechanisms, although plasminogen activation inhibitor (PAI-1) is likely to be a factor [50]. Clotting leads to fibrin formation, and this protein and possibly immunoglobulins trigger the release in the lesion site of TGFβ1, PAI-1, and reactive oxygen species (ROS) [50,52,63,72,99], the main pro-fibrotic factors in the kidney, vascular system, and other organs.

There is a concurrent release of other cytokines, including monocyte chemotactic protein 1 (MCP-1), associated to a substantial acute inflammation that usually persists in a chronic phase [90,100,101], and that is probably responsible for the spontaneous induction of inducible nitric oxide synthase (iNOS) [102].

The combination of these factors, plus other members of the TGFβ1 family, such as myostatin and their common signaling via the Smad pathway [83,95], and other unknown agents, causes excessive collagen deposition, elastin degradation, myofibroblast differentiation from fibroblasts or stem cells in the tunica, oxidative stress, and eventually calcification.

Recent research has focused on why the established scar does not undergo normal remodeling and resolution. It appears from one study that there is an abnormal accumulation of TIMPs and other inhibitors of metalloproteinases and collagenases, as well as a relative paucity of collagenases, thus interfering with the normal breakdown of the accumulated collagen [103], and possibly interfering with therapeutic collagenase administration to the plaque [104].

The PD tissue is in constant cellular and molecular turnover and spontaneous mechanisms of defense develop that try to counteract fibrosis and oxidative stress, among them iNOS induction that produces a steady output of nitric oxide that inhibits collagen synthesis and quenches ROS producing peroxynitrite, and of cGMP that also reduces collagenase administration to the plaque [104].

The therapeutic mimicking of iNOS induction, by either biological modulation via gene therapy with iNOS cDNA [35] or long-term continuous pharmacological treatment with the NOS substrate L-arginine or PDE5 inhibitors [81,82], is able to prevent or even partially regress the development of the PD-like plaque in rat models by inhibiting fibrosis and oxidative stress, not by vasodilation effects. Conversely, blocking iNOS activity with L-NIL intensifies fibrosis in these models [63]. This is remarkably similar to the therapeutic prevention and regression of fibrosis by continuous, long-term administration of PDE5 inhibitors in the corpora cavernosa that leads to the amelioration of erectile dysfunction in rat models [98,108,109].

III. NON SURGICAL MANAGEMENT OF PEYRONIE’S DISEASE

1. INTRODUCTION

Non-surgical therapy has been proposed since the time of de la Peyronie. Due to the lack of a clear understanding of the etiopathophysiology, a cure has not been found. Therefore a variety of treatment options have been used. The most current therapies are reviewed. The value of many published reports has been questioned as most were not
well controlled, oftentimes had a small number of subjects in various phases of stability and with limited reports on objective measures of deformity change. Studies focus on reduction of pain which appears to resolve with time untreated, and reduction of plaque size, which has never been found to correlate with curvature improvement. In the opinion of the authors reduction of erect penile deformity (i.e.-curve, narrowing, shortening) is the most critical outcome measure.

Muller and Mulhall recently reviewed the published literature on PD drug trials in an effort to make subsequent studies more evidence-based and clinically useful. Their recommendations for the ideal PD intervention trial included a randomized, placebo-controlled design with a PD patient set representative of the general PD population and a comprehensive symptom and sign assessment before and at the end of treatment which includes an assessment of at least deformity, pain, and sexual function [24]. Table 5 reviews the methods of curvature assessment.

2. ORAL THERAPY

a) Potassium para-aminobenzoate

The first clinical trial with potassium para-aminobenzoate for treatment of Peyronie's disease was carried out by Zarafonetis et al. in 1959 [110]. To date, two prospective randomised, placebo-controlled, double-blind trials have been published. Shah et al. in 1983 treated 60 men with 12 g daily of potassium para-aminobenzoate or placebo for 12 months [111]. The authors found positive, but not significant improvement, of symptoms for potassium para-aminobenzoate when compared to placebo. More recently, Weidner et al. conducted a placebo-controlled, randomized, double-blind study on 103 patients with a history of less than <12 months of Peyronie's disease with non-calcified plaques and without any other treatment. Patients were randomized into two treatment arms: 51 received potassium para-aminobenzoate (4 x 3g/day for 12 months) and 52 received the placebo [112]. Their results showed a significant decrease of plaque size with the potassium para-aminobenzoate compared to the placebo (-117 vs -26; p = 0.042). No significant differences with regards to a decrease in pain was observed between the two groups (82.6% vs. 77.3%). Pre-existing curvature did not improve (p=0.066), but remained stable for those taking the active drug. In the placebo group, penile curvature worsened significantly in 32.5% of the cases (p<0.001). The authors concluded that potassium para-aminobenzoate appears to stabilize the disorder by preventing the progression of penile curvature in patients in the early stage of disease. This well-done controlled trial needs to be repeated to confirm these conclusions. It also should be noted that this treatment requires taking up to 24 tablets daily and is associated with gastrointestinal side effects.

b) Vitamin E

Vitamin E is the most common non-surgical therapy prescribed by urologists for treating Peyronie's disease [23, 113]. In 1983, a placebo-controlled, double-blind, crossover study demonstrated that no superior effects were achieved with vitamin E when compared to the placebo [114]. In 2007, Safarinejad et al. conducted a well designed double-blind, placebo controlled, randomized study in order to assess the efficacy and safety of oral vitamin E and propionyl-L-carnitine, both separately or in combination, for treatment of Peyronie’s disease [115]. A total of 236 men were randomized to receive 300 mg vitamin E orally twice daily, 1 g propionyl-L-carnitine orally twice daily, 300 mg vitamin E and 1 g propionyl-L-carnitine orally twice daily or placebo for 6 months. After treatment, there was no statistically significant differences between the 4 groups with respect to change in penile curvature (p = 0.9). Pain decreased in 60.4%, 63%, 62.3% and 59.2% of the patients and a reduction in plaque size was noted in 11.3%, 12.9%, 13.2% and 11.1% of patients who were treated with vitamin E, propionyl-L-carnitine, vitamin E plus propionyl-L-carnitine and placebo, respectively (p = 0.1).

This study did not show any significant improvement in pain, curvature or plaque size in PD patients when treated with vitamin E, propionyl-L-carnitine, or vitamin E plus propionyl-L-carnitine when compared with those treated with placebo. The authors concluded that Vitamin E is not recommended for treatment of Peyronie’s disease. To date there is no evidence proving the efficacy of vitamin E in the treatment of Peyronie’s disease, however it continues to be widely used. It is well-tolerated and inexpensive.

c) Tamoxifen

In 1992 Ralph et al. conducted a preliminary study on 36 patients with Peyronie’s disease who received tamoxifen 20 mg twice daily for 3 months. Their results showed that 16 out of 20 patients reported an improvement in penile pain, 11 out of 31 patients reported an improvement in penile curvature and 12 out of 35 patients presented a decrease of at least 1 cm in plaque size. Improvement was observed in 6 of the 8 patients with an inflammatory infiltrate of the plaque who had early stage disease (less than <4 months), but not in any of the 4 patients without an infiltrate. The conclusions of the study emphasized that tamoxifen could be effective in patients with early stage disease [116].

A placebo-controlled, randomized study was carried out in order to assess the effectiveness of tamoxifen in Peyronie’s disease, compared with placebo. 25 patients were treated with tamoxifen 20mg twice daily or placebo for 3 months. Investigators used penile radiography, ultrasound, and pharmacologically-

induced erections to objectively compare baseline status prior to treatment with a follow-up 4 months later. No statistically significant differences were noted between tamoxifen and placebo with respect to decreased penile pain (66.6% vs 75%, respectively), a reduction in penile deformity (46.1% vs 41.7%, respectively), or a decrease in plaque size (30.7% vs 25%, respectively). This study did not show any advantages in treating Peyronie’s disease with tamoxifen compared to placebo [117].

d) Colchicine

In a 1994 pilot study, 24 patients with Peyronie’s disease who were previously untreated received colchicine orally for 3 to 5 months. The results of this study showed a decrease in plaque size in 12 of the 24 patients, a significant relief in 7 of 9 patients with painful erections and an improvement of penile curvature in 7 of 19 cases. [118].

In 2000, Kadioglu and associates treated 60 men suffering from Peyronie’s disease with oral colchicine. Penile curvature improved in 30% of patients, remained unchanged in 48% and worsened in 21%. 95% of the patients reported relief from pain. Based upon these results, the authors concluded that colchicine may be effective in the early phase of the disease [119].

More recently, the first randomized double-blind, placebo-controlled study with colchicine for treatment of Peyronie’s disease was performed. 84 patients with Peyronie’s disease without calcified plaque received 0.5-2.5 mg of colchicine daily or a placebo for 4 months. After treatment, pain resolved in 60% and 63.6% of the patients treated with colchicine and placebo, respectively (p>0.05). A decrease in penile curvature was shown in 17.1% of patients treated with colchicine and in 18.4% of patients treated with placebo (p>0.05). A reduction in plaque size was noted in 10.5% of patients treated with colchicine and 10% of patients treated with placebo (p>0.05) [120]. The results of this study showed that colchicine is no better than placebo in improving pain, curvature angle, or plaque size in patients with Peyronie’s disease.

e) Vitamin E and Colchicine

A double blind, randomized study published in 2003, evaluated the effectiveness and safety of a combination of vitamin E and colchicine in patients with early stage Peyronie’s disease. 45 patients were randomized into two arms: 22 patients received ibuprofen 400 mg/day for 6 months, while 23 received a combination of vitamin E 600 mg/day plus colchicine 1 mg every 12 h. There was no statistically significant relief in pain response between the groups (p = 0.58) however there was an increase in plaque size in the ibuprofen group, while a reduction was evident (p<0.001) in the combination group. There was also a significant improvement in penile curvature in the combination group (p< 0.001) [121].

f) Acetyl esters of Carnitine

In 2001, Biagiotti and Cavallini evaluated the effectiveness of Acetyl-L-carnitine for the treatment of Peyronie’s disease compared to tamoxifen in a randomised, double-blind study. 48 patients with acute or early chronic stage Peyronie’s disease were randomly assigned to equal groups. Group 1 was composed of 8 patients with acute, and 16 patients with early chronic disease who received tamoxifen 20 mg twice daily for 3 months and group 2 was composed of 7 patients with acute and 17 with early chronic disease, who received acetyl-L-carnitine 1 g twice daily for 3 months. Results showed that acetyl-L-carnitine is significantly more effective than tamoxifen in reducing pain and penile curvature in patients with Peyronie’s disease. No significant difference was noted in the reduction of plaque size between the two drugs. The disease progressed in 13 patients in group 1 (54%) but in only two patients in group 2 (8%; p<0.01). Tamoxifen induced significantly more side-effects than acetyl-L-carnitine. The authors of this small but well designed study concluded that acetyl-L-carnitine is significantly more effective and safe than tamoxifen in the treatment of acute and early chronic Peyronie’s disease [122].

The same research group randomized 60 patients with stable Peyronie’s disease into two subgroups who were treated with verapamil intraplaque injection (10 mg weekly for 10 weeks) plus a 3-month oral propionyl-L-carnitine (2 g/day) or verapamil injection plus oral tamoxifen (40 mg/day) for 3 months. They found that the reduction in pain was the same in both subgroups however propionyl-L-carnitine plus verapamil significantly reduced penile curvature, plaque size, and the need for surgery, as well as increased the International Index of Erectile Function score, while tamoxifen plus verapamil had none of these effects. In this study, the combination of propionyl-L-carnitine and verapamil is recommended as the first therapeutic choice for advanced and chronic Peyronie’s disease [123].

The previous cited study of Safarinejad et al. which was published in 2007, did not show significant improvement in pain, curvature or plaque size in patients treated with oral vitamin E, propionyl-L-carnitine, or a combination when compared with a placebo. This study has demonstrated that propionyl-L-carnitine and Vitamin E are not effective alone or in combination for treating Peyronie’s disease [115].

g) Pentoxifylline

In vitro studies suggested a possible role of the NO-cGMP pathway in the pathogenesis of Peyronie’s disease. An increase of NO levels by administration
of nitrergic agents or inhibitors of phosphodiesterase (PDE), may be effective in preventing progression of or reversing the fibrosis [81]. Brant et al. reported a single case of a patient with Peyronie’s disease who was treated with Pentoxifylline, which is a non-specific PDE inhibitor, at 400 mg three times a day, for 6 months. The patient demonstrated an improvement in penile curvature, erectile function and in the ultrasonographic appearance of the plaque. 

Based upon these observations we can conclude that pentoxifylline deserves further investigation as a treatment for Peyronie’s disease [124]. While such results are interesting, they underscore the need to perform large-scale placebo-controlled studies to further explore the role of agents which may increase systemic levels of nitric oxide in clinical cases of Peyronie’s disease.

3. INTRAPLAEQUInJECTIONS

a) Steroids

Six studies using injectable corticosteroids for the treatment of Peyronie’s disease were published from 1954 to 1980 and all six showed positive outcomes from treatment. However none of the studies were randomized or reliably reported objective measures of deformity change [125-130].

In a single blind, randomized, placebo-controlled study, 30 men suffering from Peyronie’s disease were treated with intralesional betamethasone (group A) or placebo (group B) for 24 weeks. After 12-months the pain upon erection disappeared in 66.6% of the patients of group A and 53.3% of the patients of group B. Penile curvature decreased in 20% of the patients in group A and in 26.6% of the patients in group B. A decrease in plaque volume and consistency was observed in 40% of the patients in group A and in 40% of the patients of group B. The authors concluded that the clinical results of the therapy were due to the mechanical effects of the injection and not to the drug action itself [131].

b) Collagenase

Gelbard and associates conducted a prospective, randomised, placebo-controlled study with intralesional injection of collagenase in patients with Peyronie’s disease. 49 patients were randomised to receive a single intraplaque injection of either collagenase or saline solution and were followed for three months. Overall, 36% of the patients who received collagenase reported a positive response compared to only 4% in the control arm. The results of this study indicated a positive response to penile deformity only in patients with a curvature of less than 30° and the maximum degree of improvement was from 15–20°. The authors considered the absolute angular change too small to suggest any clinical benefit [104].

In 2008, Jordan conducted a prospective, single center, non-placebo controlled study in order to assess the efficacy and safety of intralesional clostridial collagenase injection therapy in a group of patients with Peyronie’s disease. 25 patients received three injections of 10,000 units of clostridial collagenase in 0.25 ml administered over 7 to 10 days and repeated at 3 months. Significant decreases from the baseline were achieved in the mean deviation angle at months 3 and 6, in plaque width at months 3, 6 and 9 and in plaque length at months 3 and 6. More than 50% of patients considered themselves “very much improved” or “much improved” after treatment. Based upon this data, intraplaque injection of clostridial collagenase may prove to be a beneficial treatment of Peyronie’s disease [132]. Clostridial collagenase is currently not available for clinical use. A randomized, placebo-controlled, multicenter phase 2B study will be completed by the end of 2009.

c) Verapamil

Intralesional verapamil injection was introduced by Levine and associates in 1994 [133-135]. Three non-controlled, quasi-experimental design (Oxford 2b) studies have been published demonstrating a measured reduction of curvature after twelve 10mg verapamil injections given every two weeks. Subjects had penile curvature measured after pharmacoinjection induced erection in the office before and at the end of treatment. The mean curvature reduction reported in those responders was 27-30°. The author suggested that this treatment may be offered as first line treatment or with a mature plaque. Subjects with acute (<12 months) or chronic disease responded in a similar manner.

Verapamil has also been shown in vitro to interfere with Peyronie’s plaque derived fibroblast cellular proliferation [136].

In 1998, Rehman et al. published a single-blind, placebo-controlled study in which 14 patients received weekly intraplaque injections of either verapamil or saline once a week for 6 months. Plaque volume decreased in 57% of patients in the treatment arm versus 28% in the control arm. In the verapamil group, the mean plaque volume decreased from 1.42 cm³ before treatment to 0.63 cm³ after treatment. Improvement in erectile function was noted in 43% of the patients treated with verapamil compared to 0% in the control group. 28.6% of the men treated with verapamil reported a decrease in penile curvature, with an average decrease from 37.7° to 29.6° following treatment. No improvement in penile curvature was observed in the saline group. This small, randomized, single-blind study suggests that intralesional injection of verapamil is a reasonable treatment for Peyronie’s disease with noncalcified plaque and penile angulation of less than 30 degrees [137].
The duration of the intralesional verapamil injection protocol may prove to be important with respect to deformity changes as it has been suggested that scar tissue remodels very slowly. One single-arm prospective study of six intralural verapamil injections given every two weeks resulted in 18% of subjects with a measured improvement in curvature (mean reduction 12°) while 60% were unchanged [138]. Therefore if a simple comparison is made between the published non-controlled single-arm, prospective trials of intralural verapamil injections, it appears that prolonged treatment with 12 injections over six months has a treatment advantage over just 6 injections over three months. The number of patients with a measured reduction of curvature following six months of treatment is 42-60% versus only 18% for three months of treatment.

In 2007, an Italian group carried out a randomized, prospective clinical trial with the aim of evaluating the efficacy and safety of three different verapamil dilutions for intralural therapy of Peyronie’s disease. 77 patients were randomly assigned to 3 treatment groups and each patient received 12 intralural injections (1 injection every 2 weeks) of 10 mg verapamil in different dilutions: group 1 received verapamil 10 mg/4 mL, group 2 received verapamil 10 mg/10 mL and group 3 received verapamil 10 mg/20 mL. Plaque size decreased in group 1, but this decrease was significantly greater in group 2 and in group 3. No significant difference was noted in penile curvature for all three groups. Pain relief was significantly greater in group 3 than in other groups. Group 3 had end diastolic flow velocity (EDV) during dynamic echocolor Doppler ultrasonography of the penis that were significantly lower than those in groups 1 and 2. This data supports the hypothesis that dilution of 10 mg of verapamil to a volume of 20 mL with injectable saline is able to improve the efficacy of intralural injections without significantly increasing the side effects [139]. Although large scale, placebo-controlled trials have not been conducted, intralural Verapamil injections can be recommended for the treatment of non-calcified acute or chronic plaques to stabilize disease progression or possibly reduce penile deformity.

d) Interferon

Hellstrom and associates conducted a single-blind, multicenter, placebo controlled, parallel study to assess the safety and efficacy of intralural interferon alpha-2B (IFN) for treatment for Peyronie’s disease [140]. 117 patients with chronic Peyronie’s disease (≥ 12 months) and a penile curvature of at least 30° were treated with either IFN or saline intralural injections biweekly for 12 weeks. Curvature improvement was noted in both groups, but more subjects responded in the IFN group (27%) than in the controls (8.9%). The mean improvement of curvature in the treatment arm was 13.5°. 67.7% of the IFN patients reported pain relief after injections compared to 28.1% of the controls. A percent change in plaque size was seen in both patient groups, but was larger in the IFN-treated patients (54.6%) than in the control group (19.8%). No statistically significant difference was noted in the IIEF score between the two groups. Results of this study showed that intralural IFN alpha-2B may be beneficial for men with Peyronie’s disease. These findings offer the largest and best-controlled trial of intralural therapy for Peyronie’s disease, as well as supports its use and demonstrates the lack of clinical benefit following intralural injection of saline. It is significantly more costly than verapamil and has been associated with flu-like side effects.

A recent trial compared the safety and efficacy of intralural interferon-alpha 2b (5.0 x 10^6 IU weekly x 12) alone or combined with oral vitamin E (400 IU BID) versus vitamin E alone. Thirty men entered this prospective randomized trial. Penile deformity was assessed before and 12 weeks after the injection treatment had ended with a full erection following intracavernous injection. At the 6-month follow-up visit there were no statistically significant changes in the objective measures of curvature or plaque size compared to the initial findings within each group or among the three groups. Subjectively there was no significant change in penile pain or quality of sexual intercourse. These authors concluded in this relatively small study that intralural interferon-alpha 2b either alone or in combination with vitamin E has limited benefits with significant side effects [141].

4. OTHER NON INVASIVE THERAPY

a) ESWT

It is very difficult to compare results from trials on extracorporeal shock wave therapy (ESWT) for the treatment of Peyronie’s disease because of the wide variations between the machines and therapeutic schedules used at different centers. However several studies report the efficacy of ESWT in Peyronie’s disease but the more recently published studies with specific documentation of the symptoms before and after treatment do not reveal a beneficial impact on the most important symptoms of penile curvature and plaque size [142-144]. In 2004 Hauck et al. published an exploratory meta-analysis in order to clarify the effect of shock wave therapy in Peyronie’s disease. A rigorous confirmatory meta-analysis was not possible because of the considerable differences in the patient selection of the study groups (medical history, symptom severity). Also, the choice of outcome measures was inconsistent and measurement was not standardized. Moreover, the definition of what constituted success varied from study to study. Results from 17 studies were compared with natural history outcomes and data from the control groups from 2 previous controlled ESWT studies. Results
differed in all outcome parameters in the 17 different series. The decrease in plaque size ranged from 0% to 68% of the cases, while an assessment of curvature reported no significant findings in 74% of the cases and a decrease in penile pain varied from 56% to 100%. Improvement of sexual function was observed in 12% to 80% of the patients. These various findings could be explained by the different groups of patients studied, the evaluation methods utilized, as well as the study designs used. Overall results suggest that ESWT has an effect on reducing penile pain and possibly on improving sexual function. Nevertheless, its effect on plaque size and penile curvature is not impressive and more varied than its beneficial effects shown on penile pain. The authors concluded that ESWT is not an evidence-based therapy for Peyronie's disease [145].

In order to evaluate the long-term effects of ESWT in Peyronie's disease, Srirangam et al. followed 38 patients for a mean period of 44 months (range 42-48). 10 patients out of 38 (26%) required corrective surgery for ineffective ESWT. Of the remaining 28 patients, 18 (47% of the total) showed a statistically significant reduction in penile curvature (mean reduction 33.2° +/- 14.4). No benefit or worsening was noted in 10 of the patients (24%). 16 patients out of 24 with pain (66.6%) reported relief after ESWT. 18 out of the 28 patients (65%) who did not undergo surgery reported erections suitable for intercourse. The treatment was well tolerated [146].

In 2009, Palmieri et al. published the first double blind, randomized, placebo-controlled trial evaluating extracorporeal shock wave therapy for the treatment of Peyronie's Disease [147]. One hundred patients with a history of PD not >12 months duration who had not received previous treatments for PD were enrolled in the study. These men were randomly assigned to receive either ESWT or placebo. Erectile function was assessed with the IIEF-5 questionnaire, pain was evaluated with a visual analog scale (VAS; 0–10), plaque size was measured in cm², and penile curvature was measured in degrees. After the first 12 weeks, a significant improvement of mean VAS score, mean IIEF-5 score and mean QoL score was seen. Nevertheless, mean plaque size and mean curvature were unchanged in the ESWT group, while a slight non-significant increase was observed in the placebo group. After 24 weeks, while mean IIEF-5 score and mean QoL score remained stable in the ESWT group, mean VAS score was significantly lower when compared with baseline in both groups. Moreover, mean plaque size and mean curvature were significantly higher in the placebo group when compared with both baseline and ESWT values. The authors concluded that ESWT appeared effective in reducing penile pain. Although no significant differences were observed in patients receiving ESWT for plaque size and penile curvature, the worsening of such values in the placebo group may suggest at best a potential beneficial effect of ESWT on disease stabilization.

b) Iontophoresis

In 2000, Riedl et al., in a prospective, non-controlled study, treated 100 patients from 28 to 70 years old (mean age 53.6) with Peyronie's disease with iontophoresis using dexamethasone, verapamil and lidocaine for 3 to 10 weekly treatments. Pain resolution was noted in 96% of patients, decrease in plaque size in 53% and improvement of penile curvature in 37%. Impaired sexual function was improved in 19 of 43 patients (44%). The treatment was well-tolerated and was more effective in patients with a short history of disease (less of 12 months). The authors recommended iontophoresis with those drugs as a first-line choice in non-surgical management of Peyronie's Disease [148].

In a randomized, double-blind controlled trial, 92 patients were randomized into two treatment groups: group 1 (47 patients) was treated with iontophoresis with verapamil 5 mg and dexamethasone 8 mg and group 2 (49 patients) was treated using lidocaine, as the control treatment. In group 1, reduction of plaque size was observed in 100% of patients (median plaque volume decreased from 824 to 348 mm³), improvement of penile curvature in 57% of patients (median curvature decreased from 43 to 21 degrees) and pain resolution was seen in 76%. The reduction of pain in the control group that received lidocaine was only temporary. The other symptoms did not improve in the control arm. 51% of patients in group 1 presented an improvement in sexual function while in the control group no significant improvements were observed. Results of this study reveal that electromotive administration of verapamil and dexamethasone for Peyronie’s disease is a safe treatment that induces significant decreases in penile curvature and plaque volume, and a durable decrease in pain [149].

Nevertheless, in 2007, Greenfield and Levine published a randomized, double-blind, placebo-controlled trial on 42 patients with Peyronie's disease [150]. Patients were randomized into two arms: group 1 received 10 mg verapamil in 4 cc saline solution. Patients in group 2 received 4 cc saline only. Treatments were delivered twice weekly for a total of 3 months. Researchers found that there were no significant differences between groups with respect to patient age, disease duration or pretreatment curvature, although a greater percent of patients had improvement in pain and curvature in the group treated with verapamil (p>0.5). The authors concluded that EMDA therapy should be considered only for the patient whose primary complaint is pain or in the patient with mild to moderate curvature (<45°) who declines intralelosional injection therapy or surgical reconstruction [150]. They also concluded that since both groups had a similar reduction in
curvature, that it may be the energy delivered to the tunic rather than the drug which induced the deformity change.

c) Penile Traction Devices

It is well-documented that gradual expansion of tissue by traction, also known as mechano-transduction, results in the formation of new connective tissue by cellular proliferation in several tissue models including bone, muscle and Dupuytren’s scar [151-153]. Levine and associates published a prospective pilot study on 10 patients treated with daily application of a penile extender device for 2–8 h per day for 6 months [154]. Results showed a mean reduction of curvature of 33% (ranging from a 10° to 45° improvement and resulting in a reduction in average curvature from 51° to 34°), an increase in flaccid stretched penile length in all subjects ranging from 0.5–2.0 cm, and an improvement in hinge effect in all those with advanced narrowing or indentation. No patients noted recurrence or worsening of curvature during 6 months of follow-up, and there was no evidence of local skin changes, ulceration, change in penile sensation, or worsening of curvature. Of course, long term and larger scale studies are needed in order to assess the effectiveness of this kind of treatment [154]. Gontero et al. also studied the effects of traction therapy on 15 men with stable Peyronie’s Disease in a prospective non-controlled trial. They did not report significant mean reduction of curvature (4°) but significant length gain was noted after 6 months of daily treatment [155]. Possible explanations for the discrepancy between these two published reports include that in the Gontero study, penile deformity was not routinely measured in the office, and 37% of the patients had a calcified plaque which is known to compromise outcomes for non-surgical therapy. Traction therapy is the newest addition to the non-surgical armamentarium for Peyronie’s disease and shows promise for reduction of curvature as well as recovery of some lost length and girth. As this treatment is non-invasive and appears safe and effective when used properly, the authors recommended use of this therapy. Future studies are ongoing to examine the effects of traction combined with intralesional injections and/or oral agents.

5. CONCLUSION

Non-surgical therapy for Peyronie’s disease has taken many forms. There do appear to be treatment options including intralesional injection and most recently traction therapy which appear at a minimum to stabilize progression of the disease and may improve deformity as well as sexual function. Clearly new, properly designed, randomised placebo-controlled trials with balanced study samples are needed to confirm the benefit of non-surgical therapy. Non-surgical therapy is an option that should be offered to the patient who has unstable disease and is therefore not a surgical candidate and to those men who are not ready to proceed with surgery regardless of the duration or severity of their Peyronie’s Disease.

IV. PEYRONIE’S DISEASE: SURGICAL THERAPY

1. SURGICAL INDICATIONS

The indications for surgical correction of the penile deformity associated with Peyronie’s disease begins with having stable disease. The concept of stable disease has not been clearly defined, but it is generally accepted to be at least six months where there has been no change in the deformity and that pain with erection or during plaque palpation has resolved. The surgical candidate should also describe a compromise or inability to engage in coitus secondary to deformity or inadequate rigidity. In addition, patients who have extensive plaque calcification are typically best treated with surgery, as non-surgical approaches have not been shown to be beneficial in this circumstance. Lastly, the patient who wants the most rapid and reliable result should select a surgical approach [26,156] (Table 6).

<tr>
<td></td>
<td>Wants the most rapid and reliable result</td>
</tr>
</tbody>
</table>

2. SURGICAL CONSENT

The preoperative consent is critical for preparing men with Peyronie’s disease for surgery (Table 7).

Table 7 Informed consent topics

<table>
<thead>
<tr>
<th></th>
<th>Incomplete/Recurrent curvature</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>

</tr>
<tr>
<td></td>
<td>Diminished rigidity</td>
</tr>
</tbody>
</table>

Many of these men are depressed, have marked reduction of self-esteem, and often times have unattainable expectations regarding the outcome from surgical reconstruction [15]. Therefore, a
detailed discussion on persistent or recurrent curvature should be initiated with the accepted goal of making the patient “functionally straight”, which is loosely defined as a curvature of less than 20 degrees [157]. Loss of length is most likely to occur with plication procedures, particularly in those with ventral curvature [158]. In addition, there may be diminished rigidity, which has been shown to occur regardless of the surgical approach. Clearly, those who have suboptimal preoperative rigidity have a higher risk of post-operative erectile dysfunction. The incision and grafting technique appears to increase the risk of post-operative ED and, therefore men who have borderline to inadequate erections pre-operatively, should avoid grafting procedures or be prepared to need subsequent penile prosthesis implantation [159]. Lastly, there is a risk of decreased sexual sensation. This has been infrequently reported in the published literature, but it seems for the most part it rarely compromises orgasm and ejaculation.

Surgical algorithms have been published to guide the choice of surgical approach (Table 8).

Table 8. Peyronie’s Disease surgical algorithm.

I. When rigidity adequate preoperatively with or without pharmacotherapy
   A. Tunica Plication when—
      i. Curvature < 60-70 degrees
      ii. No destabilizing hour-glass or hinge
      iii. Predicted loss of length < 20% erect length
   B. Plaque Incision/ Partial Excision and grafting when—
      i. Curvature > 60-70 degrees
      ii. Destabilizing hinge
II. When Rigidity suboptimal
   A. Penile prosthesis implantation

Two main pre-operative factors contribute to this decision, including penile rigidity and severity of deformity [161-163]. When rigidity is adequate, with or without drug assistance, two approaches have been suggested including tunica plication techniques, which are recommended when there is a simple curvature of less than 60-70 degrees, and no hour glass deformity, and when the presumed loss of length caused by the plication will be less than 20% of total erect length. For men who have more complex curvature greater than 60 degrees, and/or a destabilizing hour-glass or hinge effect then plaque incision, or partial plaque excision and grafting is preferred. It is important to stress that this approach is recommended for men who have good quality, preoperative erections.

3. SURGICAL APPROACHES

a) Plication Procedures

This review of surgical approaches begins with the plication procedures, which are designed to shorten the long side of the penis. If the curvature is in a dorsal direction, the plaque causes shortening of the dorsal aspect, and, therefore to correct the curvature with plication, the ventral aspect is shortened. This approach is based upon the Nesbit procedure where an erection is created and a wedge of tunica is excised from the convex, (longer) side, then the edges are reaproximated to create the shortening effect [164]. Currently, there are many variations of the plication procedure, which include procedures where a portion of the tunica is not excised, but instead plicated such as the Essed-Schroeder technique [165]. The Yachia technique utilizes the Heinke-Mikowitz principle where a vertical incision is closed transversely so as to shorten the convex side of the penis [166]. The tunica albuginea plication technique (TAP) corrects the deformity by plicating a series of paired incisions into the tunica without exposing the underlying cavernosal tissue [157]. The 16-dot procedure utilizes an extended Lembert type of suturing technique [167]. In this procedure, a dorsal curve is corrected with sutures placed into the tunic on both sides of the urethra, then progressively tied down so as to create shortening and straightening. There is no tunica incision or tissue excision performed; therefore, the correction of deformity relies upon the non-absorbable sutures. All these procedures appear to adequately straighten the penis with little risk of compromising erectile function. It is critical that during the performance of any straightening procedure the surgeon is able to induce an erection, usually by needle injection of saline by pump or syringe.

Table 9 demonstrates the results with various plication procedures with respect to straightness, post-operative ED, sensation, and follow-up.

The advantages to the plication approach are that they are simple, minimally invasive, and tend to preserve potency in most patients. The disadvantages are that they can result in penile shortening, which has been shown to be exacerbated by correction of curvature greater than 60 degrees, and/or a ventral curvature where dorsal plication is necessary [158]. Lastly, plication procedures may worsen an existing hour-glass or hinge effect, particularly if large plications are used.

b) Incision or Partial Excision and Grafting Techniques

Surgical grafting techniques include plaque incision or partial excision. Historically, total plaque excision was designed to “remove the diseased tunica”
but this causes an unacceptably high rate of post-operative erectile dysfunction. This has been suggested to occur as a result of a compromised veno-occlusive mechanism, due to changes in the relationship between the cavernosal tissue and the overlying tunic or graft [168]. Therefore, minimizing the excision or making simple releasing incisions have been recommended so a smaller graft may be used [169].

The search for the ideal graft continues. As of this time, no ideal graft has been identified, which would take reliably, not contract, be resistant to infection and preserve erectile capacity (Table 10).

</tbody>
</table>

Currently, it appears that the nature of the graft is less likely the determining factor with respect to post-operative ED. On the other hand, it is most likely due to patient selection with respect to pre-operative erectile status and operative technique [159]. Larger grafts, men older than 60 years old, and those with ventral grafting also appear to have a higher risk of post-operative erectile dysfunction [162,171]. A variety of autologous grafts have been used including dermis, tunica vaginalis, temporalis fascia, buccal mucosa, and fascia lata [173]. The most frequently used autologous graft currently in use is saphenous vein, which requires a separate incision to harvest, adding a risk of local side effects, and longer operating time with a second incision to heal. Synthetic grafts were used historically, including polyester (Dacron) and polytetrafluoroethylene (PTFE), but these have not
been met with enthusiasm because of the increased risk of infection, an unnatural feel and may have the potential for more local inflammation and fibrosis [174]. The modern era of grafts include off-the-shelf processed human cadaveric tissue or xenografts. These are felt to be advantageous because they can reduce operating time substantially, they appear to have similar mid-term outcome results as compared to autologous grafts, and there is no harvest morbidity. These grafts include human and bovine pericardium, porcine small intestinal submucosa (SIS), and porcine and human dermis. All these grafts undergo an extensive processing to clear the tissue of cells, bacteria, viruses, and presumably prions. As of this time there has been no report of host viral infection secondary to processed allograft or xenograft implantation.

The operative procedure is done essentially the same for all grafting techniques— an artificial erection is created demonstrating the curvature and the penis is typically degloved using a circumcising incision allowing exposure of the entire shaft of the penis. In the area of maximum curvature, Buck’s fascia containing the neuro-vascular bundle is elevated, either from a pair of parallel incisions lateral to the urethral ridge allowing elevation of Buck’s fascia dorsally, or by coming through the bed of the deep dorsal vein. It is felt that the deep dorsal vein approach may not offer adequate lateral exposure, which would be especially important for patients who have severe lateral indentation or hour-glass deformity. The elevation process is best performed with loupe magnification and bi-polar electrocautery so as to reduce the likelihood of injury to the neuro-vascular tissues. Once Buck’s fascia is properly elevated an artificial erection is recreated, demonstrating the area of maximum deformity. Surgeons differ in their approach as to whether a simple modified H-like incision should be made to the area of maximum curvature or whether partial plaque excision is recommended, particularly when there is significant indentation and/or calcification. Regardless, the goal is to remove as little plaque as possible, but to allow proper correction of the deformity by expanding the tunic in both girth and length. Edygio has championed the geometric principle approach to graft sizing [175]. This technique has proven useful in his hands, but a recent report suggested a higher risk of post operative ED [172]. Once the graft is positioned, Buck’s fascia is reapproximated to provide support and a vascularized cover over the graft.

**c) Post-Operative Care and Rehabilitation**

Following surgery, post-operative rehabilitation is recommended to enhance recovery of erectile function. Massage and stretch therapy, is performed by grasping the glans penis and pulling it gently and repeatedly away from the body while also gently massaging the graft area. This is initiated two weeks after surgery and performed twice a day for four weeks. It is advised that the patient’s partner get involved in the rehabilitation process to lessen the anxiety associated with the resumption of sexual activity for both partners. Bedtime phosphodiesterase inhibitors have been recommended to begin seven to ten days after surgery and to be maintained for 6 weeks, in order to enhance nocturnal erections, stretch the tissue, encourage nourishment of the graft [159], and possibly reduce the risk of post-operative ED. Finally, the use of external penile traction therapy has been noted to reduce post-operative penile shortening for patients who have undergone either plication or grafting procedures. Traction is initiated two to three weeks post-operatively when the circumcising incision has adequately healed and is performed on a daily basis for a minimum of two to eight hours for three months [176]. Table 11 outlines the results from published reports on grafting, on average 74-100% of patients were adequately straight, with a post-operative erectile dysfunction ranging from 5-53%. Long-term follow up reports on grafting are limited and found in Table 12. Kalsi, et al, studied 40 patients who underwent vein grafting and followed for at least five years. They reported a post-operative erectile dysfunction rate of 22.5% and a loss of length was noted in 35% [177]. At the 2004 Annual Meeting of the American Urological Association Society, Montorsi, et al reported on 50 patients with a five year follow-up after venous grafting where there was either persistent or recurrent curvature in 12%, length loss in 100%, post-operative ED in 22%, diminished orgasm in 41%, and overall patient satisfaction of only 60% [178]. Taylor and Levine recently reported a mean follow-up of just short of five years on 111 patients undergoing partial plaque excision with processed human pericardial grafting where the patients reported persistent or recurrent curvature of greater than 20 degrees in 8% (none required surgical correction), a measured loss of stretched penile length was found in 47%, but was subjectively reported by 65% of patients. The post-operative ED rate was 24% with 31% noting diminished sensation, but 89% experienced normal orgasm. Overall, patient satisfaction was reported at 76% [157]. Post-operative traction therapy had not been introduced for these studies.

Recent studies have also examined the risk of post-operative erectile dysfunction following penile grafting procedures [170,172]. For the most part, no significant contribution was found due to duration of disease, vascular risk factors (including diabetes, hypertension, elevated lipids and smoking), a dorsal or lateral curvature, graft or tunica defect size, or whether there was pre-operative narrowing or hinge effect. A higher risk of erectile dysfunction was found in those who underwent grafting for ventral curvature and there was a trend towards increased ED risk for men over the age of 60 [159]. In this published...
analysis, the primary component which helped predict an increased risk of post-operative ED was when the patient reported pre-operative diminished rigidity.

b) Penile Prosthesis Implantation with Straightening Maneuvers

Finally, for those men who have poor quality erections and/or do not respond adequately to pharmacological therapy for their erectile dysfunction, penile prosthesis implantation is recommended. Table 13 reviews the recommended surgical algorithm for men with PD and ED [160,162]. Prosthesis alone may result in satisfactory straightening of the penis for those with mild deformity, but when residual curvature is more than 30 degrees, manual modeling is recommended [179]. Manual modeling should be performed with care. Once the prosthesis is placed and the corporotomies are closed, the prosthesis is inflated with a surrogate (i.e. outside the body) reservoir of saline to demonstrate the deformity. The surgeon will then model the penis by bending it in the contralateral direction to the curvature maintaining the pressure on the bent penis for 30 to 60 seconds. The tubing between the pump and the cylinders should be occluded with rubber shod hemostats, so as to protect the pump from high pressure damage. In addition, when performing the modeling process, pressure on the glans penis should be avoided to prevent a urethral erosion by the cylinder tip. An alternative approach is to pre-place plication sutures in the 16-dot method before implanting the prosthesis and then tying them down to correct the curvature. Regardless of the approach, if there is residual curve less than 30 degrees, no further treatment is recommended, as the prosthesis will act as an internal tissue expander and will likely result in correction of deformity in six to nine months. On the other hand, if there is substantial residual curvature, then releasing incisions can be made on the concave side, often times through the same scrotal incision or may require degloving of the penis with elevation of Buck’s fascia. If these incisions create a tunic defect greater than 2 cm in any dimension, patching is recommended to decrease the risk of cicatrix contracture resulting in recurrent curvature or herniation of the cylinders. An off-the-shelf graft is now recommended to fix the tunic defect. Freshly harvested dermal grafts are not recommended as there is risk of transferring bacteria within the dermal tissue increasing the possibility of post-operative infection.

4. CONCLUSION

This review is intended to be a guide to making decisions about surgical correction of Peyronie’s disease. The intent is that it will be useful to the practicing surgeon so that they may provide appropriate advice to their patients regarding the proper surgical procedure. The most critical part of the surgeon’s role in the preoperative phase is to set appropriate expectations for the patient and to review the potential complications of surgery, including incomplete straightening, recurrent curvature, shaft shortening, diminished sensation and erectile dysfunction. Although surgical correction of Peyronie’s disease has historically had a negative reputation, the more recent refinements in technique make it a viable and successful treatment option for the properly selected patient.

**RECOMMENDATIONS**

1. **Peyronie’s Disease (PD) -Overview  Grade A**
   PD is a physically and psychologically devastating problem manifest by fibrous inelastic scar of the tunica albuginea, which results in palpable scar causing penile deformity (e.g. bending, narrowing, hinging, shortening), as well as painful erections, all of which may lead to difficulty with intromission. It remains a therapeutic dilemma. There are relatively few high-level evidence-based therapeutic studies.

2. **Prevalence of Peyronie’s Disease  Grade B**
   Multiple demographic studies have been performed world-wide indicating a prevalence rate of 3-9% in adult men. Therefore PD is not a rare disorder.

3. **Natural History  Grade C**
   The natural history of PD has been evaluated in only a few level 2&3 studies indicating that spontaneous deformity resolution is not common and remains less than 13%.

4. **PD-Pathogenesis  Grade C**
   PD is a wound healing disorder occurring in a presumed genetically susceptible individual whose tunica albuginea responds inappropriately to an inciting event (i.e. trauma) with a proliferative, fibrotic reaction resulting in an exuberant, inelastic scar. A closer understanding of the etiopathophysiology is not yet established.

5. **Common Comorbidities  Grade D**
   Multiple comorbidities have been identified, including ED, hypertension, diabetes mellitus, hyperlipidemia, low testosterone and Dupuytren’s disease. It remains unclear whether any of these contribute to the development of PD.

6. **Clinical Diagnosis-Overview  Grade D**
   There is no international standard for evaluation or reporting on treatment outcomes for PD. A detailed history should be obtained focusing on onset, duration, pain and deformity.

7. **Clinical Diagnosis-Objective Assessment  Grade D**
   Suggested objective measures include: measuring stretched penile length, and describing plaque location (dorsal, ventral, septal, proximal, distal, etc.)

8. **Clinical Diagnosis-Plaque Size  Grade D**
   Plaque measurement is inaccurate by any modality, as well as operator dependent and therefore is not a reliable assessment of treatment response.

9. **Clinical Diagnosis-Duplex Ultrasound  Grade D**
   Dynamic duplex ultrasound provides assessment of plaque calcification, vascular flow parameters and objective measures of deformity. It is a useful but not necessary test.

10. **Candidates For Non-Surgical Therapy  Grade C**
    Men with early phase disease (i.e. <12 months induration) manifest by unstable or progressive deformity and painful erections as well as those not psychologically ready or interested in surgery may be considered candidates for non-surgical therapy.

11. **Oral Therapy  Grade B**
    There is evidence that there is no benefit with respect to deformity reduction with any oral therapy, including Vitamin E, Potassium Aminobenzoate, Colchicine, Tamoxifen, and Carnitine.

12. **Treatment-Injection Therapy**
    Intralesional injection may be used with the following admonitions:
    - **Steroids**-no objective measures of therapeutic benefit.  Grade D
    - **Verapamil**-appears to make scientific sense but no large scale placebo-controlled trials.  Grade C
    - **Interferon**-One (Level 1) placebo-controlled trial showed an outcome benefit with interferon over saline.  Grade B
    - **Collagenase**-Several small non-controlled trials showed limited benefit. It is currently being studied in a phase 2b trial.  Grade D

13. **Treatment-Topical Verapamil  Grade D**
    As there are no independent controlled trials and no evidence of adequate levels within the tunica albuginea, no recommendation is possible for topical Verapamil.

14. **Treatment-Topical Energy- Iontophoresis  Grade C**
    Several controlled trials had evidence of reduced deformity following iontophoresis treatment using verapamil and dexamethasone.

15. **Treatment-Shock Wave Therapy  Grade B**
    There is evidence that ESWT does not improve PD-related deformity.

16. **Treatment-Traction Therapy  Grade C**
    Early evidence from two small non-controlled prospective trials have reported a reduction of deformity and increased penile length with traction therapy.
17. Non-Surgical Treatment Overview Grade C  
Non-surgical treatment has limited evidence of benefit, but multiple reports of deformity stabilization or reduction makes it reasonable to offer EMDA, and/or intralesional injection of verapamil or interferon, and/or traction therapy.

18. Surgical Treatment Grade C  
Surgery remains the gold standard for correcting erect penile deformity in the man with stable disease.

19. Indications for Surgical Reconstruction Grade C  
Surgical reconstruction is indicated in the man who has stable disease for ≥ 6 months, painless deformity, compromised or inability to engage in coitus secondary to deformity and/or inadequate rigidity, when there is extensive plaque calcification, and for the man who desires the most rapid and reliable result.

20. Surgery-Pre-Operative Consent Grade D  
The pre-operative consent is critical to set proper outcome expectations for the patient. It is imperative to have a discussion on the risks of persistent or recurrent curvature, loss of erect length, diminished rigidity and decreased sexual sensation.

21. Surgical Algorithm Grade C  
Several surgical algorithms have been published with general agreement that for men with adequate pre-operative rigidity, some form of tunica plication procedure is best for those with curvature less than 60° and with no hour-glass deformity resulting in a hinge-effect. For those with more severe deformity (>60° and/or hourglass) and good pre-operative rigidity, incision or partial excision and grafting is recommended.

22. Surgery-Plication Procedures Grade C  
There is no evidence that one surgical approach provides better outcomes over another, but curvature correction can be expected with low risk of new ED or sensory change.

23. Surgery-Grafting Procedures Grade C  
There is no evidence that surgical outcomes are consistently better with one graft type, and overall there is an increased risk of post-operative ED. Autologous grafts require more time and a second incision. Allograft and Xenograft procedures appear shorter in duration with no reported transmission of disease. Synthetic grafts increase the risk of infection and are not recommended.

24. Surgery-Penile Prosthesis Grade C  
Penile prosthesis implantation with additional maneuvers to correct the deformity is recommended when there is pre-operative ED not responsive to oral medication (PDE-5 Inhibitors).

25. Surgery-Penile Prosthesis Grade D  
Following prosthesis implantation the following maneuvers are recommended including manual modeling followed by plaque incision if the residual erect curvature exceeds 30°. If a tunica defect in excess of 2 cm is noted after incision, then grafting the defect is recommended to reduce the risk of post-operative recurrent curvature or cylinder herniation. Autologous dermal grafts should not be placed over a prosthesis due to the increased risk of infection.

26. PD Surgery-Overview Grade D  
Following published surgical algorithms is imperative, as well as obtaining a pre-operative consent to set proper outcome expectations for the patient. A plication procedure is indicated for less severe deformity (≤60°) and when there is borderline ED, while grafting is reserved for severe deformity (>60-70° +/- hinge with normal erectile function) and requires an experienced surgical team. Lastly, prosthesis placement is indicated with additional maneuvers for those men with refractory ED and PD.

B. PENILE TRAUMA

I. PENILE FRACTURE

Penile fracture is defined as the traumatic rupture of the tunica albuginea. It usually occurs during sexual intercourse when the erect penis is thrust against the partner’s symphysis pubis or perineum [1,2,3,4]. Other causes, particularly in Middle Eastern countries, include masturbation, compression of a nocturnal erection and from “Taghaandan”, a process of kneading and snapping the erect penis to achieve detumescence [4].

The site of the fracture usually occurs laterally or ventrally, in the mid to lower shaft, where the outer and inner fibres of the tunica are less prominent. These areas thin to 0.25mm on expansion and with the high intracorporal pressure during forced straining are liable to rupture [3,5].

1. PRESENTATION

The classical presentation includes a cracking sound at the moment of injury, a sharp pain, detumescence, swelling and ecchymosis [1,2,3,4]. The typical appearance has been named as ‘eggplant deformity’ or ‘aubergine sign’ by some authors [3,4,6]. A palpable defect in the tunica albuginea can occasionally be felt but usually the swelling conceals this sign. It is important to remember that a concomitant urethral injury, partial or complete, may occur in 2% - 20% of patients [1,6,7].

2. INVESTIGATION

Imaging is useful to confirm the diagnosis of a tunical or urethral injury and to possibly exclude alternative diagnoses such as a ruptured dorsal vein or suspensory ligament injury which could be managed conservatively [8]. If the site of the tear is visualised then this also would help in choosing the type of surgical access to be used. Imaging should be used if the equipment and expertise is available and time permitting but these are only supplementary to the clinical assessment which should take priority.

Cavernosography has been shown to be reliable in the diagnosis of penile fracture with 100% accuracy in one series of 21 patients that went on to a surgical repair [9]. Non invasive techniques such as grey scale and colour Doppler ultrasound can be useful but is operator dependant [10]. MRI scanning is likely to be more accurate but may not be available in all units [3].

A urethral injury should be suspected in all cases particularly if there has been urethral bleeding or that a ventral tear has been diagnosed. Retrograde urethrography may be used pre-operatively to diagnose this but may become unnecessary if a surgical exploration is to be performed. In this situation the urethra can be directly inspected at the fracture site with or without an on-table urethrogram with methylene blue or betadine [6].

3. TREATMENT

Conservative management of a penile fracture with catheterisation, compression dressings, analgesia, antibiotics and erection-inhibiting agents should be avoided. Complications including painful erection, penile deformity, arterial-venous fistulae, hematomas, abscess formation and erectile dysfunction due to venous leakage [3,12,13,14] may occur in over 30% of patients.

Once diagnosed, surgical exploration is widely accepted as the ‘gold standard’ therapeutic option in men presenting with penile fracture even in the event of a delayed presentation (48 hours after injury) [3,4,7].

Even after surgical repair long term erectile dysfunction may be present in 17% of patients and they should be warned of this [4]. Surgical intervention commences with either a degloving incision, often combined with a circumcision, or a local incision over the fracture site if known. The haematoma is then evacuated and the tunical tear repaired. The urethra is inspected and repaired by mucosal apposition without debridement or spatulation. Any subsequent stricture formation can be dealt with at a later [1,3,4,15,16].

A study comparing the long term outcomes of surgical and conservative treatment in men with penile fracture showed a 92% and 59% patient reported satisfaction rate respectively, thus suggesting immediate surgery seems superior to non operative therapy [14].

II. PENILE PENETrATING TRAuMA

Penetrating trauma to the penis should be explored immediately with an anatomic repair performed. The management of bullet injuries depends on velocity. Low velocity injuries of the urethra should be primarily reconstructed while ‘high’ velocity injuries should be managed by diversion and delayed reconstruction of urethral strictures, or correct penile curvature which commonly occur secondary to damage to the surrounding tissues [17].

III. DEGLOVING INJURIES OF THE PENIS

Degloving injuries are encountered in cases in which the penis or scrotal skin is trapped and stripped from the deeper structures. In such cases bleeding is usually not a problem due to the lack of large
vessels in this space. The injured area, if clean, should be dressed in sterile saline-soaked bandages and immediately reconstructed using partial or full thickness skin grafts [9].

IV. AMPUTATION OF THE PENIS

The treatment of penile amputation includes surgical replantation of the amputated part, tailoring of the remaining penile stump, or total phallic reconstruction at a later date.

Reimplantation with microsurgical reanastomosis is the most widely accepted approach which gives the most physiologic and aesthetic results [18]. In the absence of a microvascular surgeon, and where the patient's condition permits, transfer to an appropriate unit should be performed. The amputated distal portion of the penis should be cleaned, wrapped in a sterile saline bandage, placed in a sterile plastic bag and kept on ice. Surgically, the penis is stabilized by stenting the urethra and completing a two-layer spatulated urethral reanastomosis using 6-0 polydioxanone suture on the mucosa and 4-0 on the corpus spongiosum. The cavernosal arteries are bilaterally anastomosed with 11-0 nylon sutures if possible followed by the approximation of the tunica albuginea. Finally, the dorsal arteries (11-0 nylon), dorsal vein (10-0 nylon) and dorsal nerve sheaths (10-0 nylon) are reapproximated [17, 18].

Total phallic reconstruction is considered for patients in whom replantation is impossible. This is best performed using the free forearm flap, first reported by Chang and Hwang, to give a sensate phallus with a neourethra [19]. A penile prosthesis implantation is performed after the recovery of sensation of the neophallus to allow rigidity for sexual intercourse.

Figure 1. Ultrasound and MRI image of penile fracture.
RECOMMENDATIONS

1. Recommendation for Penile Fracture
   Grade C
   Imaging (Cavernosography, US or MRI) can be used for localisation of the injury, while retrograde urethrogram (pre/peri op) can be performed if there is a suspicion of a urethral injury. The ultimate decision for surgery is based on clinical findings and once diagnosed, there is no indication for conservative management.

2. Recommendation for Penile Skin Loss Injuries
   Grade
   There is evidence to support surgical replacement of shaft skin with either split, mesh or full thickness skin.

3. Recommendation for Penile Amputation
   Grade D
   Critical warm and cold ischaemia time is unknown. Surgical re-attachment is therefore a clinical decision and is best performed by an experienced microsurgeon. Psychological evaluation should be offered to patients who self mutilate. If re-implantation fails or is impossible, patients should be referred for phalloplasty at an appropriate time interval.

C. GENDER REASSIGNMENT AND PENILE RECONSTRUCTION

• GENDER REASSIGNMENT

I. GENITAL GENDER REASSIGNMENT IN TRANSSEXUAL PATIENTS

1. INTRODUCTION

Transsexualism (TS) or Gender Identity Disorder (GID) is defined as a strong and persistent cross-gender identification with the patients’ discomfort with his/her sex and the sense of inappropriateness in the gender role of that sex (Diagnostic and Statistical Manual of Mental Disorders, fourth revision, text revision [DSM-IV-TR]) [1].

Gender reassignment surgery together with hormonal therapy is generally accepted as a somatic method to resolve this discomfort by altering a person’s external sexual characteristics to resemble those of the opposite sex [2].

The prevalence of GID among the general population and the ratio between male to female has a country variation reflecting different cultural and social conditions and the ability to keep registers. Most countries have a male:female ratio of 3:1 although a ration of 1:1 has been noted in Serbia [3, 4, 5, Table 1].

The World Professional Association for Transgender Health (WPATH), formerly known as the Harry Benjamin International Gender Dysphoria Association (HBIGDA) continuously updates Standards of Care (SOC) for diagnosis and treatment of transsexual patients as well as the criteria for surgical procedures [6]. At present a minimum age of 18 years is demanded for gender reassignment surgery although hormonal treatment may start earlier than this [7].

2. DIAGNOSIS

The diagnosis of GID is determined by mental health professionals, who firstly have to exclude any underlying medical condition such as schizophrenia or a personality disorder and to exclude alternative diagnoses such as transvestism and fetishism. A thorough medical examination is also mandatory to exclude an intersex condition [5].

Patients must spend a period of time living in their chosen gender before being considered for surgery. This Real Life Test is usually for one year although hormone therapy may be commenced earlier to help the adjustment [6, 8].

The following sections deal with genital surgery in this group of patients. Other reassignment procedures of breast surgery and hysterectomy are well defined and established, even if their performance in transsexual patients may require specific skills and knowledge.

II. GENITAL REASSIGNMENT SURGERY IN MALE-TO-FEMALE TRANSSEXUAL PATIENTS

1. SURGICAL AIM

The surgical aim is to create a perineogenital complex as feminine in appearance and function as possible. The perineogenital area should be free of poorly healed areas, scars and neuromas. The neovagina should ideally be lined with moist, elastic and hairless epithelium. Its depth should be at least 10 cm and its diameter should be 30 mm [9].

Bilateral orchiectomy, amputation of the corpora cavernosa, creation of the neovaginal cavity, lining of this cavity with hairless skin, reconstruction of a urethral meatus in such a way, that the direction of the urinary stream is downward in a sitting position and finally the construction of labia and clitoris have been defined as the five major steps for surgery in all recent techniques [2, 5, 10, 11, 12, 13, 14, 15].

2. OPERATIVE TECHNIQUES
Usually penoscrotal skin flaps are used for lining of the neovagina and for vulval reconstruction [2, 5, 10, 11, 12, 13, 14, 15, Figure 1]. The inverted penile skin is used as a tube and augmented by a triangle of perineoscrotal flap for construction of the posterior introitus. Modifications with the inclusion of a pedicled and opened urethral segment allows for diameter enlargement and better lubrication [14]. For patients with a short penis and/or radical circumcision the length of the inverted penile flap may be augmented by split skin or full scrotal skin after thinning and epilation [10, 16]. Intraoperative sacrospinous ligament fixation for neovaginal prolapse prevention has been proposed recently and the creation of a sensitive and well-vascularized neoclitoris has become a standard step of the procedure [17, 18]. This may be facilitated by a reduction glansplasty with preservation of the neurovascular bundle for sexual sensation which is essential [5, 6, 10, 13]. Complete resection of the corpora cavernosa and partial resection of the corpus spongiosum help to refine the vestibulum and introitus area to avoid obstruction during intercourse due to arousal induced swelling of erectile tissue [5, 10, 12, 16]. Reconstruction of the prepuce of the clitoris, of the labia minora and of a female appearing mons pubis should be performed using a variety of techniques [5,10,13,15, Figures 2,3,4]. Labia majora generally can be formed during the primary procedure from the remaining scrotal skin [ 5, 10]. Postoperatively patients have to remain in bed for 5-6 days with an intravaginal dilator in place. Regular dilation of the neovagina has to be maintained life-long at varying intervals [10].

3. POSTOPERATIVE RESULTS
From previous reports it becomes obvious that complications, readmissions and reinterventions significantly dropped after switching to newer operative techniques as described above [19]. From a comparative study by Eldh et al it can be concluded that overall 80 % of the patients were content with the surgical result and 32 of 40 patients reported satisfaction with their neovaginal volume after introducing penoscrotal flaps for skin lining [19]. This data was confirmed in another study of 66 patients, where a 75% satisfaction rate with vaginal volume was noted [16]. If the neurovascular bundle was preserved, an 80-87% clitoral orgasm rate can be achieved [5, 19, 20].

The largest follow up study of 232 patients operated on by a single surgeon showed a satisfaction rate of 94% although most patients had additional genital surgery [21]. Complications included vaginal stenosis (8%), misdirected urinary stream (33%), urethral stenosis (4%), genital pain (9%), clitoral necrosis(3%) and anorgasmia (18%). Other lower urinary tract symptoms of a degree of incontinence may occur in 19% of patients [22]. An overview of expected complications is shown in Table 2.

The new sexual experience can be expected to be improved and pleasurable in > 80% of patients with long term genital sensitivity being retained [23, 24]. These results have been confirmed in other studies with satisfaction rates of 80% [25]. Vaginal depth was considered adequate by 61%, urinary problems reported by 27 % and 48% were able to achieve orgasm.

The most recent report on the physical, mental and sexual health in 50 patients showed that transsexual operated women functioned well on a physical, emotional, psychological and social level. With respect to their sexuality, they suffered from specific difficulties, concerning arousal, lubrication and pain. These findings confirmed a previous report by the same authors that stated an overall satisfaction rate of 86% [15,26]. All results are summarized in Table 3.

III. GENITAL REASSIGNMENT SURGERY IN FEMALE- MALE TRANSSEXUAL PATIENTS

1. SURGICAL AIM
The ideal aims of phallic construction should ideally address the following requirements [27]:

1) It should involve a limited number of surgical stages
2) The formation of a competent neourethra to allow micturition in a standing position
3) It should create a phallus that has both tactile and erogenous sensibility
4) It should allow for enough bulk to tolerate the insertion of a penile prosthesis
5) It should be aesthetically acceptable to the patient
6) There should be minimal scarring and disfigurement and no functional loss in the donor area

The actual variety of free and pedicled flaps used for phalloplasty suggests that there does not yet exist one single ideal technique, which could fulfill all demands in neopenis formation, even if the radial free forearm flap seems to emerge as most widely used alternative [2,5]. There is however agreement that a complete functional neopenis formation can still not be reached in one operative session.
Patients often have different desires with regards to the type of genital surgery and the amount of morbidity from scarring that is acceptable to them. Therefore all phalloplasty techniques should be offered to the patient even if it means referral to an alternative unit. Hysterectomy, oophorectomy and vaginectomy may be performed prior to phallus formation or during one of the stages of phalloplasty depending on the surgical preference. Vaginectomy is usually done at the same time as the proximal urethral reconstruction [5].

The options available include metoidioplasty, the use of local flaps or free microvascular flaps.

Metoidioplasty is the creation of a micropenis by lengthening of the clitoris from the release of the ventral clitoral chordae, urethral advancement to the tip of the clitoris using vaginal and labial flaps and finally scrotal formation by approximation of the labia majora [28, 29, Figure 5]. Phallus length is dependent on the initial androgen clitoral enlargement and never long enough to house a penile prosthesis for sexual intercourse. Despite the high complications of urinary fistulae and strictures with revision rates up to 88%, to stand to void is often all that is desired by some patients and so this method should still be offered [5].

Flaps more suited to total phallic construction has led to the development of the use of infraumbilical skin and groin flaps [30-33]. The phallus is often wedged shaped with minimal sensation and often without a urethra. A neourethra can be fashioned from a

2. OPERATIVE TECHNIQUES

Patients often have different desires with regards to the type of genital surgery and the amount of morbidity from scarring that is acceptable to them. Therefore all phalloplasty techniques should be offered to the patient even if it means referral to an alternative unit. Hysterectomy, oophorectomy and vaginectomy may be performed prior to phallus formation or during one of the stages of phalloplasty depending on the surgical preference. Vaginectomy is usually done at the same time as the proximal urethral reconstruction [5]. The options available include metoidioplasty, the use of local flaps or free microvascular flaps.

Metoidioplasty is the creation of a micropenis by lengthening of the clitoris from the release of the ventral clitoral chordae, urethral advancement to the tip of the clitoris using vaginal and labial flaps and finally scrotal formation by approximation of the labia majora [28, 29, Figure 5]. Phallus length is dependent on the initial androgen clitoral enlargement and never long enough to house a penile prosthesis for sexual intercourse. Despite the high complications of urinary fistulae and strictures with revision rates up to 88%, to stand to void is often all that is desired by some patients and so this method should still be offered [5]. Flaps more suited to total phallic construction has led to the development of the use of infraumbilical skin and groin flaps [30-33]. The phallus is often wedged shaped with minimal sensation and often without a urethra. A neourethra can be fashioned from a
pedicled tube of labial skin in a one or two stage procedure, to allow patients to void in a standing position, although urethral complications can be as high as 70% [34]. Despite this, in a series of 85 female to male patients, a 68% patient satisfaction rate was reported with 16 patients also able to have penetrative sexual intercourse without the insertion of penile prosthesis [34, Figure 6].

Musculocutaneous thigh flaps based on the gracilis muscle have been reserved for a salvage procedure as generally the cosmetic and functional results are poor due to muscular contracture [35].

The gold standard technique for total phallic construction is with the use of free flaps first described by Chang [36]. The reconstructive procedure involved the creation of ‘a tube within a tube’ using forearm skin with the urethra fashioned from the non hair bearing area and the whole flap base on the radial artery. The arm is subsequently grafted with split or full thickness skin with a resultant morbid scarring. With the advent of microsurgical techniques, microvascular anastomoses are fashioned as well as nerve coaptation of the antebrachial nerves to the dorsal nerve of the clitoris and to the ilioinguinal nerves to form a sensate and cosmically acceptable phallus. [Figure 7]. Following the success of this series many teams have adopted this technique and applied some modifications in flap design in order to improve the cosmesis of the neophallus and to minimize the overall complication rate that may occur in up to 45% of cases. In particular the shape of the forearm flap has been modified in order to improve the blood supply to the flap and to reduce the risk of meatal stenosis [37– 40]. In a further attempt to minimize donor site morbidity, free osteocutaneous iliac flaps have been introduced with a neourethra fashioned by prelaminated tunneling of a skin graft; [41].

After urethral continuity has been confirmed and the phallus has become sensate, a penile prosthesis is then inserted to give rigidity for sexual intercourse [5]. Inflatable prostheses are generally used to minimize the risk of erosion and are often inserted in stages together with testicular prostheses. Anchorage of the prosthesis is aided by placing the rear part in a Dacron or PTFE sock that is sutured to the pubis [41, Figure 8].

3. POSTOPERATIVE RESULTS

The results of the radial forearm flap phalloplasty give excellent satisfaction rates of 80 – 85% although complication rates are high as shown in Table 4.

Due to the complex nature of the operation, possible complications are numerous and should be explained in detail to the patients. Traditionally local flaps without the need for microsurgical vascular anastomoses are less prone to complications than free flaps. From recent publications of experienced high-volume centers, it becomes obvious that the more complex the primary procedure, the more possible complications that occur, independent from the surgeon [5,34,39,40]. Partial or total skin necrosis of the phallus is not uncommon and a third of patients will have a urethral complication (Table 4).

Even if revisions for urethral problems are successful, nearly half of the patients report urinary symptoms of a reduced urinary stream, dripping or recurrent urinary infections [22].

Penile implant complications are common due to the excessive use of prosthetic material [Table 4]. In the largest series of 129 implants, a revision rate of 41% was reported at 30 months follow-up, with an erosion/infection rate of 20% [44].

Nevertheless, the vast majority of patients do not regret having undergone such complex procedures. More than 80% may reach orgasm or sexual satisfaction by stimulation or sexual intercourse, if clitoral nerves can be successfully adapted to correspondent sensory nerves of the forearm flap [5, 24, 39]. In contrast to male to female surgery, patients must be informed, that a functionally and aesthetically appealing genital reassignment can only be reached by a staged procedure, eventually followed by one or more revisions due to complications [5, 45].

• PENILE RECONSTRUCTION

I. PENILE AUGMENTATION

1. INTRODUCTION

Insufficient penile size is a source of anxiety for men who often seek augmentation using one of a variety of techniques, some used centuries ago [46]. The injection of exogenous substances into the penis or stretching with external weights has been popular in different cultures with the focus on “bigger is better” [47].

The “small penis syndrome (SPS)” may be defined as an anxiety about insufficient penile size despite the clinical examination being normal [48]. It may be part of a body dysmorphic disorder (BDD), a psychiatric condition which frequently leads to depressive episodes and social isolation, or part of a psychosis [49].

However, the attractiveness of the male genitalia has a much lower priority ranking for women than men. In one survey, 90% thought that girth was more important than length [48,50,51] and others have shown that 85 % of women are satisfied with their partners penile size compared to 55 % of men being satisfied with their length [52].

In the early 1970’s, surgical methods to lengthen the penis were by pediatric urologists [53]. The surgical principle of dividing the suspensory ligament and visual elongation of the penis by an infrapubic VY-plasty or similar regional advancement-flaps was adapted to adult men by Roos, who published a large series of 260 cases in 1994 [54].

It can be estimated that from 1990 to 1997 more than 10,000 men have undergone this or a similar procedure in the USA , the vast majority of which have a normal sized penis [55].

Due to a growing number of complications and litigation after failed penile augmentation procedures, main stream sexual medicines societies regard these procedures as “experimental surgery” without proven safety or efficacy data [56].

Due to the recently published comprehensive reviews and the growing number of innovative operative techniques in this field, the need for an evidence based systematic evaluation is essential [46, 57, 58].

2. PENILE SIZE

The measurement of penile dimensions is a basic requirement for evaluating the success-rates of penile enlargement surgery. Different study populations and measurement methods may explain the variance of the average penile size in various studies. The stretched penile length is a good guide to the potential erect length, but stretched penile girth does not reliably reflect erect girth [56, 59]. Overall, the average penile length in the flaccid state is 9-9.5 cm and depends on several situational variables. Average erect length ranges from 12.8 – 14.5 cm with an average girth of 10 -10.5 cm. Two standard deviations away from the mean equates to a micropenis being defined as that which measures < 7.5cm erect. The various studies describing normal penile dimensions are shown in Table 5 [56].

3. CONDITIONS CAUSING PENILE SHORTENING

Penile shortening may be associated with certain medical and surgical conditions, including penile cancer, penile trauma, Peyronie’s Disease, excessive skin loss, buried penis, epispadias and hypospadias and intersex disorders [56, 57, 60-62].

The general consensus is that patients suffering from these conditions are candidates for penile lengthening or other reconstructive procedures [53, 57, 58, 61].

These operations may be challenging and may demand a variety of reconstructive procedures including phalloplasties and penile prosthesis-implantation [57,61, Figure 9]. A broad spectrum of techniques has been published, mostly in small case-series or case reports [60, 62-67]. The level of evidence to support these procedures is low, however, due to the severity of these conditions, surgical relief by an experienced reconstructive surgeon using individualized surgical approaches can be recommended.

4. PENILE AUGMENTATION PROCEDURES

a) Penile lengthening procedures

The mainstay of penile lengthening procedures are a combination of release of the suspensory ligament of the penis, resection of supra- and/or infrapubic fat and penopubic skin advancement. Detachment of the suspensory ligament from the symphysis pubis allows forward movement of corpora and enables the flaccid penis to extend closer to its erect length. Reattachment and resulting penile reshortening may be prevented by filling the defect with either fat or other types of bio-compatible material (autologous vascularized fat or silicone spacers) [57]. In most studies the infrapubic incision is closed as an inverted VY-plasty [68]. Postoperative traction on the penis is recommended by most authors for several months to maintain the length gain, using penile weights, vacuum constriction devices or mechanical penile stretching systems [53, 57, 58, 68].

It should be pointed out, that the above mentioned techniques only allow an “optical” penile lengthening.
One technique of “true” penile lengthening consists of complete penile disassembly with interposition of a rip cartilage between the mobilized glans and corpora [69]. The authors performed the operation in 19 patients and reported an increase in erect and flaccid penile length of between 2 and 4 cm with a follow-up of 3 years.

The literature reports an extremely wide spectrum of success and patient satisfaction rates with penile augmentation procedures [53,57,58]. For example, Panfilow reported a mean lengthening in the flaccid state of 2.4 cm after 12 months with a satisfaction rate of 97% in 88 patients [70]. However, Li et al reported a mean increase in stretched penile length of 1.3 cm with an overall satisfaction rate of only 35% in a series of 42 patients with 16 months follow-up [68]. Long term satisfaction data are scarcely found in the literature and complications of penile lengthening procedures may be significant. Penile reshortening seems to be the major complication as well as loss of sensation, angling of the penis downward due to lack of support and hypertrophic hairbearing scarring of the penile shaft. [53,57, 71,72].

The use of penile stretching systems without previous operative penile lengthening may be an alternative in future studies. A pilot-phase II prospective study published by Gontero et al showed a mean penile flaccid length increase of 2.3 cm and erect length increase of 1.7 after 6 months of daily use of the device [73]. A previous pilot study by Levine et al. in patients with Peyronie’s disease had shown similar effects with length gain of up to 2.5 cm and curvature correction [74].

b) Penile girth enhancement techniques

Penile girth enhancement techniques are also controversial. Metallic mercury or Vaseline injections as well as allograft surgical implantation have been described with deleterious effects and complications [75-77]. Hylaroronic acid gel injections have been described for glans augmentation in a single study [78]. The injection of autologous fat was initially thought to be a promising technique but is now considered unpredictable due to irregularity and nodule formation from fat reabsorption [57]. The use of dermal fat grafts consisting of all layers of skin and the underlying subcutaneous tissue after removal of the epidermis seemed to offer more reliable results, but was accompanied by significant complications of persistent postoperative penile oedema and induration, venous congestion and possible skin injury [57, 71,72, 87]. Penile curvature due to fibrosis and penile shortening can also occur if inadequate graft take or infection occurs. Nevertheless a recent peer-reviewed paper reported a good subjective and objective outcome of the procedure in well selected patients [79].

Perovic reported the use of biodegradable scaffolds seeded with autologous fibroblasts for penile girth enhancement in 84 patients, followed-up for a median of 24 months [80]. A mean increase in flaccid girth of 3.15 cm and in erect girth of 2.47 cm was reported with 81% of patients satisfied with the result. Postoperative complications of skin necrosis or infection occurred in 10 of the 84 patients. With the recent advances in tissue-engineering, possible further applications for phallic reconstruction have been tested in animal models and might be expected to be translated into clinical use soon [81].

The technique of bilateral longitudinal incisions of the tunica albuginea with saphenous grafting to enhance girth was reported in 39 patients [83]. Penile diameter increases of 1.2 – 2.1 cm was observed without complications and complete satisfaction at 9 months follow-up. Similar results have been reported using synthetic grafts [84].

The injection of liquid silicone into the penile shaft is a highly controversial issue. Whereas FDA-approved trials of liquid injectable silicone (LIS) for soft tissue augmentation are currently being conducted in the USA, the use of any liquid silicone substance outside of a protocol should be discouraged [46]. Only the microdroplet-technique in which very small
volumes of LIS (up to 0.75 ml) is injected for soft tissue augmentation. In order to reach satisfactory results in penile girth enhancement 30 to 60 ml of LIS injection are needed with the possibility of disastrous complications [82, Figure 10].

CONCLUSIONS

From the literature it is not possible to draw evidence-based conclusions on a possible future role of penile enlargement procedures [46, 57, 58]. Most men consulting for penile augmentation have a normal sized penis and thus a surgical solution is being used to address a psychological condition [48, 55]. A well conducted recent study showed that the vast majority of patients with a normal sized penis chose not to undergo penile augmentation surgery after participating in a structured management and counseling protocol developed for this purpose [85]. Psychological assessment using validated questionnaires should always precede any surgical procedure in this group of patients [48, 86].

The current surgical techniques of penile lengthening and girth enhancement do not have proven efficacy when evaluated by objective and subjective outcome, and the complications can be significant [57]. Until reliable data is available, penile augmentation should be offered only to patients with congenital or acquired anomalies when reconstruction of the penis is required for sexual function [57]. The possible use of non surgical alternatives such as stretching devices should be assessed in future studies using validated instruments for subjective and objective evaluation.

RECOMMENDATIONS

1. Definition of Gender Identity Disorder/Transsexualism Grade A

The desire for at least 2 years, to live and be accepted as a member of the opposite sex, usually accompanied by the wish to make his or her body as congruent as possible with the preferred sex through surgery and hormone therapy.

2. Male to Female Genital Surgery Grade B

Bilateral orchiectomy, amputation of the corpora cavernosa, creation of a neovaginal cavity that is lined by hairless skin, the formation of a sensate neoclitoris and an esthesic vulval appearance are the aims of genital surgery. The outcome may be achieved in one or two stages with satisfaction rates of 80% expected.

3. Female to Male Genital Surgery Grade B

Breast reduction, oophorectomy, hysterectomy and vaginectomy should be offered to all patients. There are many phalloplasty techniques involving local or free flaps and microsurgery. Patients should be warned that multiple stages are often needed with high urethral and prosthetic complication rates. However, a universal satisfaction rate of 80% should be expected. Metoidioplasty can be offered to those who wish to stand to void but do not want sexual intercourse.

4. Recommendations For Penile Augmentation

– Indications Grade D

A stretched penile length of < 7cm should be considered as a micropenis with many surgical techniques being recommended. The indications for augmentation in men with a normal sized penis cannot be drawn from the literature.

– Surgical Techniques Grade D

Figure 9. Before and after forearm flap phalloplasty for extrophy penis.

Figure 10. A 26 year old patient two years after liquid silicone injection into the penile shaft: massive granuloma formation.

Figure 10.
● There are many lengthening techniques described with variable success rates
● The complications may be significant
● Stretching devices may be an alternative treatment option
● All operative methods of girth enhancement have no proven efficacy outcome data
● Liquid silicone injection should be discouraged
● Psychological assessment should proceed any surgical approach

I. INTRODUCTION

Ejaculatory dysfunction is one of the most common male sexual disorders. The spectrum of ejaculatory dysfunction extends from premature ejaculation, through delayed ejaculation to a complete inability to ejaculate (known as anejaculation), and includes retrograde ejaculation.

The sexual response cycle can usefully be conceptualized as having four interactive stages: desire, arousal, orgasm, and resolution. Within the sexual response cycle, orgasm/ejaculation in men is both a biological (reproductive) and psychological (reward) endpoint. Arousability and arousal—distinct but interrelated constructs—are precursors to this endpoint. Arousability and/or sexual libido are psychological constructs used to explain variability in the intensity and/or desire for a sexual response. Arousability might best be conceptualized as the organism’s readiness to respond. This state of readiness depends on both internal (hormonally “primed” diencephalic brain structures) and external (appropriate partner and situation) stimulus conditions. Sexual arousal or excitement—the organism’s actual response to the stimulus conditions—represents both a subjective/cerebral state of sympathetic activation and peripheral physiological responses (e.g., erection) that prepare the man for sexual activity. During sexual activity, increasing levels of sexual arousal reach a threshold that triggers the ejaculatory response, which then typically terminates the sexual episode for the male. The subjective (brain) perception of urethral distension and bladder neck closure of the emission phase of ejaculation is associated with the sensation experienced as “ejaculatory inevitability.” The perception of the striated muscle contractions and resulting semen expelled during ejaculation, mediated through sensory neurons in the pelvic region, gives rise to the experience of orgasm, a distinct cortical event, experienced phenomenologically both cognitively and emotionally.

Sexual dysfunction may involve disruption of any of the above phases [1]. This four-stage model is consistent with the overall paradigm shift within urology, where both organic and psychogenic factors are recognized and integrated into our understanding of sexual function and dysfunction. Conceptualizing four stages provides a better heuristic platform for understanding ejaculatory dysfunctions as secondary to disruptions of any stage in the ejaculatory process, leading to appropriate and specific treatments [2].

Specific to ejaculation and orgasm, the latency to ejaculation, that is, the time (and more importantly, the amount of stimulation) extending from the onset of penile stimulation to the moment of ejaculation, represents a continuum of time that shows variation across men and, within men, across situations. Although the great majority of men appear to reach ejaculation and orgasm following several minutes of penile vaginal stimulation and are, along with their partners, quite satisfied with the latency of their ejaculatory response, others report dissatisfaction. For example, some men ejaculate very rapidly after, or sometimes even prior to, penetration and do so with minimal stimulation. Others may ejaculate only with great difficulty or not at all, even following prolonged stimulation. These conditions, as noted above, represent subsets—at opposite ends of the spectrum—that fall into the categories of male ejaculatory disorders.
II. THE ANATOMY AND PHYSIOLOGY OF THE EJACULATORY RESPONSE

The anatomy and physiology of ejaculation is still not clearly understood. The ejaculatory reflex comprises sensory receptors and areas, afferent pathways, cerebral sensory areas, cerebral motor centres, spinal motor centres and efferent pathways. Neurochemically, this reflex involves a complex interplay between central serotonergic and dopaminergic neurons, with secondary involvement of cholinergic, adrenergic, oxytocinergic and gamma aminobutyric acid (GABA)ergic neurons.

The ejaculatory process integrates actions that occur in the central (CNS) and peripheral nervous systems (PNS). Structures in the CNS that are involved in ejaculation include the medial preoptic area (MPOA), nucleus paragigantocellularis (nPGi), posteromedial bed nucleus of the stria terminalis, posterodorsal medial amygdale, and the medial parvicellular subparafascicular nucleus of the thalamus. While the MPOA is involved in stimulation of ejaculatory response, the nPGi has an inhibitory influence: specifically, descending serotonergic pathways from the nPGi to the lumbosacral motor nuclei inhibit ejaculation. The MPOA can inhibit the nPGi which in turn results in ejaculation [3]. Several brain areas are activated after ejaculation by ascending fibers from the spinal cord and may have a possible role in satiety and the post-ejaculatory refractory time [4].

Based upon functional, central and peripheral mediation, the ejaculatory process is typically subdivided into three phases: emission, ejection (or penile expulsion), and orgasm. (Table 1) Emission consists of contractions of seminal vesicles (SV) and the prostate, with expulsion of sperm and seminal fluid into the posterior urethra, and is mediated by sympathetic nerves (T10 to L2). Ejection is mediated by somatic nerves (S2 to S4), and involves pulsatile contractions of the bulbocavernousus and pelvic floor muscles together with relaxation of the external urinary sphincter. Ejection also involves a sympathetic spinal cord reflex upon which there is limited voluntary control. The bladder neck closes to prevent retrograde flow; the bulbocavernous, bulbospongiosus and other pelvic floor muscles contract rhythmically, and the external urinary sphincter relaxes. Intermittent contraction of the urethral sphincter prevents retrograde flow into the proximal urethra [5].

Orgasm is the result of cerebral processing of pudendal nerve sensory stimuli resulting from increased pressure in the posterior urethra, sensory stimuli arising from the verumontanum and contraction of the urethral bulb and accessory sexual organs.

1. THE EJACULATE

The ejaculate can be divided into several fractions by serial biochemical analysis [6]. It comprises secretions from the seminal vesicles, and prostate and bulb-urethral (Cowper’s) glands, as well as spermatozoa. It is produced when the combined secretions of the prostate and the contents of the ampullary parts of the vasa deferentia are washed out by fluid from the seminal vesicles and expelled from the urethra [7]. The spermatozoa are stored in the tails of the epididymides and the vas deferens ampullae. Approximately 50-80% of the entire ejaculatory volume is contributed by the seminal vesicles, 15-30% by the prostate gland, and a small portion from the bulbo urethral (Cowper’s) glands which are rich in enzymes and plasminogen activator [8]. Spermatozoa normally constitute less than 0.1% of the ejaculatory volume. The first fraction of the ejaculate contains the maximum number of spermatozoa, and subsequent fractions contain sequentially less. Acid phosphatase, citric acid and zinc that emanate from the prostate are also in highest concentration in the initial fractions of the ejaculate.

Table 1: The three stages of normal antegrade ejaculation

| Emission | Sympathetic spinal cord reflex (T10–L2)  
Genital and/or cerebral erotic stimuli with considerable voluntary control  
Peristaltic contraction of epididymis and vas deferens  
Contraction of seminal vesicles and prostate  
Expulsion of spermatozoa/seminal/prostatic fluid into posterior urethra  
Ejaculatory inevitability sensation resulting from distension of posterior urethra |
|---|---|
| Ejection | Parasympathetic spinal cord reflex (S2–S4)  
Limited voluntary control  
Rhythmic contractions of bulbocavernous/pelvic floor muscles  
Bladder neck closure  
Relaxation of external urinary sphincter |
| Orgasm | Build-up and release of pressure in posterior urethra  
Smooth muscle contraction of accessory sexual organs and urethral bulb  
Sensation due to cerebral processing of pudendal nerve sensory stimuli |
Subsequent fractions contain fructose from the seminal vesicles, which increases in concentration towards the end of the ejaculatory process. The pH of the ejaculate increases in successive fractions as the acid component provided by the prostate is serially mixed with the more alkaline contribution of the fructose rich fluid from the seminal vesicles.

2. NEUROLOGICAL CONTROL OF EJACULATION AND ORGASM

The ejaculatory reflex, including its sensory and motor pathways, and spinal and cerebral areas, is shown in Figure 1 and 2 (Figure 1,2) [9, 10].

a) Sensory receptors and areas

The mucosa of the glans penis contains specialized sensory receptors, the Krause Finger corpuscles. These receptors discharge along afferent nerves to the spinal cord and brain when repetitive and cumulative stimulation applied to the glans penis exceeds the excitation threshold. Sensory information from the penile shaft, perineum, testes and variable extra genital erotogenic organs (e.g. nipples, anal sphincter) modulates—usually enhancing—afferent information from the Krause Finger corpuscles.

b) Afferent pathways

Sensory information from the glans penis travels along afferent pathways to the spinal cord. Sensory fibers of the pudendal nerve that are contained within the dorsal nerve of the penis extend to the S4 level, and autonomic fibers within the hypogastric plexus transmit information to the sympathetic ganglia located along the spinal cord.

c) Cerebral control of ejaculation and orgasm

Seminal emission and ejaculation are controlled centrally by the paraventricular nucleus of the anterior hypothalamus (PVN) and the MPOA (Figure 1) [11].

The MPOA is located rostral to the anterior hypothalamus and appears to have a pivotal role in augmenting copulatory behavior. Electrical stimulation of the MPOA can elicit seminal emission or ejaculation in monkeys and rats [12]. Electrical stimulation of the MPOA also elicits the urethrogenital reflex in rats, which may mimic orgasm in humans [10, 13]. This response occurs in the absence of genital stimulation and is usually elicited in anesthetized, spinal-transected rats by distending the urethra with saline and then suddenly releasing the pressure. This release results in rhythmic firing of the hypogastric, pelvic, and motor pudendal nerves and rhythmic contractions of the perineal muscles, similar to those seen during orgasm in humans.

Microinjection of moderate doses of a mixed D1/D2 dopamine agonist (apomorphine), or of a pure D1 agonist (thienopyridene), into the MPOA promotes erections and copulation of male rats, apparently by increasing parasympathetic tone [14, 15]. Higher doses of a mixed D1/D2 agonist, or of a selective D2 agonist, favor seminal emission and ejaculation [13]. Reduced libido during the ejaculatory refractory period may result from decreased dopamine release in the nucleus accumbens, a major terminal of the mesolimbic dopamine tract [16]. Dopamine is released in the MPOA of male rats in the presence of an estrous female and increases during copulation [17]. The levels of extracellular dopamine in the MPOA may regulate the phases of copulation, with high levels triggering ejaculation.

Figure 1: Emission and ejaculation are centrally integrated and highly co-ordinated processes. The brain structures involved in the control of ejaculation include the thalamus, structures in the hypothalamus such as the medial preoptic area (MPOA) and the paraventricular thalamic nucleus (PVN), structures in the midbrain such as the periaqueductal grey nucleus (PAG) and structures in the pons such as the paragigantocellular nucleus (nPGi). These structures integrate sensory ejaculation-related inputs from the genital areas with higher excitatory and inhibitory controls.
In a series of sophisticated rat experiments involving selective pharmacologic and/or radiofrequency lesions, Liu et al demonstrated that the parvocellular neurons of the hypothalamic PVN mediate erectile function in rats, whereas the magnocellular PVN neurons mediate ejaculation [18]. Oxytocinergic PVN neurons possibly modulate the male sexual response, as evidenced by increased cerebrospinal fluid concentrations of oxytocin after ejaculation, augmented male sexual behavior following intraventricular administration of oxytocin, and decreased seminal emission in rats with lesions of the parvocellular PVN neurons. The MPOA is also important to the cholinergic influence on sexual behavior. Injections of the cholinergic agonists oxotremorine and carbachol stimulate sexual behavior in male rats as demonstrated by a reduced number of intromissions preceding ejaculation, whereas injection of scopolamine reduces the number of animals intromitting and ejaculating [19]. The paragigantocellular (nPGi) reticular nucleus in the ventral medulla is a supraspinal locus of descending inhibitory influence on spinal nuclei mediating ejaculatory reflexes in the male rat [20], and approximately 78% of the descending neurons from nPGi are serotonergic [21]. Lesions of the nPGi facilitate both the elicitation of the urethrogenital reflex and reflexive penile erections [22]. Selective serotonin neurotoxin lesions of the nPGi or transection of the spinal cord release the urethrogenital reflex from tonic inhibition, allowing the reflex to be elicited by urethral distension. However, stimulation of the MPOA can elicit the reflex, even if the nPGi and spinal cord are intact, suggesting that the MPOA may inhibit the nPGi as well as stimulate an excitatory site.

d) Spinal motor centers

It has been known for many years that men with complete transaction of the thoracic spinal cord are often able to ejaculate with appropriate peripheral stimulation. Therefore, the fact that ejaculation can occur in the absence of neuronal input from the brain indicates an independently functional reflex arc of the spinal cord, which mediates the ejaculatory reflex and is located distal to the thoracic spine. A spinal center, located at the Th12 L1-L2 spinal level, is controlled by the sympathetic nervous system and is responsible for emission (Figure 2,3). A second center, located at the S2-S4 level, is controlled by the somatic nervous system and is responsible for expulsion. The position of the lumbar spine between the brain and peripheral nerves allows this area to be the center for the integration of afferent and efferent neuronal information. Since the lumbar and sacral portions of the spinal cord are known to be critical in the regulation of other pelvic organ processes, it is possible that this area also regulates ejaculation [23]. The existence of a lumbar spinal ejaculation pattern generator (EPG) was proposed in 1991 [24]. Further investigation by retrograde axonal tracing studies confirmed that neuronal fibers from the lumbar spinal cord innervate the bulbospongious muscle and the prostate [25], and that the relevant neuronal cell bodies are located in the L3-L4 segment of the spine [26]. It has also been demonstrated that these specific lumbar neurons are activated with ejaculation but not with other components of sexual response in rats [27]. This finding was supported by the earlier study’s results demonstrating that injury to the lumbar spine at this segment level in rats specifically interrupts ejaculation [28].

The lumbar spinothalamic neurons (LSt) have axonal connections to the thalamus [29]. They have efferent projections to pudendal somatic motor neurons as well as to sympathetic and parasympathetic preganglionic neurons [28], and are adjacent to neurons modulating afferent sensory input from the penis via the pudendal nerve. Recently published results may indicate the precise localization of a lumbar spinal center critical to both the initiation and maintenance of ejaculation [25, 30]. Specifically, stimulation of the LSt neurons leads to ejaculation of semen in anesthetized rats and to ejaculation of motile spermatozoa in rats. Also found were marked increases in vas deferens (VD) and spermatic vesicle (SV) pressure, constantly followed by increased electrical activity of the bulbospongious muscle in all animals treated with stimulation of the LSt neurons. These effects were maintained despite T10 spinal transaction, injury to the hypogastric and pelvic nerves, and transaction of the dorsal penile nerves. In contrast, direct injection of a GABA agonist into the LSt neurons prior to electrical stimulation prevented the increase in VD and SV pressure and electrical activity of the bulbospongious muscle. Application of the same GABA agonist immediately after LSt stimulation blunted bulbospongious electrical activity. Such results provide strong evidence that LSt neurons with cell bodies located in the L4 spinal segment represent an essential anatomical component in the regulation of ejaculation [23].

e) Efferent pathways

The efferent pathways mediate the ejaculatory motor responses of emission and ejection (expulsion).

1) EMISSION

Emission is controlled by the sympathetic nervous system. The cell bodies of the sympathetic neurons are located in the lateral columns of the gray matter in the thoracolumbar segments of the spinal cord. Efferent sympathetic nerves emerge from the ventral roots of the spinal column at Th12-L2 to reach the sympathetic chains bilaterally (Figure 2). The nerves proceed via the thoracic sympathetic chain to the caudal (inferior) enteric plexus, the major/minor splanchnic nerves, the celiac/cranial mesenteric plexuses, and the intermesenteric nerves. Descending nerves from these ganglia
Figure 2. Central control of ejaculation is mediated via spinal ejaculation centres including lumbar spinothalamic (LSt) cells which integrate peripheral signals from the genital areas with excitatory and inhibitory control from supraspinal centres such as the nucleus paragigantocellularis (nPGi). The spinal ejaculation generators send co-ordinated outputs to the anatomic structures that allow ejaculation to occur.

Figure 3. The spinal ejaculation generator (LSt cells) controls the prostate and the bulbospongiosus (BS) muscle. The spinal ejaculation generator projects to the parasympathetic (L5–S1) and sympathetic (T13–L2) preganglionic neurons, and DM motoneurons (L5–L6). The parasympathetic centres project to the prostate via the major pelvic ganglion (MPG) and the pelvic nerve (PN). The sympathetic centres project to the prostate through the intermesenteric ganglion (IMG) and the hypogastric nerve (HN). The motoneurons of the BS muscle project to the muscle through the motor branch of the pudendal nerve. (BS: bulbospongiosus; DM: dorsomedial nucleus; HN: hypogastric nerve; IMG: intermesenteric ganglion; L: lumbar segment of spinal cord; LSt: lumbar spinothalamic; MPG: major pelvic ganglion; PN: pelvic nerve; T: thoracic segment of spinal cord; VH: ventral horn)
encircle the aorta on each side before joining in
the midline to form the hypogastric plexus just
below the bifurcation of the aorta. The nerves
proceed via the lumbar sympathetic chain and the
lumbar splanchnic nerves to the caudal mesenteric
plexus. The intermesenteric nerves and all lumbar
splanchnic nerves merge into the inferior mesenteric
and superior hypogastric plexuses. The caudal
mesenteric plexus mainly innervates the colon via
the colonic nerve from which paired hypogastric
nerves arise. The junction of the hypogastric nerve
and the pelvic nerve constitutes the pelvic plexus in
the pelvis, which is an integration of sympathetic and
parasympathetic nervous systems. The branches
from this plexus innervate the epididymis, vas
deferens, seminal vesicle, prostate, bladder neck
and urethra (Figure 2) [31].

Norepinephrine is released from the axon terminal
of the postganglionic neurons of the seminal tract
in response to sympathetic signals passing through
the hypogastric nerves. Norepinephrine activates
smooth muscle alpha, adrenergic receptors,
causing a rise in intracellular calcium, actin myosin
interaction, vas deferens smooth muscle contraction,
a marked elevation of intraluminal pressure in the
caudal epididymis/proximal vas, and propulsion of
spermatozoa out to the ampulla. This ampullary wall
distension and nerve signals trigger contraction of
the ampulla to emit the content into the posterior
urethra. Many substances, including acetylcholine
and neuropeptide Y, might modulate neurotransmitter
release and/or the resting tone of the smooth muscle
of the vas deferens. Both nerve signal and distention
of the wall of the ampulla might trigger contraction
of the ampulla to emit the content into the posterior
urethra. Retrograde axonal tracing methods have
demonstrated that the majority of post-ganglionic
neurons distributed in the vas deferens originate from
the pelvic plexus [32]. The pelvic plexus receives
neural input from both the hypogastric and pelvic
nerves. Electrical stimulation of the hypogastric
the pelvic plexus elicits contraction of the vas deferens, while
stimulation of the pelvic nerve causes no detectable
motor responses [33]. Histochemical studies of the
vas deferens have also shown that the adrenergic
fibers mainly innervate the smooth muscle layers,
whereas cholineric fibers chiefly innervate the
subepithelial layer [34].

Almost all the lumbar splanchnic nerves originate
from L2 and/or L3 lumbar sympathetic ganglia (cor-
responding to L1-2 spinal levels) [34]. Preservation
of the L2 and/or L3 lumbar splanchnic nerve in retro-
peritoneal lymph node dissection of testicular cancer
allows preservation of ejaculatory function [35]. Par-
tial interruption of the pathway from the spinal cord
to the seminal tract would be expected to cause ins-
sufficient closure of the bladder neck and retrograde
ejaculation. Complete interruption of the pathway is
likely to cause failure of emission.

The anatomical architecture of the peripheral sym-
pathetic nervous system suggests probable cross-
innervation and has been confirmed in the dog and
rat [36]. Some signals in the lumbar splanchnic nerve
cross to the other side of the body at the level of the
caudal mesenteric plexus and/or the pelvic plexus.
Preganglionic axons in the hypogastric nerve prob-
ably provide a bilateral innervation to postganglionic
neurons in the pelvic plexuses, which also exhibit
crossing to the bilateral vasa deferentia [36].

The pudendal nerve arises from the S2-4 segments
of the sacral spinal cord and does not enter the pel-
vic plexus, but exits the pelvis through the greater
sciatic foramen, re-enters it through the lesser sci-
atic foramen, and innervates the perineal striated
muscles (Figure 2). Rhythmic contractions of these
perineal striated musculatures, including the bulboc-
cavernosus and ischiocavernosus muscles, propel
the seminal fluid. Sacral spinal cord injury patients
usually show dribbling ejaculation due to the lack of
contribution of the musculature.

2) EJECTION/EXPULSION

Ejection is controlled by the parasympathetic nervous
system. Efferent somatic fibers emerge from the an-
terior horn of the S2-S4 spinal segments (Onuf's nu-
cleus) and travel in the motor branch of the pudendal
to innervate the striated muscles of the pelvic
floor, including the bulbospongiosus and bulbocaver-
nosus muscles. Rhythmic contractions of the bulboc-
cavernosus, ischiocavernosus, and other pelvic floor
striated muscles propel seminal fluid into the ure-
thra. These muscles are innervated by the pudendal
nerve and show excitement during ejaculation. Shaik
measured the electromyographic (EMG) response of
the bulbocavernosus, ischiocavernosus muscles and
the external urethral sphincter during ejaculation
induced by glans penis vibration and demonstrated
that the ejaculatory mechanism consists of two dis-

tinct reflexes [37]. One is the glans vasal reflex which
is responsible for the emission phase, and the other
is the urethromuscular reflex which is responsible for
the ejection phases of ejaculation. In another study
in dogs, Shaik reported increased electrical activ-
ity of the pelvic floor muscles and the external anal
sphincter (EAS) and the urethral sphincter (EUS)
during electroejaculation [38]. He suggested that
the increased puborectalis muscle activity might
express the prostatic secretions into the posterior
urethra, that the levator ani contraction elevates the
prostate and partially straightens the prostatic mem-
branous urethral kink that might occur during erec-
tion, and that the EAS and EUS contractions are
believed to abort the urge to defecate or urinate and
prevent leak of feces, flatus, or urine during coitus.
The rhythmic EUS contraction at ejaculation might act
as a “suction ejection pump,” drawing the geni-
tal fluid into the posterior urethra while relaxed and
jecting it into the bulbous urethra upon contraction.
3. NEUROCHEMICAL CONTROL OF EJACULATION

Many neurotransmitters are involved in the control of ejaculation, including dopamine, norepinephrine, serotonin, acetylcholine, oxytocin, GABA and nitric oxide (NO) [4]. Of the many studies conducted to investigate the role of the brain in the development and mediation of sexuality, dopamine and serotonin have emerged as essential neurochemical factors.

a) Dopaminergic control

It has long been known that treatment with dopaminergic drugs has a significant effect on the sexual behavior of rodents. Kimura et al attributed the dopaminergic system, particularly that in the anterior hypothalamus, with a sexual facilitatory role [39]. Five types of dopaminergic receptors have been identified. On a pharmacological basis, these subtypes have been divided into two families, D1 and D2. A possible sexual response regulatory role of dopamine is suggested by the observation that dopamine is released in the MPOA of male rats in the presence of an estrous female, and progressively increases during copulation, eventually triggering ejaculation [16].

b) Serotonergic control

Whereas dopamine promotes seminal emission/ejaculation via D2 receptors, serotonin is inhibitory.

The development of antibodies against 5-HT and autoradiographic techniques have enabled identification of detailed 5-HT receptor locations [40]. Currently, at least 16 different receptors have been characterized, e.g., 5 HT1a, 5 HT1b, 5 HT2a, 5 HT2b, etc. [41]. Although the function and localization of many of these receptors are becoming increasingly clear, much remains unknown.

Serotonergic neurons are widely distributed in the brain and spinal cord and are predominantly found in the brainstem, raphe nuclei, and the reticular formation.

Serotonergic neurons use a variety of different mechanisms to self-regulate their own activity. Synaptic cleft 5 HT and 5-HT neurotransmission are regulated by somatodendritic 5 HT1A autoreceptors, presynaptic 5 HT1B 1D autoreceptors, and a 5 HT transporters re-uptake system (Figure 4). Large numbers of 5 HT transporters (5-HTT) are located predominantly on axonal terminals but are also found on the serotonergic cell bodies and their dendrites and glial cells. As 5-HT is released into the synaptic cleft from presynaptic axonal vesicles, 5 HT transporters re-uptake and remove 5 HT from the synaptic cleft, preventing overstimulation of the postsynaptic receptors. After blockage of 5 HT transporters by selective serotonin reuptake inhibitor class drugs (SSRIs), synaptic cleft

Figure 4. Synaptic cleft 5-HT and 5-HT neurotransmission are regulated by somatodendritic 5-HT1a autoreceptors, presynaptic 5-HT1B 1D autoreceptors and a 5-HT transporters re-uptake system.
5-HT increases but is counteracted by activation of 5-HT1A autoreceptors which inhibit further 5-HT release. Activation of 5-HT1A receptors is attenuated or blocked by activation of 5-HT2C receptors. It has been shown that 5-HT2C and 5-HT1A receptors play important roles in the speed and ease of ejaculation. Stimulation of the 5-HT2C receptor with 5-HT2C agonists results in delay of ejaculation in male rats, whereas stimulation of post-synaptic 5-HT1A receptors results in shortening of ejaculation latency [42]. Waldinger et al suggested the hypothesis that men with premature ejaculation (PE) may have hyposensitivity of 5-HT2C and/or hypersensitivity of the 5-HT1A receptor [3, 43].

4. SIDE EFFECTS OF SPECIFIC DRUGS ON EJACULATION

a) Evidence based primarily on animal studies

Dopamine. The centrally acting neurotransmitter dopamine is known for its involvement in control of male rat sexual behavior. Taking the parameters of mount and intromission frequencies and latency to ejaculation as measures of copulatory activity, most reports indicate that dopamine has a stimulatory effect on ejaculation that is exerted via D2 receptors. Enhancement of the ejaculatory behavior and the decrease in intromission frequency stimulated some authors to call this altered behaviour a rat model for “early ejaculation”. Some dopamine (DA) receptor agonists, such as apomorphine, N-n-propyl-norapomorphine, lisuride and 3-(3-hydroxyphenyl)-N-n-propyl-piperidine (3-PPP) may cause ejaculation in male rats with receptive females sooner and after fewer penile intromissions than controls. The doses of DA agonists needed to produce “early ejaculation” in male rats are within the low dose range needed to stimulate DA autoreceptors. In this manner, it is suggested that this phenomenon in rats results from inhibition of DA neurotransmission [44].

Morphine. Several studies have shown that systemic and central administration of morphine inhibits male rat sexual behavior. It is suggested that the inhibitory effects of morphine may be mediated by the kappa receptor [45]. However, in one study, a small proportion of male rats reacted differently on a low dose of systemic morphine: there was a decrease of ejaculation latency, and in the number of intromissions prior to ejaculation [45]. In another recent study, morphine had marginal effects on sexual motivation in general, but reduced ambulatory activity in male rats. In this study, neither dopamine nor opioids seemed to be important for sexual incentive motivation [46]. These conflicting results indicate that enkephalines may have only a modulating role on sexual behavior in the rat.

Ecstasy. The amphetamine analog MDMA, better known as the recreational drug ecstasy, is known and feared for its neurotoxic properties. It reduces brain concentrations of serotonin by inhibition of the metabolism and by long lasting degeneration of 5-HT nerve terminals, as well as by decreasing the number of 5-HT uptake sites. In an experiment with male rats, Dornan and collaborators found that a chronic administration of MDMA caused fewer rats to display mounting behavior, and an increase in ejaculation latency in the responders [47]. These results are conflicting with the above described studies with serotonin receptor agonists and antagonists, because a decrease in central 5-HT would cause an increase in male rats’ sexual behaviors. Probably, since MDMA has such dramatic effects in the brain, other factors may have played an important role in this experiment.

GABA. The neurotransmitter gamma aminobutric acid (GABA) occurs in the brain tissue. Two distinct types of GABA receptors are recognized: GABAa and GABAb. There is some evidence that the GABAb receptor agonists (like baclofen) inhibit sexual behavior in male rats, independently from the effects on motor systems. But in other study, baclofen was ineffective in reduce sexual behavior in male rats while muscimol (a GABAa receptor agonist) when given into the paraventricular nucleus of the hypothalamus reduce dose-dependently male rats sexual behavior [48].

Yohimbine. The alpha2 adrenoceptor blocking agent yohimbine has been known for its aphrodisiac properties in rats and humans. In male rat studies, it increased mounting behavior without the need for physiological levels of serum testosterone. When looking at the effects on ejaculation, a decrease in ejaculation latency, intercopulatory interval, and post ejaculatory interval is found. Others alpha2- adrenoceptor antagonists, such Rauwolscine and Idazoxan also have stimulatory effects on ejaculatory function in animal models [49].

b) Specific drug effects in human studies

Monoamine oxidase inhibitors. The monoamine oxidase inhibitors (MAOIs) are mainly used in the treatment of neurotic or atypical depression. These drugs increase the levels of epinephrine, norepinephrine, dopamine, and serotonin. The MAOIs have been known for their sexual side effects, with an incidence up to 20-40%. Delayed or inhibited ejaculation is reported for isocarbazid, phenelzine and tranylcypromine.

Cyproheptadine. Cyproheptadine is an antihistaminic, formerly used in Cushing’s disease and anorexia nervosa. It also increases serotonin levels in the brain. Several reports indicate that cyproheptadine is able to convert drug induced orgasmic failure in both men and women.

Benzodiazepines. A number of benzodiazepines effective in treating generalized anxiety and panic attacks are also known to inhibit ejaculation in some
men, presumably by enhancing gamma-aminobutyric acid (GABA). These drugs include diazepam, lorazepam, flunitrazepam, flurazepam, nitrazepam, chlordiazepoxide, and alprazolam. However the effect on ejaculation is not so intensive as that other psychotropics such SSRIs. Less than 10% of men experience an inhibition of ejaculation with these anxiolytic drugs [50].

Stimulants. Amphetamine is a stimulating drug with affinity for different receptors in the central nervous system. It stimulates release of dopamine, inhibits monoamine oxidase and blocks the reuptake of both catecholamines and serotonin. In male rats, methamphetamine inhibits intromittent and ejaculating behavior [51]. It is reported to delay ejaculation in subjects without ejaculatory dysfunction. Cocaine is an addictive “recreational” drug and stimulates the central nervous system through blocking of monoamine transporters. Different reports confirm that delayed ejaculation appears to be the most common sexual side effect.

Dopamine antagonists. Dopamine antagonists block central dopamine receptors and are clinically used as antipsychotics or neuroleptics. Ejaculation may be prevented by centrally acting dopamine receptor blockers such as pimozide, sulpiride and haloperidol [44, 52]. Thioridazine and chlorpromazine delay ejaculation but also block adrenergic receptors [53]. Atypical neuroleptics such as risperidone and clozapine, that block dopamine and serotonin receptors have been reported to delay ejaculation.

Alpha 1-blocking agents. Potent alpha-adrenergic blocker agents such as phenoxybenzamine hydrochloride, alphuzosine and terazosine suppress ejaculation by inhibition of the sympathetic nervous activation of the ejaculatory reflex [54-57].

Nitric Oxide Donors. NO-donors such as sodium nitroprusside, S-nitroso-glutathione, S-nitroso-N-acetylcysteine, S-nitroso-N acetylcysteine-ethylester and linsidomine have been demonstrated to reduce adrenergic tension in isolated human seminal vesicle strip preparations. A potential role for these agents in the treatment of early ejaculation exists [58].

Antidepressants. Selective Serotonin Reuptake Inhibitors class antidepressants (SSRI) increase synaptic cleft 5-HT levels delay ejaculation probably by action on 5-HT2 and 5-HT3 receptors. The antidepressants nefazodone (5-HT2 antagonist) and mirtazapine (5-HT2 and 5-HT3 antagonist) antagonize these receptors and produce no clinically significant ejaculatory delay [59]. Tricyclic class antidepressants inhibit ejaculation in a dose dependent manner due to their anticholinergic and alpha-adrenergic antagonistic properties [60].

The influences of different drugs on ejaculation are delineated in Table 2.

5. SUMMARY

In summary, despite the significant progress in understanding the anatomy and physiology of ejaculation, our knowledge of the anatomy and physiology of ejaculatory disorders, including premature, inhibited (or delayed), and painful ejaculation, remains incomplete. Many critical central, peripheral and other mechanisms yet require clarification, and further animal and human basic and clinical investigations are warranted.

III. PREMATURE EJACULATION: DEFINITION, EPIDEMIOLOGY, & PATHOPHYSIOLOGY

1. DEFINITION AND CLASSIFICATION

a) Traditional definitions

Both DSM-IV-R and ICD-10 provide definitions of premature ejaculation. Specifically, DSM-IV-R [61] defines premature ejaculation as “the persistent or recurrent ejaculation with minimal stimulus before, on, or shortly after penetration and before the person wishes it. The clinician must take into account factors that affect duration of the excitement phase, such as age, novelty of the sexual partner or situation, and recent frequency of sexual activity. The disturbance causes marked distress or interpersonal difficulty. The early ejaculation is not due exclusively to the direct effects of a substance (e.g., withdrawal from opioids).”

ICD-10 [62] indicates “the general criteria for sexual dysfunction must be met. There is an inability to delay ejaculation sufficiently to enjoy lovemaking, manifest as either of the following. Occurrence of ejaculation before or very soon after the beginning of intercourse (if a time limit is required: before or within 15 seconds of the beginning of intercourse); ejaculation occurs in the absence of sufficient erection to make intercourse possible. The problem is not the result of prolonged absence from sexual activity.”

These two sources provide similar though not identical conceptual frameworks for classifying an individual as having premature ejaculation. Included in both is reference to three general criteria: short ejaculatory latency, concomitant distress or a lack of sexual satisfaction, and a lack of self-efficacy regarding the condition. This last component is noted as “ejaculation before the person wishes” in DSM IV-R, and the “inability to delay ejaculation sufficiently to enjoy lovemaking...” in ICD-10.

b) Operationalizing the criteria

Each of the three criteria above has been operationalized, although not always with consistency [63]. The first criterion – short ejaculatory latency – is

</table>
typically operationalized by intravaginal ejaculatory latency time (IELT), defined by the number of seconds/minutes between vaginal intromission and ejaculation. ICD-10 indicates that latencies of 15 sec or less are consistent with a PE diagnosis but provided no evidence for this cut-off point. In both a stopwatch study and a self-reported IELT study in an unselected cohort of men with lifelong PE, 90% of men ejaculated within 60 seconds, and about 10% within 1 to 2 minutes after vaginal penetration [64, 65]. In two studies in unselected cohorts of men in the general male population of five countries (Netherlands, UK, Spain, Turkey and the USA), the IELT, measured with a stopwatch and a blinded timer device, showed skewed distributions, with median values of 5.4 min (range: 0.55 to 44.1 min) and 6.0 min respectively (range: 0.1 to 52.1 min) [66, 67]. Using values beneath 0.5 and 2.5 percentiles as statistical standards of abnormality, both studies showed that IELT values under 60 seconds were indeed abnormal in the cohort of the general male population.

In recent years, there has been a debate whether latencies should be exactly timed (e.g., using chronometers of some sort) or whether estimations by the man and/or his partner are sufficiently accurate to quantify this short ejaculation criterion. Currently, it seems that the use of a stopwatch is the most objective and accurate instrument to measure the ejaculation time. Interestingly, the use of a blinded timer device in male volunteers of the general population provided a similar IELT distribution as in men of the same countries who used a stopwatch [67]. However, this study also showed that in these men self-perceived IELT highly differed from stopwatch measured IELT [67]. This result contrasts with the outcome of two studies in men with lifelong PE that showed that the majority of men were quite accurate in estimating their ejaculatory latencies [64, 65]. Therefore, it may be concluded that the stopwatch method is in general an accurate way to measure the IELT, may offer greater precision and less bias, and might best be used in epidemiological studies of the IELT in the general male population. On the other hand, both stopwatch and self-perceived IELT measurement are adequate tools to measure IELT in cohorts of men with lifelong PE. However, self-perceived IELT assessment may lead to less accurate values in men with IELTs greater than 1 minute.

Mere temporal latency—that is, penile time spent intravaginally—does not capture a relevant defining characteristic of PE, namely “ejaculation with minimal stimulation” (DSM-IV-TR). As a result, the “number of penile thrusts” to ejaculation probably represents a more valid assessment of the amount of penile stimulation. However, IELT is generally considered the more reliable measure and is, within the larger population of men, correlated with the number of penile thrusts [68]. The second criterion—self-efficacy, or the patient’s ability to control the dysfunctional condition—distinguishes men who ejaculate rapidly because they are incapable of prolonging their latency from those who do so for any number of other reasons, including ones related to the situation or the partner. In recent research, self-ratings of “control over ejaculation” have been used successfully as a self-efficacy measure that differentiates PE men from sexually functional men [69-71]. Men with PE rate their ejaculatory control around 2 to 4 (1 = not at all; 7 = complete control), whereas functional men typically rate their control at 4 or higher. Since actual control over the ejaculatory reflex is itself something of a matter of debate, measures of self-efficacy more relevant to assessing successful treatment of PE may include such items as the “ability to delay ejaculation” or to “the ability to overcome early ejaculation”.

The third criterion—concern or distress about the condition—is usually satisfied by the fact that the man (often with his partner) approaches the clinic seeking help for the sexual problem. In situations where participants are recruited into an experimental or clinical investigation, several questions might be included in a screening questionnaire that directly addresses the issue of concern or distress. Most commonly these items query the man (and when possible his partner) about his general level of sexual satisfaction, with further elaboration about anxiety or concern surrounding the sexual problem and about the quality of the sexual relationship. Standardized measures of general anxiety (e.g., BSI [72]), sexual functioning (e.g., GRISS [73]) or dyadic distress (Dyadic Adjustment Scale [74]) might also be included to further assist in operationalizing this criterion.

c) ISSM definition of lifelong premature ejaculation

Based on the aforementioned considerations, the International Society for Sexual Medicine (ISSM) organized an international panel to convene in Amsterdam in 2007 to develop a consensus definition for premature ejaculation. The ISSM panel concluded that there were insufficient data for an evidence-based definition of acquired premature ejaculation. However, it succeeded in formulating an evidence-based definition of lifelong premature ejaculation [75]. According to this new definition, lifelong premature ejaculation is characterized by: an ejaculation which always or nearly always occurs prior to or within about one minute of vaginal penetration; an inability to delay ejaculation on all or nearly all vaginal penetrations; and with negative personal consequences, such as distress, bother, frustration and/or the avoidance of sexual intimacy.

d) Classifications of premature ejaculation

In 1943, Schapiro proposed a distinction of premature ejaculation into Types A and B [76]. Men
with Type B have always suffered from a very rapid ejaculation (or short latency), whereas in Type A, the rapid ejaculation develops later in life and is often associated with erectile dysfunction. In 1989, these types were respectively referred to as lifelong (primary) and acquired (secondary) premature ejaculation.) [77]. Over the years, other attempts have been made to identify various classifications of PE, including several that have been incorporated into PE definitions (e.g., global vs. situational, the effect of a substance, etc.). In 2006, Waldinger [78, 79] proposed a classification of premature ejaculation according to a “syndromal” approach and suggested adding two new categories, “Natural Variable Premature Ejaculation” and “Premature-like Ejaculatory Dysfunction.”

(Table 3) In the category of Natural Variable Premature Ejaculation, men suffer only occasionally from rapid ejaculations or short latencies. This pattern might be regarded as part of the normal variability of ejaculatory performance in men rather than a symptom of an underlying psychopathy. In the category of Premature-like Ejaculatory Dysfunction, men subjectively experience and/or voice complaints of premature ejaculation, while having typical or even long ejaculatory latencies of 4-20 minutes. Thus, including the longstanding “lifelong” and “acquired” classifications, four premature ejaculation syndromes are defined [80].

1) **Lifelong Premature Ejaculation**

With lifelong PE, ejaculation occurs too early at nearly every intercourse, with (nearly) every woman, and from about the first sexual encounters onwards. Based on self-selected samples, the majority of these men (80-90%) ejaculate intravaginally within 30-60 seconds, and most of the remainder (10%) between 1-2 minutes. (Figure 5) The ejaculation remains rapid during life in the majority (70%) of these men or may be aggravated during the course of aging (30%). Some men ejaculate during foreplay, before penetration (ejaculatio ante portas), or as soon as their penis touches the vagina (ejaculatio intra portas). No accepted cure for lifelong PE is known, but various drugs (including SSRIs) and psychotherapy treatments may be effective in postponing the ejaculatory response [80].

2) **Acquired Premature Ejaculation**

Complaints of men with acquired PE differ in relation to the underlying somatic or psychological problem. In these men, premature ejaculation occurs at some point in a man’s life after experiencing normal ejaculatory latencies; the onset may be either sudden or gradual. The appearance of the PE may be due to (i) urological dysfunctions, for example, erectile dysfunction or prostatitis [81], although there is yet debate as to the role of prostatitis in acquired PE, (ii) thyroid dysfunction [82], and (iii) psychological or relationship problems [83, 84]. The acquired form of premature ejaculation may be cured by medical and/or psychological treatment of the underlying cause [80].

3) **Natural Variable Premature Ejaculation**

Men exhibiting this pattern only coincidentally and situationally experience short ejaculatory latencies. This type of response should not be regarded as a symptom or manifestation of underlying psychopathy but of normal variation in sexual performance. The syndrome is characterized by the following symptoms. (i) short ejaculatory latencies are inconsistent and occur irregularly, (ii) the ability to delay ejaculation, that is, to withhold ejaculation at the moment of imminent ejaculation, may be diminished or lacking, and (iii) the experience of diminished control of ejaculation is associated with either a short or normal ejaculation time, that is, an ejaculation of less or more than 1.5 minutes. Treatment of these men should consist of reassurance and education that this pattern of ejaculatory response is normal and does not need drug treatment or psychotherapy [80].

4) **Premature-like Ejaculatory Dysfunction**

Men under this classification experience or complain of premature ejaculation while the ejaculation time is in the normal range, i.e. around 2-6 minutes, and in some instances the ejaculatory latency may even
be of very long duration, i.e., between 5-25 minutes [80]. This response should not be regarded as a symptom of medical or (neuro)biological underlying pathology although psychological and/or relationship problems may underlie the complaint. The syndrome is characterized by the following symptoms: (i) subjective perception of consistent or inconsistent short ejaculatory latency during intercourse, (ii) preoccupation with an imagined early ejaculation or lack of control of ejaculation, and (iii) the intravaginal ejaculatory latency time (IELT) in the normal or even long range (i.e., an ejaculation that occurs between 3 and 25 minutes), and (iv) the ability to delay ejaculation may be diminished or lacking.

As the duration of the ejaculation latency in these men is normal, the experience of the response is not related to a medical or neuro-biological disturbance [80]. Rather, there is either a misperception of the actual ejaculation time, for various reasons, or the ejaculation latency is too short for the female partner to attain an orgasm. Complaints of these men may be alleviated by the various sorts of psychotherapy and treatment should not a priori assume the use of pharmaceuticals. However, evidence-based controlled trials are required to investigate the optimal treatment for couples affected by this pattern of responding.

2. THE PREVALENCE OF PREMATURE EJACULATION

Although various epidemiological studies have shown that about 20-30% of men have complaints of premature ejaculation [85], reliable information on the prevalence of lifelong PE and acquired PE in the general male population is lacking. As the prevalence of IELTs of less than 1 minute in unselected male cohorts in mainly Western countries is about 1-3%, the prevalence of lifelong PE may be rather low. With regard to the prevalence of acquired PE, data are essentially lacking, in part related to the lack of an evidence-based definition for this condition. Taking into account recent epidemiological data that about 25% of men are discontent with their ejaculation response time, the duration of which is rather equal to the normal ejaculation time in men [67], and accepting the recently proposed PE subtype of Premature-like Ejaculatory Dysfunction, it may be that discontent with ejaculatory response time may have greater prevalence than actual premature ejaculation, particularly when the latter is defined by a 1 min IELT.

3. ETIOLOGY OF PREMATURE EJACULATION

Historically, attempts to explain the etiology of premature ejaculation have included a diverse range of biogenic and psychological theories (Table 4). Most such proposed etiologies have not been strongly grounded in empirical evidence. Psychological theories include the effect of early experience and sexual conditioning, anxiety, sexual technique, the frequency of sexual activity, and psychodynamic/developmental explanations. Biogenic explanations include evolutionary theories, penile sensitivity, central neurotransmitter levels and receptor sensitivity, degree of arousability, the speed of the ejaculatory reflex, and the level of sex hormones. The lack of an operationalized definition for PE and the presence...
of methodological problems related to the use of inadequate definitions used are common problems in many of these studies. Finally, the determinants of PE are undoubtedly complex and multivariate, with the etiology of lifelong premature ejaculation likely different from that of acquired premature ejaculation.

a) Lifelong premature ejaculation

The determinants of lifelong premature ejaculation are currently unknown. However, genetic and epigenetic factors may play a role in its development, and several hypotheses are currently under investigation.

1) Genetic predisposition

A familial predisposition to premature ejaculation was first reported by Schapiro in 1943 [76] and since then, others have hypothesized that IELT varies according to a continuum in the general male population and that this variation is genetically determined [86]. In support of this, a small study reported that 10 of 14 first-degree male relatives of men with lifelong PE also suffered from PE with an IELT of less than 1 minute [87], generating odds ratio of a familial occurrence of PE that far exceeded the incidence within the general community. Thus, Schapiro's initial contention that PE may have a genetic component may have validity.

Waldinger et al hypothesised that lifelong early ejaculation in humans may be explained by either hyposensitivity of the 5-HT2C and/or hypersensitivity of the 5-HT1A receptor [86]. Specifically, they suggested that men with low 5-HT neurotransmission and probable 5-HT2C receptor hyposensitivity may have an ejaculatory threshold genetically "set" at a lower point and therefore ejaculate quickly and with minimal stimulation and often prior to reaching their erectile threshold. In contrast, men with a genetically determined higher set point could sustain more prolonged and intense sexual stimulation and could exert more control over ejaculation. Finally, men with a very high set point may experience delayed or absent ejaculation despite prolonged sexual stimulation and achieving a full erection [88]. Treatment with an SSRI class drug may activate the 5-HT2C receptor, adjust the ejaculatory threshold set point, and thus delay ejaculation. The extent of ejaculatory delay may vary widely in different men according to the dosage, the frequency of administration of the SSRI, and the genetically determined ejaculatory threshold set point. Cessation of treatment results in re-establishment of the previous set point within 5-7 days in men with life long PE. Identification of the specific 5-HT receptor subtypes involved in early ejaculation would be possible by administering subtype selective 5-HT2C or 5-HT1A receptor ligands, but unfortunately such agents are not yet available for human use.

Both animal models and human data have been invoked to support the idea that ejaculatory latency is naturally distributed and constitutionally influenced. In various sexual behavior tests in male Wistar rats, a continuum of the ejaculation latency has been demonstrated [89]. Moreover, in an unselected cohort of men in five countries (Netherlands, UK, Spain, Turkey and the USA), the IELT distributed in a skewed pattern with a median IELT of 5.4 minutes (range: 0.55 to 44.1 min) [66], confirming IELT variation across men. (Figure 6) A preliminary indication for a genetic basis for ejaculatory latency was recently demonstrated by Janssen and colleagues [90] who reported that gene polymorphism of the 5-HT transporter (5-HTT) is associated with the rapidity of ejaculation in men with lifelong PE. Men with lifelong PE and with LL-genotype have 100% shorter latencies than men with SS-genotype of the 5-HTTLPR. This study suggested that the short IELTs in men with lifelong PE may be associated with more gene polymorphism of 5-HT metabolism and gene polymorphism of other neurotransmitters. Finnish twins has also demonstrated that genetic factors may play a role in premature ejaculation [91]. However, a methodological limitation of this study was a lack of objective IELT measurement in these men and the absence of a distinction between lifelong and other forms of PE.

2) SEROTONERGIC SYSTEMS IN EJACULATION: AN ATTEMPT TO UNDERSTAND THE NEUROCHEMISTRY OF PE

Male rat studies (Table 5) have demonstrated that serotonin (5-hydroxytryptamine: 5-HT) and 5-HT receptors are involved in the ejaculatory process. As far as is currently known, 5-HT2C, 5-HT1A and 5-HT1B receptors determine the speed of ejaculation. For example, studies with d-lysergic acid diethylamide and quipazine, which are nonselective 5-HT2C agonists, suggest that stimulating 5-HT2C receptors delays ejaculation [92]. However, 2,5-dimethoxy-4-iodophenyl-2-aminopropane, which equally stimulates 5-HT2A and 5-HT2C receptors, also increases ejaculation latency [93] whereas the selective 5-HT2A receptor agonist 2,5-dimethoxy-4-methylamphetamine does not have this effect [92]. On the other hand, activation of postsynaptic 5-HT1A receptors by the selective 5-HT1A receptor agonist 8-hydroxy-2-(di-n-propylaminotetralin) in male rats results in shorter ejaculation latency [92]. Administration of selective serotonin reuptake inhibitors (SSRIs) results in higher levels of 5-HT in the synapse due to active blockade of 5-HT transporters in the presynaptic membrane [86]. Initially, the 5-HT level is only mildly increased, but due to desensitization of the 5-HT1A and 5-HT1B/1D autoreceptors, 5-HT levels in the synapse increase highly. The higher levels of 5-HT consequently activate the post-synaptic 5-HT2C and 5-HT1A receptors [86, 94]. Acute administration of clomipramine and SSRIs does not lead to a significant change in sexual behavior of male rats [95]. However, chronic administration with fluoxetine [96] and paroxetine [97] significantly delays ejaculation latency in male rats. Chronic administration of fluvoxamine, however, exerts only a mild change in male rat sexual behavior.

Based on 5-HT2C and 5-HT1A receptor interaction data in animals, it has been hypothesized [86, 88, 98] that men with premature ejaculation have a hypopensitivity of the 5-HT2C and/or hypersensitivity of the 5-HT1A receptors. (Table 5) The hypothesis that activation of postsynaptic 5-HT receptors delays ejaculation is supported by numerous studies in humans with different SSRIs. However, in these studies it is not obvious whether similar receptor subtypes, that is, 5-HT2C and 5-HT1A receptors, are also involved in human ejaculation since SSRI treatment activates many different postsynaptic subtype receptors. To address this issue, two human studies with the 5-HT2C blocking antidepressants, nefazodone [99] and mirtazapine [100], were performed. In a double-blind placebo controlled study with the 5-HT2C/5-HT2A receptor antagonist and 5-HT/noradrenaline reuptake inhibitor nefazodone, 400 mg nefazodone daily did not exert any ejaculation delay, in contrast to either 20 mg paroxetine daily or 50 mg sertraline daily, both of which induced significant delays. In a similar study the 5-HT2C/5-HT3 receptor antagonist and noradrenergic and...
specific serotoninergic antidepressant mirtazapine did not induce ejaculation delay compared with the significant delay resulting from 20 mg paroxetine daily. In both studies nefazodone and mirtazapine did not delay ejaculation. Further studies with selective 5-HT2C and 5-HT1A agonist and antagonists may yet elucidate undiscovered pharmacological mechanisms underlying the ejaculatory process.

b) Acquired premature ejaculation (A-PE)

As with many other sexual symptoms, the notion that men with PE are a homogeneous group is erroneous [101]. As mentioned earlier, Shapiro [102] initially classified men with PE into two subgroups: those with lifelong PE (i.e., from the beginning of active sexual life) or those who acquired the condition after a period of normal ejaculatory control. And, indeed, those classified in this latter group may themselves show a variability in symptoms and etiologies [60, 76, 81, 82, 84, 103-115]. For example, acquired PE may be absolute/generalized (irrespective of partners or context) or situational (relative to a partner and/or context), and the condition may vary greatly in its frequency and severity [116].

The definition of acquired PE (A-PE) is an ongoing process. While it has been relatively easy to define lifelong PE on the basis of existing data [75], similar objective parameters have thus far not been produced for A-PE. Although no logical reasons exist for suspecting substantial differences in intravaginal latencies (IELTs) and patient reported outcomes (PROs) in patients with lifelong or acquired PE, the lack of evidence-based IELT and PRO data has thus far frustrated the efforts of scientific societies and consensus conferences to reach a definition of acquired PE, with the only consensus at this juncture being that acquired PE occurs after a period of normal ejaculatory control. The obvious inferring of this is that lifelong PE is more likely to be sustained by congenital causes, while the acquired form must be grounded in psychological events or organic noxae able to affect the complex mechanism of ejaculation.

The pathophysiology of acquired PE may be either neurobiogenic (endocrine, urologic, neurobiologic) or psychogenic, or in some instances, both [117]. In other words, A-PE may be viewed as a psychoneuroendocrine and urological symptom with possible comorbidity with another sexual disturbance: thus A-PE has been correlated with psychological, neurological, hormonal, and urological conditions and diseases, and other sexual symptoms such as ED. Since the psychological etiology is largely treated in other sections of this chapter, the following discussion focuses on organic pathologies. As with the psychological aspects of PE [118], no single neurological, endocrine, or urological pathology listed here has been demonstrated to be a direct cause of A-PE. Rather, all these must be considered, at best, pathological conditions associated with PE, thereby deserving medical attention and treatment in order to maximize the therapeutic efforts toward alleviating the symptoms of PE. In other words, rather than causes or determinants, the candidate etiologies of A-PE listed here should be regarded as organic risk factors (Table 4).

1) Neurological risk factors

Although logical, the association between PE and hypersensitivity is still under debate. The sensitivity of the glans, the organ triggering ejaculatory reflex, undoubtedly has an important role in the ejaculatory mechanism, and possibly in some forms of PE. Penile sensation is unique when compared to other body regions [119]. The human glans penis is covered by stratified squamous epithelium and a dense layer of connective tissue, equivalent to the dermis of normal skin. The majority of nerve terminals are free nerve endings (FNEs) which are present in almost every dermal papilla as well as scattered throughout the deeper dermis. FNEs are characterized by an incomplete Schwann cell investment and contain irregularly scattered neurofilaments and neurotubules, clusters of mitochondria, vesicles of variable size, and various inclusions. The unique corpuscular receptor of the glans penis consists of axon terminals that at an ultrastructural level resemble a tangled skein of FNEs. Simple Pacinian and Ruffini corpuscles have occasionally been identified, predominantly in the corona glandis [120].

Table 5: Level of Evidence - The Effects of Drugs on Orgasm and Ejaculation
On these anatomical bases, it has been shown that patients with PE, not necessarily with the acquired form, may have hypersensitivity and hyperexcitability of the glans penis, which may give rise to uncontrolled ejaculation and which therefore may contribute to the risk for organically based PE [121]. Evoked sacral potentials have in fact been used to study the bulbocavernous reflex in men with PE [122]. In perineal and perianal measurements, the amplitudes of the evoked responses were greater in men with PE relative to controls, thereby suggesting a reflex hyperexcitability or an impaired "modulation" of the motor neurons of the pudendal nucleus in men with PE. On the glans penis and penile shaft, sensory threshold values in patients with PE have been found significantly lower than those in normal potent men [123]. Furthermore, using somatosensory evoked potential, patients with PE showed greater cortical representation of sensory stimuli from the genital areas than normal ejaculators [124]. However, Rowland and colleagues found thresholds for premature ejaculators to be commensurate with controls, while men with erectile dysfunction or combined erectile dysfunction and PE showed significantly elevated thresholds [125]. Although premature ejaculators did not show penile hypersensitivity, there was a significant correlation in this group between ejaculation latency and threshold. Overall, these findings argue against a primary role for penile sensitivity in ejaculation latency and suggest that other somatic or cognitive factors may play a more critical role in PE. Furthermore, faster conduction along the pudendal sensory pathway or a greater cortical representation of the sensory stimuli from the genital area or hyperexcitability of the BC reflex has not been consistently confirmed in patients with PE [126]. This lack of effect was further confirmed using a vibrometer with precision and reproducibility higher than analogue-type biothesiometers [127]. Such findings suggest that the electrophysiological approach is probably not sufficient to clarify some causes of either lifelong or acquired PE, although more investigation in this area of research is warranted [128].

2) **Endocrine risk factors**

Hormones play a central role in the machinery of emission-ejaculation [129]; thus pathological hormonal levels have the potential to directly or indirectly affect ejaculatory control [130]. An example occurs with thyroid hormone, although with respect to this hormone, the hormone condition may affect ejaculatory latency just as the condition of PE may affect or modify the hormone level itself. Similar patterns may occur with respect to the relationship between testosterone and prolactin levels and A-PE.

- **The role of sex steroids**

  Low serum testosterone levels have been inconsistently associated with PE [131, 132]. However, some reports have anecdotally suggested that hypogonadism may be a cause of delayed or retarded ejaculation. Testosterone plays a crucial role in male sexual response, acting at both the central and peripheral levels, and it is a clear determinant of motivation to seek sexual contact. Several studies on hypogonadal men have demonstrated that testosterone replacement has an unequivocal role in restoring sexual desire, spontaneous sexual thoughts, and attraction to erotic stimuli. The testosterone-dependency of PDE5 expression and activity has also been demonstrated in other portions of the male genital tract (MGT) such as the vas deferens, a critical effector for semen emission and ejaculation [133].

Recent data suggest that testosterone plays a facilitating role in the control of ejaculatory reflex [134], with different testosterone levels identifying different subsets of ejaculatory disturbance. While higher testosterone levels characterize PE, lower testosterone levels have been associated with delayed ejaculation. Taken together, these data suggest a role for androgens in the mechanism of ejaculation [134], and both central and peripheral systems have been advocated to explain this association. The first explanation is psycho-endocrinal. Testosterone, in addition to its action on sexual response, profoundly influences male behavior. High testosterone in human adults is associated with leadership, toughness, personal power, and aggressive dominance [135]. Rowland considers some cases of delayed ejaculation to represent the uncoupling of subjective arousal and genital response—where genital reaction is preserved in the face of diminished subjective sexual arousal [136]. It could thus be speculated that hypogonadism and a related reduction in sexual confidence and aggressiveness could play a critical role in the control of ejaculation timing, reducing the internal cues for reaching orgasm and ejaculation. The second hypothesis is neurological. Recent data from animal models seem to support the central action of testosterone in the control of the ejaculation reflex. Keleta et al [137] have demonstrated that long-term testosterone treatment in rats significantly decreased 5-HT in the brain. Another intriguing possibility involves the peripheral role of testosterone in regulating MGT motility. In rabbit hypogonadism, PDE5 is less expressed and biologically active in the vas deferens [138], but testosterone administration completely reverses these alterations. Hence, it is possible that hypogonadism-associated delayed ejaculation is due to an increased inhibitory nitric tone on MGT smooth muscle cells. A "mechanical" effect of testosterone action in ejaculation control is also possible. A hypogonadism-induced reduction in semen volume may perturb the dynamics of the seminal bolus propulsion, possibly explaining ejaculation difficulties in some men. In fact, low testosterone directly reduces ejaculate volume which may result in a lack of stimulation of accessory glands...
such as the prostate and seminal vesicles, which are well-known androgen targets. Finally, the explanation that the observed testosterone differences are the consequences of sexual disturbances mirror differences in sexual behaviour, such as copulation frequency [139].

In conclusion, several possible mechanisms may relate androgen levels with the complex machinery of ejaculation. Clinical studies are currently in progress to further establish the role of testosterone on ejaculatory dysfunction.

- The role of prolactin

In a consecutive series of studies investigating 2,531 patients interviewed using the SIEDy structured interview (a 13-item tool for the assessment of ED-related morbidities) [140] and the Middlesex Hospital Questionnaire [141] for the evaluation of psychological symptoms, low prolactin (PRL) levels were found to be associated with PE and anxiety symptoms [142]. However, low PRL seems to be an effect rather than a cause of PE. In fact, many psychological disturbances (such as stress and frustration related to chronic or acquired inability to enjoy sex) are able to provoke a neuroendocrine imbalance, such as that of the central serotoninergic system, mirrored by the relative hypoprolactinemia found in patients with PE.

- The role of thyroid hormones

The impact of thyroid hyper- and hypo-function in male sexual function has been studied only recently. This lack of previous analysis is probably the consequence of: i) the apparently low clinical significance given to male sexual symptoms in comparison with the systemic effects of thyroid hormone excess and defect; ii) the paucity of clinical studies, as thyroid disease is less common in men than women; and iii) the embarrassment of patients and physicians when discussing sexual dysfunction in the "traditional" setting of the endocrine outpatient clinic [143]. Nevertheless, a high prevalence of A-PE has been found in hyperthyroid patients, whereas delayed ejaculation has been the major sexual complaint in hypothyroid men [144, 145]. Both the premature and delayed ejaculatory dysfunctions have been reversed on achievement of euthyroidism in the absence of any other treatment for the sexual symptom. Interestingly, suppressed levels of TSH (as a marker of hyperthyroidism) have been demonstrated in A-PE [145] but, obviously, not in patients with lifelong PE [146]. Such findings suggest direct involvement of thyroid hormones on the physiology of ejaculation.

As the specific relationship between thyroid hormones and ejaculatory mechanisms is currently unknown, three possible sites of action have been suggested: the sympathetic nervous system, the serotoninergic pathway, and the endocrine/paracrine system. Most manifestations of thyrotoxicosis and sympathetic nervous system activation overlap, thereby suggesting a similar action on ejaculation, a reflex largely dependent on sympathetic and parasympathetic tone. However, plasma catecholamines and their urinary metabolites are usually normal in hyperthyroidism [147]. On the other hand, some studies have found that thyroid hormones augment sensitivity to a-adrenergic agonists by increasing a-adrenoceptor density and Gs/Gi protein ratio through an over-activation of adenylate cyclase [148]. This action leads to increased sympathetic activity with normal circulating catecholamine levels. In hyperthyroid patients, the increased adrenergic tone may trigger both premature and delayed ejaculation, either acting directly on smooth muscle contractility/relaxation or indirectly on anxiety and irritability. The opposite may occur in hypothyroid patients [149]. Considering the neuropsychological reactions to thyroid hormone excess (hyperkinesia, nervousness, anxiety, emotional lability), PE may also be a non-specific disease-related complaint, disappearing when a euthyroid state is achieved. However, in light of the widespread distribution of thyroid hormone nuclear receptors within the brain, it can be hypothesized that iodothyronines specifically alter the central serotoninergic pathway [150], leading to diminished ejaculatory control. In animals with experimentally-induced hypothyroid states, increased serotonin turnover in the brainstem is consistently reported [151], and thyroid hormone replacement is associated with increased cortical serotonin concentrations and augmentation of serotonergic neurotransmission by desensitization of the serotonin inhibitory 5-HT1A (auto-inhibition) [151]. Finally, delayed ejaculation is a common and therapeutically useful side effect of serotonergic drugs, indicating that this pathway is fundamental for ejaculatory control.

Another possible way that thyroid hormones may affect the ejaculatory mechanism is through estrogen metabolism. Hyperthyroidism increases levels of sex hormone binding globulin (SHBG), which binds androgens with higher affinity than estrogens, leading to a relative hyperestrinism. It has been demonstrated in hypogonadic rabbits that estrogens, but not androgens, fully restore oxytocin-induced epididymal contractility, up-regulating oxytocin receptor gene and protein expression, and that deprivation of endogenous estrogens induces oxytocin hypo-responsiveness [152, 153]. As oxytocin is closely involved in the ejaculatory mechanism [154] both centrally [155] and peripherally [156], this may account for the close correlation between hyperthyroidism and premature ejaculation. As an ancillary possibility, thyroid hormone receptors have been described in the animal [157] and human testis [158], and may also be present in other male genital tract structures, triggering ejaculation. Finally,
although excluded in the original report [144], some cases of PE in hyperthyroidism are comorbid with impotence, which may in turn exacerbate the loss of ejaculatory control [159].

3) **Urological risk factors**

- The role of the prostate

For unexplained reasons, the relationship of prostate and PE was largely neglected in the past but now has been attracting increasing interest. This neglect is particularly surprising since the main function of the prostate is to store and secrete the clear, slightly basic fluid that constitutes up to one-third of the volume of semen. The prostate also contains smooth muscle that helps expel its secretions during ejaculation.

In the classic model explaining the human ejaculatory process, the emission, with formation of a “pressure chamber” created in the prostatic urethra, is followed by expulsion (rhythmic bulbospongiosus muscle contractions) of seminal fluid [160]. The first phase is mediated by activated adrenergic contractions of the smooth muscle in the capsules of the testes, seminal tract, and genital glands, including the prostate. This pressure build-up is claimed then to “trigger” the intermittent relaxation/contraction of the distal sphincter and activate the contractions of the striated pelvic musculature, especially that of the bulbocavernosus, which forcefully expels the semen along the urethra by powerful, rhythmical spurts. Electric waves discharged from the prostate at rest seem to produce prostatic contractions that appear to be responsible for increases in the prostatic urethral pressure [161]. Shafik [162] noted that, at ejaculation, the intermittent and significant increase in wave variables and urethral pressure coincided with the ejaculatory spurs and apparently denotes intermittent prostatic smooth muscle contractions. These prostatic contractions seem to squeeze the prostatic secretions into the prostatic urethra. However, some important pieces of experimental evidence, against the notion that “distension” of the prostatic urethra by the entering semen is the probable trigger for the ejaculation reflex, have been produced. a) Alpha-adrenergic blocking agents (phenoxybenzamine, phentolamine) prevent the discharge of semen into the urethra but do not inhibit the initiation of ejaculation despite there being no fluid to ejaculate (dry orgasms), nor do they change significantly the subjective experience of orgasm [163]. Moreover, a healthy subject could experience a dry emission/ orgasm with a complete absence of secretions. b) It has been reported that a decrease in echogenicity of the prostatic urethra during the pre-ejaculatory phase signifies the secretion and movement of prostatic fluid to the prostatic urethra, which in turn leads to the inevitability of expulsion [7] and that the prostatic urethra is distended 3-5 sec before the start of seminal expulsion [164]; however, in 8 normal healthy volunteers, the expulsion of the contents of the seminal vesicles into the inframontanal urethra always occurred without prior ballooning of the prostatic urethra [165], suggesting that a “pressure chamber” does not appear to be formed before prostatic contractions take place. c) In copulating male rats, urethral stimulation by the ejaculate does not contribute to the activation of the striated muscle component of the ejaculation reflex [166], further suggesting that candidate sites for the ejaculation “trigger” could be present in the penile glans, spinal cord, and/or the brain.

Although the formation of the “pressure chamber” in the prostatic urethra is currently undetermined, it is well known that the antegrade propulsion of seminal fluid into the distal urethra requires coordinated dynamic changes at the bladder neck, prostatic urethra, and external sphincter [167].

- Effects of prostatic disorders on ejaculatory process

Prostate inflammation/infections have been anecdotal-correlated with PE [168]. Jannini and co-workers first demonstrated, using the Meares and Stamey test [169], a relatively high prevalence of prostatic inflammations and infections in men with PE. Furthermore, this sexual symptom is in turn common in subjects with prostatitis [170]. Following the report of these findings, the European Association of Urology (EAU) Guidelines on Ejaculatory Dysfunction recognized that “PE may be strictly organic (e.g. prostatitis-related),” and thus prescribed rectal examination with evaluation of the prostate in patients with ejaculatory disturbances [171].

Assuming that the relationship is causal, prostatic inflammation may alter sensations arising from the male genital tract such that the man is unable to recognize the emission phase [116], an effect that has been replicated by other researchers. Prostatic inflammation or infections (variously demonstrated or simply admitted by patients in a population survey) have been found in 3,115 patients with PE (variously defined) examined in several countries, with a prevalence ranging from 15 to 64% (Table 6). Inversely, PE has been found in 2,360 patients with prostatitis and/or lower urinary tract symptoms (LUTS) (Table 7). Note that LUTS have been also related with retarded and painful ejaculation [172, 173].

Some researchers argue that the correlation between prostatitis and PE is actually mediated via prostatitis-induced erectile dysfunction [174]. However, the physiological correlation between the machinery of erection and prostate function is quite poor, while—considering the physiological role of the prostate—the physiological correlation between ejaculation and this gland is robust, so this latter possibility cannot be ruled out, at least in patients with such comorbidity. However, other authors have been able to cure A-PE using only a specific antibiotic treatment
against the bacteria responsible of prostatitis [175-177]. Thus, although the relationship between prostate problems and ejaculatory response is not fully elucidated, examination of the prostate, always important in the andrological setting, may be critical during assessment of patients with A-PE [178].

4) OTHER SEXUAL SYMPTOMS AS RISK FACTORS

Sexual dysfunctions such as hypoactive sexual desire disorders or erectile dysfunction may be either the cause of or consequence of A-PE. Furthermore, A-PE may result from female sexual dysfunctions such as vaginismus or dispareunia. Inversely, a partner’s sexual dysfunction may also result from A-PE.

- Premature ejaculation and erectile dysfunction

Even though a patient may present with PE, the clinician should assume neither its presence nor singularity. For example, some patients consider it easier and less humiliating to admit to a rapid ejaculation caused by “enthusiasm” than to other more “stigmatizing” sexual dysfunctions such as ED. For this reason, the possibility that other sexual problems co-exist with the PE should routinely be investigated. Although most men with lifelong PE do not suffer from concomitant erectile dysfunction [3], PE co-exists in about 1/3 of patients complaining of erectile dysfunction [145]. In fact, PE correlates significantly with erectile dysfunction in all of the regions tapped by the Global Study of Sexual Attitudes and Behaviors [85].

In some instances, PE and ED may form a vicious circle, where a man trying to control his ejaculation instinctively reduces his level of excitation (which can lead to erectile dysfunction), or where a man trying to achieve an erection basically attempts to do so by increasing his excitation and arousal (which can lead to PE) (Figure 7). Thus, although reduced time to ejaculation is only rarely an early manifestation of erectile dysfunction, it may occur when the man has an unstable erection due to fluctuation in penile blood flow. In this case, the man may reach ejaculation quickly to compensate for the weak erection.

Furthermore, some men with PE may express their complaint using language that suggests an erectile problem, indicating how they are unable to keep their erection or to “last” (due actually to penile detumescence after ejaculation occurs rapidly). Furthermore, erectile dysfunction may be superimposed on lifelong PE by efforts to minimize sexual excitement. Finally, PE and ED may be further linked in that lack of ejaculatory control may generate reactive impotence, due to anxiety arising from poor sexual performance.

- Premature ejaculation and low sexual desire

Hypoactive sexual desire may lead to PE, due to an unconscious desire to abbreviate unwanted penetration. Similarly, diminished sexual desire can be a consequence of chronic and frustrating PE. Interestingly, low sexual desire may be due to a lack of sexual arousal, such as in erectile dysfunction. Premature ejaculation and low desire, singly or in combination, are, in fact, significantly associated with severe rather than mild erectile dysfunction at presentation [179]. There is limited but increasing evidence to support a potential role for PDE5Is used alone or combined with daily or on-demand SSRIs in the treatment of A-PE in men with comorbid erectile dysfunction [180].

- Partner sexual dysfunction

Finally, female sexual dysfunctions (such as anorgasmia, hypoactive sexual desire, sexual aversion, sexual arousal disorders, and sexual pain disorders, as vaginismus [181]) may also be related to acquired PE. The female dysfunction may be secondary to the male PE with or without erectile dysfunction, and can be considered as a frequent complication of this condition. In other cases, PE may be the result of hidden female arousal difficulties [182]. Such

5) A POSSIBLE FLOW-CHART FOR THE DIAGNOSIS OF A-PE

Current literature suggests that no particular diagnostic efforts can be performed in the normal clinical practice to recognize the etiology of lifelong PE [184]. In contrast, evidence of an acquired PE condition should maximize the effort to identify the etiology of the PE and to alleviate its possible cause.

Together with a careful sexological and medical anamnesis [185], physical examination is the keystone of the diagnosis of A-PE. In the large majority of patients with A-PE, it is in fact unnecessary to use instrumental or laboratory tools. The first diagnostic aim is to perform a differential diagnosis with subclinical [186], mild, or overt erectile dysfunction, which can be causal of, contributing to, or simply comorbid with A-PE. It is in fact mandatory to recognize such relationships so as to avoid therapeutic failure using both psychotherapy and/or drugs.

A simple neurological examination helps to rule out evident neurological diseases and, together with several anamnestic questions, hyperthyroidism. A digital prostate examination, routine in an andrological setting for all men over 40, is useful in identifying possible evidence of inflammation or infection, confirmed with the Meares and Stamey test and eventually echoscan if necessary [187].

Patients with A-PE should be clinically evaluated for currently suspected etiologies including: psychological, neurological, hormonal and urological, and for co-morbidity with another sexual dysfunction [188]. Etiological therapies (psychological, sexological, pharmacological) should be performed first when possible whereas symptomatic treatment (psychological, sexological, pharmacological) should further be considered in patients unresponsive or poorly responsive to etiological therapies.

In conclusion, although the absence or deficiency of ejaculatory control is among the most common sexual problems [189], the acquired subtype of PE is still under-diagnosed and under-treated, despite the fact that it can be successfully treated [190]. However, with increased medical awareness, careful diagnosis and sub-typing, recognition of the pathogenic mechanism in individual patients, and the forthcoming availability of new drugs specifically designed for PE, clinicians will be provided new opportunities to treat the severe suffering of many patients suffering from this condition.

IV. THE TREATMENT OF PREMATUR EJACULATION

1. PSYCHOLOGICAL CONSIDERATIONS AND TREATMENT

a) The psychological burden of premature ejaculation

Premature ejaculation (PE) exerts a significant psychological burden on men, their partners, the male/partner relationship, and their overall relationship [191]. For example, recent empirical studies in which diagnostic criteria were specified verified decreased sexual satisfaction as an identifying factor in men with any sexual dysfunction [63, 192, 193]. Men with PE show other negative effects, including a general negative affect associated with sexual situations, and more intense feelings of embarrassment/guilt, worry/tension and fear of failure [84, 194]. Relative to men without PE they indicate decreased self-confidence, increased distress and interpersonal difficulty, and mental preoccupation with their condition [84, 193]. Because partner satisfaction may play a greater role in PE than ED, it is not surprising that
relationship dysfunction is reported as the second most common negative effect of PE [84, 195]. PE is not only associated with marital discord [196], but the insecurity of men with PE about satisfying the partner also serves as an obstacle to initiating and maintaining new relationships [195, 197].

Further evidence of the significant and negative impact of PE on psychological and relationship functioning in men and their partners has been documented through a study using a large sample size and validated outcome measure reports [191]. Men with PE reported significantly lower frequency of and satisfaction with intercourse, greater personal distress and interpersonal difficulty, and lower self-esteem and confidence in their sexual and overall relationship with their partner. The impact of PE was not felt just by the man, as women were well aware of the lack of control over ejaculation by the male partner. And they too reported lower sexual satisfaction, and higher personal distress and interpersonal difficulty. Although not clinically dysfunctional, partners of men with PE report more problems related to general sexual functioning than women who do not have a partner with PE.

Thus, the negative psychosocial impact or burden of PE provides an essential element in the characterization of PE, yet it remains distinct and independent of ejaculatory control and IELT. In fact, not all men with a short IELT are distressed by the condition [191], and IELT only weakly correlates with other dimensions associated with PE, including lack of ejaculatory control, low sexual satisfaction, and high personal distress and interpersonal difficulty. Accordingly, using dimensions beyond simple ejaculatory latency to characterize premature ejaculation, particularly those related to concern, distress, and other negative consequences, is critically important to the understanding and diagnosis of PE [191].

b) Psychological treatment of premature ejaculation

Psychotherapy and behavioral interventions improve ejaculatory control by helping men/couples to: (1) learn techniques to control and/or delay ejaculation, (2) gain confidence in their sexual performance, (3) lessen performance anxiety, (4) modify rigid sexual repertoires, (5) surmount barriers to intimacy, (6) resolve interpersonal issues that precipitate and maintain the dysfunction, (7) increase communication [198, 199], and (8) come to terms with feelings/thoughts that interfere with sexual function. Regarding this last point, for examples of the kinds of thoughts and cognitions that are likely to disrupt sexual function in men with PE, see Table 8. Present day psychotherapy for premature ejaculation most often represents an integration of psychodynamic, systems, behavioral, and cognitive approaches within a short-term psychotherapy model [200-209]. The guiding principles of treatment are to learn to control ejaculation while understanding the meaning of the symptom and the context in which it occurs. However, only 5 studies have compared psychotherapy techniques for PE, either versus a control condition (remaining on a waiting list) or against other psychological treatments. [205-209], (Table 9) Three studies have compared psychotherapy in combination with pharmacotherapy against psychotherapy or pharmacotherapy alone. [210-212]One study has compared pharmacologic treatment against a behavioural intervention.[213] Overall, there is little evidence to date that psychological interventions are effective in the treatment of lifelong PE.

1) The rationale for psychological/behavioral strategies

Even though a physiological basis for some types of PE has been suspected for years [214, 215], until recently treatment options relied, quite understandably, mainly on behavioral and psychological procedures. First, psychological factors such as anxiety and negative affect have frequently been associated with sexual dysfunctions such as PE [1, 200] and therefore treatment addressing such issues has represented a logically consistent approach. In contrast there had been little or no evidence pointing to a physiological mechanism that might underlie PE. Second, until the past eight years, few tested and well-tolerated biologically based therapeutic procedures were available to clinicians for the treatment of PE. And third, the psychological-behavioral strategies for treating PE have been at least moderately successful in alleviating the dysfunction [216].

Although the new and often more expedient pharmacological therapies are overshadowing these traditional psychological-behavioral methods in the treatment of PE, the psychological-behavioral approach remains an attractive option for several reasons. The treatment is specific to the problem, is neither harmful nor painful, is less dependent on the man’s medical history, produces minimal or no adverse side effects, encourages open communication about sexuality in the couple which is likely to lead to a more satisfying sexual relationship [217, 218], and has a permanence about it. Once the techniques have been learned and incorporated into lovemaking, PE men continue to have access to strategies that help them control their ejaculation. At the same time, there are drawbacks to the psychological-behavioral approach: it is time-consuming, often requires substantial resources of both time and money, lacks immediacy, requires the partner’s cooperation, and has mixed (and less well-documented) efficacy [219, 220].

2) Empirically supported psychological approaches

In addition to countering the current trend toward
pharmaco-therapeutic treatment for PE, clinical practitioners considering the use of behavioral and psychological strategies as part of their treatment protocol face particular difficulties. Strong pressure exists to provide a therapeutic treatment that fails within today's cost containment managed care environment and that meets the criteria of being empirically validated or at least empirically supported. To be considered "empirically supported," a therapeutic approach must be backed by (1) at least two studies showing it more effective than a waiting-list control group, or (2) at least two studies demonstrating effectiveness but which may have flawed sample heterogeneity, or (3) by a series of case studies in which the client sample was clearly specified and the treatment procedure described in a detailed manual.

Because of the tension between therapeutic and research objectives, it has been difficult to conduct carefully controlled, well-conceived studies that simultaneously provide needed treatment to clients whose lives are being adversely affected by their PE. As a result, there have been few treatment vs. matched-control tests of behavioral-psychological therapy on PE men, and relatively few self-as-control, waiting list, or even no-control studies [220]. More importantly, the lack of specific treatment protocols and of research funds to carry out well-designed studies to test those protocols has diminished the attractiveness of these approaches relative to evolving pharmacological strategies [221, 222]. Therefore, at this juncture the majority of psychotherapy treatment outcome studies can be characterized as underpowered, unblinded trials, with none meeting the requirements for high level evidenced-based studies. Existing research has generally used small to moderately sized cohorts of subjects who received different forms of psychological interventions with limited or no follow-up. Generally, active treatment was not compared to placebo, control or wait list groups [83].

3) Details of Successful Psychological-Behavioral Methods of Treatment for PE

Several psychological-behavioral strategies enjoying substantial popularity among sex therapists have at least come close to meeting the criteria of empirically-supported. The first is the "start-stop" method, developed by Semans [223] and later modified to become the "stop-squeeze" method by Masters and Johnson [224] in their sex therapy clinic. Another method, advocated by Kaplan [225], is a variant of start-stop method. These three methods suppress the urge to ejaculate primarily by stopping sexual stimulation, but the one substitutes a squeeze of the glans penis for a pause in stimulation at the point of impending ejaculation.

The stop-squeeze method calls for the man to signal his partner as the ejaculatory urge builds. The couple then stops the sexual stimulation and the partner applies manual pressure to the glans of the penis until the urge is reduced, though not to the point where the erection is lost. Different amounts of time for the squeeze have been advocated, but there is no evidence to support any particular duration. Rather, an individualistic approach that balances urge reduction while maintaining a moderate level of sexual arousal appears most effective [204]. With this strategy, the man must pay careful attention to his sexual sensations and stop activity well before ejaculatory inevitability. The stop-squeeze method is typically employed first with masturbation in a cycle of three pauses before proceeding to orgasm. Once successful, the method then progresses to a cycle of two pauses with intercourse in the female superior position, and finally to a cycle of two pauses with intercourse in the lateral position. This training requires an almost exclusive focus on the male's experience of sexual stimulation and needs. While Masters and Johnson's initial report of only a 2% short-term failure rate and 3% long-term failure for the stop-squeeze method revolutionized a field of PE treatment, subsequent studies have reported much lower success rates, in the neighborhood of 50-60% [226-228]. Long term success rates may be even lower. Undoubtedly, the success rates reported by Masters and Johnson were influenced by their carefully-selected clients, the intense format of their treatment, and the relatively high sexual naiveté of couples common during that era.

A variant start-stop behavioral approach to the treatment of PE men was developed by Kaplan

[225] because it better simulated the final behaviors required to prolong ejaculation latency during intercourse. Weekly outpatient therapy resulted in a high success rate (80-90%) in men with primary, generalized PE (i.e., with all partners and often during masturbation). The combination of the start-stop method with marital therapy for couples who showed "resistance" (discussed below) during the treatment process has also been quite successful in men with secondary PE [1, 200]. Although Kaplan’s high success rates have been challenged, the differential procedures for patients with primary versus secondary appear to be a robust finding [228].

Detailed descriptions of both the stop-squeeze and start-stop behavioral methods have been provided in the literature [204, 221, 227], with different therapists emphasizing their own variations. Some therapists advocate using techniques such as slowing down, breathing deeply, or moving in a circular fashion, techniques that many men without PE develop without conscious awareness [227]. Others advocate adding a stage of ejaculatory control training with oral sex as an intermediate step between masturbation and coitus for couples who are comfortable with this particular activity. [204] Still others emphasize the importance of providing the couple with accurate information about the sexual response cycle and its physiological underpinnings [229, 230]. Almost all agree that intercourse position is a relevant factor: The female superior and lateral positions allow for greater control than the male superior position [227, 231].

**c) Parameters affecting psychological treatment**

The general procedures described above rather than any specific variations have received the strongest empirical support for effective treatment of PE. Furthermore, the purported lack of efficacy of various psychological/behavioral strategies may result less from the specific behavioral techniques associated with stop-squeeze/start methods and more to a lack of attention to the parameters and context surrounding the treatment. In addition, long-term adherence is likely to be as much a mitigating factor for behavioral and psychological efficacy as it is with pharmacotherapeutic efficacy.

Three factors are important to successful outcomes when behavioral and psychological strategies are used. First, the man's attention to and awareness of sexual and visceral sensations must be heightened. Second, the couple must de-emphasize the focus on coitus and develop a broader range of sexual expression. And third, the man, and to a lesser degree his partner, must develop alternative cognitive and behavioral strategies to enhance ejaculatory control. Beyond these specific techniques, the man's motivation for treatment and openness to behavioral interventions and the partner's positive assessment of the relationship are significant predictors of positive therapeutic outcomes. In addition, a number of parameters, including the frequency of treatment, treatment format, and success in dealing with patient resistance and relapse appear to affect treatment efficacy with psychological-behavioral strategies.

**1) Frequency and intensity of treatment**

The two-week inpatient/intensive outpatient format originally described by Masters and Johnson offers advantages of great intensity and rapid change. Nevertheless, time, cost, and insurance factors make this sort of treatment unrealistic for most couples [204]. However, research does suggest that long intervals between sessions (bi-weekly or monthly) are insufficient during the early phase of therapy. The most effective treatment begins with 1-2 weekly sessions in order to provide adequate support for the change process, to allow time for the couple to practice behavioral assignments at home, and to "unlearn" adjunctive behaviors (discussed below) that might exacerbate the dysfunction.

Because the long term benefits of psychological-behavioral treatment for PE often decline over time, treatment that lacks sufficient intensity or duration increases the likelihood of a "relapse," that is, a reappearance of early ejaculation symptomatology [228]. If the couple is not adequately prepared for such relapses, the resulting setback
can lead to sexual avoidance, the development of comorbid dysfunction (e.g., lack of desire or erectile problems), and other adverse secondary effects.

The concept of relapse prevention has begun to be incorporated into sex therapy: Therapists may schedule periodic “booster or maintenance” sessions such that patients are scheduled for follow-up in 6 months. In addition to working out any “glitches” that have interfered with patient’s progress [232], such sessions can help couples deal with relapses common to men with sexual problems. Strategies from the relapse prevention model [233], originally developed for the management of substance abuse, suggest that initial treatment intensity and duration should be designed to reduce the likelihood of relapse. For example, weekly treatment should continue until marked progress is made. Then, larger treatment intervals serve to maintain change and deal with difficulties that arise, with periodic sessions continuing six months after success is attained [227, 229]. A further implication of the relapse prevention model is the need to plan for an appropriate response, should relapse occur. This includes decreasing the negativity associated with the setback by predicting its occurrence and assisting the couple in developing coping strategies to deal with the relapse. If follow-up appointments are yet continuing, the couple’s success in dealing with the relapse should be discussed in the session; if treatment has ended, the couple should be instructed to resume therapy if they are unable to cope with relapses.

2) TREATMENT FORMATS

A number of alternative formats for the treatment of PE have been investigated, including the use of bibliotherapy, group versus individual therapy, couples versus individual therapy, and marital versus sex therapy. Clinical research supports the use of bibliotherapy combined with some type of therapist contact for men having high motivation and relatively straightforward PE without co-morbid disorders [204, 229]. Specifically, psychoeducational interventions, often combining bibliotherapy and therapist intervention, can be useful in helping the couple rework their behavioral repertoire or “sexual script” [234]. For example, men with PE often limit foreplay because they fear becoming too excited too quickly. As a result, intercourse may become mechanical and rigid, yet these strategies seldom help the man delay ejaculation. By modifying rigid and narrow scripts, psychoeducational strategies enable the couple to explore the first steps toward establishing a more satisfying sexual life [226]. However, PE men who have complicating factors such as individual or relationship difficulties (which includes the majority of sex therapy clients) or concomitant erectile problems benefit less from reliance on this short-term, limited format.

Data on group (vs. individual) treatment for PE are mixed. Some investigations have found the two formats equivalent whereas others have not [227]. Use of group therapy is primarily a matter of the couple’s preference and openness to receiving treatment in this structure. Some couples benefit from knowing that their sexual problems are not unique and from hearing how other couples deal with them. A group format also provides an opportunity for men and women to meet with same-sex peers. On the other hand, most men find PE a highly sensitive issue (as is the couple’s overall sexuality) and are not comfortable discussing the topic in the presence of others. At present, the research literature cannot be used to defend either an exclusive use of a group format (which certain insurance plans might prefer) or an exclusive avoidance of group format (which some practitioners might prefer).

Treatment of PE in an individual format, however, is not as successful as working with couples. Individual treatment in the absence of a partner precludes the opportunity to practice behavioral and cognitive strategies in-situ. Still, instances arise when individuals are bothered by their PE and thus seek treatment without a partner. In such instances the stop-squeeze and start-stop techniques may be adapted to masturbation, especially when intensity of arousal is enhanced by adding a lubricant and using erotic literature or fantasy [221]. This self-sexuality training can be complemented with education about the female and male sexual response cycles. Training of ejaculatory control through masturbation typically entails a goal of 15 minutes of sexual stimulation of varying intensity before reaching orgasm.

The relative importance of marital vs. sex therapy is an issue that has received some attention from researchers, but results are not sufficiently clear to yield specific answers. The question may be framed in the following way: Does marital therapy lead to enhanced sexual functioning or does sex therapy lead to enhance marital functioning. Generally, marital therapy prior to sex therapy for couples with significant relationship issues leads to better outcomes in sexual functioning, while marital therapy in non-distressed couples does not typically lead to improved sexual functioning. Conversely, sex therapy in non-distressed couples often does lead to improved marital functioning.

3) DEALING WITH RESISTANCE, INCLUDING PRIOR SELF-STRATEGIES

Some patients who seek counseling for PE exhibit various forms of “resistance” to the traditional behavioral approaches. Sources for this resistance include situations where the dysfunction maintains a sexual equilibrium or hides the female partner’s sexual disorder or concerns; where the individual or couple has unrealistic expectations about sexual performance; where major relationship problems exist; where part-
ner deceit is present; and where PE is the consequence of a major health problem [216]. Given the increasing attention to emerging pharmacological solutions for sexual problems, the refusal to reasonably explore cognitive/behavioral and relationship issues and the insistence on taking the “right pill” are becoming new sources of resistance.

Related to the concept of treatment resistance is the issue of “home remedies.” Prior to treatment, PE men may adopt coping strategies that actually worsen the condition [218], that is, the attempted solutions contribute to rather than ameliorate the problem [235]. For example, most PE men assume that paying less attention to the sexual stimuli through active distraction might help control their ejaculation. Yet this strategy counters the greater attention to sexual sensations needed to gain control over the timing of ejaculation. As a result, this remedy typically leads to an unsatisfying orgasm as well as PE and may result in avoidance of sexual situations altogether. A second home remedy involves harder and faster thrusting by the man during his orgasm in an attempt to satisfy his partner. This strategy decreases the awareness of the sexual sensations of the ejaculatory response needed to gain greater control and reduces the enjoyment of the orgasm due to increased anxiety and focus on sexual performance. A third home remedy is for the man to apologize for the premature ejaculation, an act that exacerbates existing feelings of anxiety and guilt and is likely to lead to avoidance. Many couples report that an exclusive focus on the duration and quality of intercourse directly contradicts a healthy focus on developing a mutually satisfying sexual life. Indeed, a strong focus on coitus is counterproductive, particularly since many men without PE ejaculate within several minutes of intromission and a sizable percentage of women achieve orgasm through direct clitoral stimulation, not through intercourse [218].

Kaplan’s work of combining sex therapy with interpersonal approaches and accurate information about sexual functioning provides a model for working through these sources of resistance and challenging the negative coping strategies that might have developed in response to the dysfunction. At times, the “working through” process itself may result in progress even if the reason for the resistance is unclear. But for most couples, a careful preliminary assessment will help prepare the therapist for impediments to progress that can arise within treatment [1].

4) Treating the Person vs. Treating the Penis

One of the great benefits of incorporating behavioral and/or psychological counseling into a treatment regime is that such approaches are more likely to address the psychoaffective and relationship concerns surrounding the dysfunctional response. The affective component of sexual response has long been theorized to play a role in causing or sustaining sexual dysfunction in men [200, 236, 237], with recent research verifying that compared with sexually functional men, men with PE exhibit higher negative and lower positive affect in response to erotic stimulation [238, 239]. What has been unclear is whether the high negative and low positive affect in PE men is part of the original etiology or cause of the dysfunction, or whether it represents a reaction to failed genital response that then serves to exacerbate the problem.

Research actually supports both possibilities [194]. For example, positive emotions such as pleasant/enjoyable increase in men with PE who respond to the ejaculatory-retarding effects of clomipramine treatment, but negative affects such as guilt/embarrassed and tense/worried do not show comparable decreases. In other words, pharmacotherapy appears effective in reinstating positive emotional responses to sexual stimuli in men with PE, but negative emotions are not diminished, even when ejaculatory latencies are increased by as much as several minutes. Thus, even when pharmacological treatment is effective, further therapeutic strategies that emphasize open communication and relaxation with the partner to ease embarrassment and tension may further assist the client in overcoming negative dispositions associated with the dysfunction.

At a broader level, this study illustrates that the interpersonal dynamics that result from the dysfunction—including such factors as avoidance of intimacy on the part of the man and subsequent anger and distress on the part of the partner—may not always be reversed by a genital solution. In such situations, psychological and interpersonal issues may need to be addressed, at least if increased sexual satisfaction and an improved sexual relationship are viewed as important outcomes. Equally important is the recognition that because pharmacotherapy can alleviate a sexual dysfunction, the cause of their problem is not necessarily rooted in aberrant or dysfunctional biological systems. Quite the contrary, sexual dysfunction caused by any number of different somatic, psychological, or interpersonal factors may respond positively to pharmacotherapeutic intervention. That is, any intervention targeted at the mechanics of ejaculation is likely to be effective in rectifying the genital component of the problem, independent of its cause [240].

Thus, the goals of integrated therapy extend far beyond establishing simple control over ejaculation. That is, the therapy typically addresses a myriad of issues related to affective response, re-establishment of confidence, and couples’ interaction dynamics, all with the goal of increasing overall sexual and relationship satisfaction [241].
d) Evaluating treatment

Because different types of treatment intervene at different stages in the dysfunctional response sequence in PE men, the choice of outcome measures depends partly on the specific treatment that is implemented. A treatment plan for PE, for example, may primarily address the endpoint of sexual satisfaction (e.g., with a somatically based problem in which pharmacological treatment is not an option). Alternatively, it could address ejaculatory latency (e.g., pharmacological treatment) which in turn affects sexual satisfaction, or it might address ejaculatory control (e.g., behavioral-cognitive techniques), which subsequently affects both ejaculatory latency and sexual satisfaction. For example, psychological-behavioral strategies instruct patients in the use of mental imagery, behavioral techniques (e.g., adjusting intercourse position, using pauses, etc.), and relationship interactions to develop greater control over the timing of ejaculation. In achieving such control, IELT would be lengthened and greater satisfaction attained. In this treatment, all three measures—ejaculatory control, IELT, and satisfaction—are relevant endpoints, as the focus of the intervention is on developing better ejaculatory control which, in turn, affects both IELT and satisfaction. Indeed, in using all three measures, the researcher or clinician is better able to verify the specific processes through which sexual satisfaction, the ultimate endpoint, is affected.

In contrast, pharmacotherapeutic treatment is aimed at inhibiting the ejaculatory reflex and may not necessarily enable greater control over the timing of ejaculation other than by delaying it. But, as with any medical treatment in which the patient is a «passive» recipient of a treatment procedure, pharmacotherapy—in delaying the ejaculatory reflex—may give the man with PE a greater sense of control over his sexual problem. As a result, assessment of self-efficacy by using a measure such as «ejaculatory control» is perhaps less germane to pharmacotherapy studies than assessment of the other two characteristics of PE—ejaculation latency and general sexual satisfaction. Indeed, research indicates that while men who respond positively to the ejaculatory-inhibiting effects of clomipramine show substantial increases in both IELT and satisfaction, the effect on self-reported «ejaculatory control» tends to be modest [70, 242]. Nevertheless, assessment of self-efficacy in pharmacotherapy studies may be warranted, as increased self-efficacy is undoubtedly related to overall satisfaction with the treatment procedure. However, self-efficacy in such studies might be better assessed with items asking about «the ability to delay ejaculation» or «the ability to control/avoid the premature ejaculation» than with one that specifically assesses «ability to control ejaculation (or its timing).»

Evidence-based research into both the methodology, content, duration and intensity

as well as the short and long term results of psychological treatment of PE is encouraged

Level 3 evidence to suggest that all men seeking treatment for PE should receive basic psychosexual education

Graded levels of patient and couple counselling, guidance and/or relationship therapy, either alone or ideally in combination with PE pharmacotherapy should be offered as a treatment option for most men with PE

Grade C Recommendation

2. PHARMACOLOGICAL TREATMENT

In 1943 Schapiro [76] described the use of topical anaesthetic ointment to delay ejaculation. The use of anaesthetics to diminish the sensitivity of the glans penis is probably the oldest known form of treating premature ejaculation. In 1973 the first report of successful ejaculation delay by clomipramine was published [243]. However, in the 1970s and 1980s, drug treatment of premature ejaculation was not used extensively. The introduction of the serotonergic tricyclic clomipramine and the SSRIs paroxetine, sertraline, fluoxetine, citalopram and fluvoxamine has revolutionized the approach to and treatment of PE. These drugs block axonal re-uptake of serotonin from the synaptic cleft of central and peripheral serotonergic neurons by 5-HT transporters, resulting in enhanced 5-HT neurotransmission and stimulation of post-synaptic membrane 5-HT2C autoreceptors. Although the methodology of the initial drug treatment studies was poor, later double blind and placebo-controlled studies confirmed the ejaculation-delaying effect of clomipramine and SSRIs.

a) Daily treatment with Selective Serotonin Reuptake Inhibitors (SSRIs)

Daily treatment with paroxetine 10-40 mg, clomipramine 12.5-50 mg, sertraline 50-200 mg, fluoxetine 20-40 mg, and citalopram 20-40 mg is usually effective in delaying ejaculation [244-249] [242, 245-269] (Table 10) A meta-analysis of published data suggests that paroxetine exerts the strongest ejaculation delay, increasing IELT approximately 8.8 fold over baseline [244]. However, the use of these drugs is limited by the lack of Food and Drug Administration (FDA), European Medicines Agency (EMEA) or other regulatory agency approval and therefore by the need to prescribe “off-label” [270]. Ejaculation delay usually occurs within 5-10 days of starting treatment, but the full therapeutic effect may require 2-3 weeks of treatment and is usually sustained during long-term use (Figure 8) [271]. Although tachyphylaxis is uncommon, some patients report a reduced response after 6-12 months of treatment.

**Figure 8:**
Selective serotonin re-uptake inhibitors produce ejaculatory delay within 5-10 days. [246]
Adverse effects are usually minor, start in the first week of treatment, gradually disappear within 2-3 weeks and include fatigue, yawning, mild nausea, diarrhea or perspiration. Hypoactive desire and ED are infrequently reported and appear to have a lower incidence in non-depressed PE men compared to depressed men treated with SSRIs [272]. This effect may be related to the protective action of increased oxytocin release in men with lifelong PE [88].

Neurocognitive adverse effects include significant agitation and hypomania in a small number of patients, and treatment with SSRIs should be avoided in men with a history of bipolar depression [273]. Systematic analysis of randomized controlled studies indicates no statistical evidence of an increased risk of suicide with SSRIs in adults [274, 275]. However, an FDA meta-analysis of all pediatric randomized clinical trials (RCTs) of antidepressants suggested a small increase in the risk of suicidal ideation or suicide attempts in youth [275]. This effect is quite variable across SSRIs and it is not clear if that variance is a measurement error or represents a real difference between medications. Furthermore, systematic questionnaire data, epidemiological and autopsy studies, recent cohort surveys, and the negligible number of suicides that occur in youth taking antidepressants at the time of death do not support the hypothesis that SSRIs induce suicidal acts and suicide, raising concerns over ascertainment artifacts in the adverse event report method [274]. However, it would seem prudent not to prescribe SSRIs to young men aged 18 years or less, and to men with a depressive disorder, particularly when associated with suicidal thoughts. Patients should be advised to avoid sudden cessation or rapid dose reduction of SSRIs which may be associated with a SSRI Withdrawal Syndrome, characterized by dizziness, headache, nausea, vomiting and diarrhoea and occasionally agitation, impaired concentration, vivid dreams, depersonalization, irritability and suicidal ideation [276, 277]. Platelet serotonin release has an important role in haemostasis [278] and SSRIs, especially with concurrent use of aspirin and non-steroidal anti-inflammatory drugs, which is associated with increased risk of upper gastro-intestinal bleeding [279, 280]. Priapism is a rare adverse effect of SSRIs and requires urgent medical treatment [281-283]. Long term SSRI use may be associated with weight gain and an increased risk of type-2 diabetes mellitus. [284].

**Level 1 evidence to support the efficacy and safety of off-label daily dosing of SSRIs (paroxetine, sertraline, citalopram, fluoxetine, and the serotonergic tricyclic, clomipramine) and off-label on-demand dosing of clomipramine for the treatment of PE**

**Grade A Recommendation**

---

**b) Daily treatment with a1-adrenoceptor antagonists**

Ejaculation is a sympathetic spinal cord reflex which could theoretically be delayed by a1- adrenergic blockers. Several researchers have reported their experience with the selective a1 adrenergic blockers, alfuzosin and terazosin, in the treatment of PE. **(Table 11)** Both drugs are approved only for the treatment of lower urinary tract symptoms (LUTS) in men with obstructive benign prostatic hyperplasia (BPH). In a double blind placebo-controlled study, Cavallini reported that both alfuzosin (6 mg/day) and terazosin (5 mg/day) were effective in delaying ejaculation in approximately 50% of the cases [54]. Similarly, Basar reported that terazosin was effective in 67% of men [55]. However, both studies were limited by the use of subjective study endpoints of patient impression of change and sexual satisfaction, and they did not evaluate actual ejaculatory latency. Additional controlled studies are required to determine the role of a1-blockers in the treatment of PE.

**Level 2 evidence to support the efficacy and safety of off-label daily dosing of a1-adrenoceptor antagonists in the treatment of PE. Further evidence-based research is encouraged**

**Grade D Recommendation**

---

**c) On-demand treatment with Selective Serotonin Reuptake Inhibitors**

Administration of clomipramine, paroxetine, sertraline and fluoxetine 4-6 hours before intercourse is modestly efficacious and well tolerated but is associated with substantially less ejaculatory delay than daily treatment [70, 285-287]. **(Table 12)** Following acute on-demand administration of an SSRI, increased synaptic 5-HT levels are down-regulated by presynaptic 5-HT1A and 5-HT1B/1D autoreceptors to prevent over-stimulation of postsynaptic 5-HT2C receptors. However, during chronic daily SSRI administration, a series of synaptic adaptive processes which may include presynaptic 5-HT1A and 5-HT1B/1D receptor desensitization greatly enhances synaptic 5-HT levels, resulting in superior fold increases in IELT compared to on-demand administration. [86] On-demand treatment may be combined with either an initial trial of daily treatment or concomitant low dose daily treatment [70, 285, 286].

The assertion that on-demand drug treatment of PE is preferable to daily dosing parallels the rationale for the treatment of ED but is contrary to the results of the only PE drug preference study [65]. The methodology of this trial was not ideal as it involved comparison of preference for daily paroxetine, on-demand clomipramine, or topical anesthetic based only on subject information/questionnaires and not on actual use of the drug/s. Well-designed preference trials will provide additional insight into the role of on-demand...
dosing. While many men suffering from PE who engage in sexual intercourse infrequently may prefer on-demand treatment, many men in established relationships prefer the convenience of daily medication.

d) On-demand treatment with Dapoxetine

Dapoxetine is an investigational SSRI with a pharmacokinetic profile suggesting a role as an on-demand treatment for PE [288-291]. Dapoxetine has a Tmax of 1.4-2.0 hours and a mean half-life of 0.5-0.8 hours with a rapid decline of plasma levels to about 5% of Cmax at 24 hours, ensuring rapid absorption and achievement of peak plasma concentration with minimal accumulation [292]. Both plasma concentration and area under the curve (AUC) are dose dependent up to 100 mg, and are unaffected by repeated daily dosing, food or alcohol [293-295]. No drug-drug interactions associated with dapoxetine, including phosphodiesterase inhibitor drugs, have been reported [296].

In randomized, double-blind, placebo-controlled, multicenter, phase III 12 week clinical trials involving 2,614 men with a mean baseline IELT ≤ 2 minutes, dapoxetine 30 mg or 60 mg was more effective than placebo for all study endpoints (Figure 9) [291] (Table 12). Arithmetic mean IELT increased from 0.91 minutes at baseline to 2.78 and 3.32 minutes at study end with dapoxetine 30 and 60 mg respectively compared to a 1.75 minutes with placebo. However, as IELT in subjects with PE is distributed in a positively skewed pattern, reporting IELTs as arithmetic means may over-estimate the treatment response, and the geometric mean IELT is more representative of the actual treatment effect [66, 260, 271, 297, 298]. Pooled data from 4 phase 3 dapoxetine studies report arithmetic and geometric mean IELTs of 1.9 and 1.2 for placebo, 3.1 and 2.0 for dapoxetine 30 mg, and 3.6 and 2.3 for dapoxetine 60mg respectively. This represents a 1.6, 2.5, and 3.0 fold increase over baseline geometric mean IELT for placebo, and dapoxetine 30 and 60 mg respectively Dapoxetine treatment is also associated with significant improvements in patient reported outcomes (PROs) of control, distress and sexual satisfaction (Figure 9). Mean patient rating of control-over-ejaculation as fair, good, or very good increased from 2.8% at baseline to 51.8% and 58.4% at study end with dapoxetine 30 and 60 mg respectively. Treatment related side effects were uncommon, dose dependent, included nausea, diarrhea, headache, and dizziness, and were responsible for study discontinuation in 4% (30mg) and 10% (60mg) of subjects. There was no indication of an increased risk of suicidal ideation or suicide attempts and little indication of withdrawal symptoms with abrupt dapoxetine cessation [299].

There have been 3 independent studies of the efficacy of dapoxetine administered on a daily basis, inconsistent with the manufacturer’s prescribing information. [300-302]

Dapoxetine, despite its modest effect upon ejaculatory latency, has a major place in the management of PE which will eventually be determined by market forces once the challenges of global regulatory approval have been met.

Level 1 evidence to support the efficacy and safety of on-demand dosing of dapoxetine for the treatment of PE

Grade A Recommendation

The decision to treat PE with either current off-label SSRI daily dosing or on-demand dosing of dapoxetine must be based on the treating physician’s assessment of individual patient requirements.

e) On-demand treatment with Tramadol

Tramadol is a centrally acting synthetic opioid analgesic with an unclear mode of action which is thought to include binding of parent and M1 metabolite to μ-opioid receptors and weak inhibition of re-uptake
Figure 9. A. Dapoxetine increased intravaginal ejaculatory latency time (IELT) from 0.91 minutes at baseline to 2.78 and 3.32 minutes at study end with dapoxetine 30 and 60 mg respectively. B. % of subjects rating Control over Ejaculation as fair, good, or very good increased from 3.1% at baseline to 51.8% and 58.4% at study end with dapoxetine 30 and 60 mg respectively. C. % of subjects rating Sexual Satisfaction as fair, good or very good increased from 53.6% at baseline to 70.9% and 79.2% with dapoxetine 30mg and 60mg respectively. (rating scale 0-5 scale, 0=very poor & 5=very good) [507]
of GABA, norepinephrine, and serotonin [303]. The efficacy of on-demand tramadol in the treatment of PE was recently reported in 2 RCTs [304, 305]. (Table 13) Both studies were limited by methodological considerations, and although tramadol is reported to have a lower risk of dependence than traditional opioids, its use as an on-demand treatment for PE is limited by the potential risk of addiction [306].

In community practice, dependence does occur but appears minimal [307]. Adams et al reported abuse rates of 0.7% for tramadol compared to 0.5% for non-steroidal anti-inflammatory drugs and 1.2% for hydrocodone based upon application of a dependency algorithm as a measure of persistence of drug use [308]. Additional flexible dose, long term follow-up studies to evaluate efficacy, safety and in particular, the risk of opioid addiction are required.

**Level 2 evidence to support the efficacy and safety of off-label daily dosing of off-label tramadol in the treatment of PE. Further evidence-based research is encouraged**

**Grade D Recommendation**

### f) Topical anesthetics

The use of topical local anesthetics such as lignocaine and/or prilocaine as a cream, gel, or spray is well established and is moderately effective in retarding ejaculation. [309-321] (Table 14)

Their use may be associated with significant penile hypo-anesthesia and possible transvaginal absorption, resulting in vaginal numbness and resultant female anorgasmia unless a condom is used. A recent study reported that a metered-dose aerosol spray containing a eutectic mixture of lidocaine and prilocaine (TEMPE®) produced a 2.4 fold increase in baseline IELT and significant improvements in ejaculatory control and both patient and partner sexual quality-of-life [320]. The physiochemical characteristics of this eutectic mixture and the spray delivery system have been designed to both optimize and limit tissue penetration to the mucosa of the glans penis and minimize penetration of the keratinized skin of the penile shaft [322]. Penile hypoanesthesia was reported by 12% of subjects; skin irritation or burning was not observed.

**Level 1 evidence to support the efficacy and safety of off-label on-demand current off-label topical anaesthetics in the treatment of PE**

**Grade B Recommendation**

### g) Intracavernous injection of vasoactive drugs

Intracavernous self-injection treatment of PE has been reported but is currently without any evidence-based support for efficacy or safety [323]. Fein reported an open study of 8 men treated with a combination of papaverine and phentolamine administered by intracavernous auto-injection where treatment success was defined as prolongation of erection after ejaculation and not by any measure of ejaculatory latency. In the absence of well-controlled studies, treatment of PE by intracavernous auto-injection cannot be routinely recommended but may be of value in treatment refractory informed subjects.

**Level 2 evidence to support the efficacy and safety of off-label penile injection therapy in the treatment of PE. Further evidence-based research is encouraged**

**Grade D Recommendation**

h) Phosphodiesterase inhibitors

Phosphodiesterase type-5 isoenzyme (PDE5) inhibitors, sildenafil, tadalafil, and vardenafil, are effective treatments for ED. Several authors have reported experience with PDE-5 inhibitors alone or in combination with SSRIs as a treatment for PE [212, 213, 316, 324-338]. (Table 15) The putative role of PDE-5 inhibitors as a treatment for PE is speculative and based only upon the role of the NO/cGMP transduction system as a central and peripheral mediator of inhibitory non-adrenergic, non-cholinergic nitricergic neurotransmission in the urogenital system [339]. A recent systematic review of 14 studies (n=1,102) on the PDE5i drug treatment of PE failed to provide robust empirical evidence to support a role of PDE-5 inhibitors in the treatment of PE with the exception of men with PE and co-morbid ED [180]. Only one study fulfilled the contemporary criteria of ideal PE drug trial design [340, 341], and this study failed to confirm any significant treatment effect on IELT [332]. Caution should be exercised in interpreting PDE5i and on-demand SSRI treatment data in inadequately designed studies and their results must be regarded as unreliable.

At this time, Level 4 evidence to support the efficacy and safety of off-label on-demand or daily dosing of PDE-5 inhibitors in the treatment of lifelong PE in men with normal erectile function. Further evidence-based research is encouraged to further understand conflicting data

**Grade D Recommendation**

i) Premature ejaculation and co-morbid ED

Recent data demonstrate that as many as one third to one half of subjects with ED also experience PE [104, 105]. There is evidence to suggest that PDE5i’s alone or in combination with a SSRI may have a role in the management of acquired PE in men with co-morbid ED [324, 329, 333]. In 45 men with PE and co-morbid ED treated with flexible doses of sildenafil (50-100mg) for periods of 1-3 months, Li et al reported improved erectile function in 40 men (89%) and reduced severity of PE in 27 men (60%) [329]. In a group of 37 men with primary or acquired PE and a baseline IIIEF EF domain score of 20.9 consistent with mild ED, Sommer et al reported and a 9.7 fold IELT increase and normalization of erectile function (IIIEF EF 26.9) with vardenafil treatment as opposed to lesser 4.4 fold IELT increase with on-demand sertraline [333].

The high correlation between improved erectile function with sildenafil and reduced severity of PE reported by Li [329] and the superior IELT fold-increase observed with vardenafil compared to sertraline reported by Sommer et al indicates that the PDE5i-related reduced PE severity is due to improved erectile function [333]. The IELT fold-increase observed by Sommer et al with on-demand sertraline (4.4) is less than that reported in reviewed studies on men with normal erectile function (mean 5.57, range 3.0-8.5) [213, 324, 330, 331], suggesting that men with PE and co-morbid ED are less responsive to on-demand SSRIs and are best managed with a PDE5i alone or in combination with an SSRI. The proposed mechanism of action of PDE5i’s as monotherapy or in combination with a SSRI in the treatment of acquired PE in men with co-morbid ED includes a reduction in performance anxiety due to better erections, down-regulation of the erectile threshold to a lower level of arousal so that increased levels of arousal are required to achieve the ejaculation threshold and reduction of the erectile refractory period [332, 342, 343], and reliance upon a second and more controlled ejaculation during a subsequent episode of intercourse.

</table>
penis augmentation in the treatment of lifelong PE refractory to behavioural and/or pharmacological treatment. [344-346] The role of surgery in the management of PE remains unclear until the results of further studies have been reported.

**Level 4 evidence i.e. no evidence, to suggest that selective dorsal nerve neurotomy or hyaluronic acid gel glans penis augmentation are effective treatments for PE. Surgery may be associated with permanent loss of sexual function and is contraindicated in the management of PE**

**Grade D Recommendation**

3. THE FUTURE OF PE DRUG DEVELOPMENT

Several in-vitro and animal studies have demonstrated that the desensitization of 5-HT1A receptors, increased activation of postsynaptic 5-HT2C receptors, and the resultant higher increase in synaptic 5-HT neurotransmission seen in daily dosing of SSRI class drugs can be acutely achieved by blockade of these receptors by administration of an on-demand SSRI and a 5-HT1A receptor antagonist [347-349]. One study reports that PE men refractory to daily paroxetine can be salvaged by the addition of high dose daily pindolol, a non-selective ß-blocker with partial beta-agonist activity and a 5-HT1A receptor antagonist [350].

An increasing number of studies report the involvement of central oxytocinergic neurotransmission in the ejaculatory process. In human males, plasma oxytocin levels are elevated during penile erection and at the time of orgasm [351, 352]. Electrical stimulation of the dorsal penile nerve produced excitation in about half of the oxytocin cells in the PVH and SON of rats [353, 354]. In a rat model, systematic administration of oxytocin facilitated ejaculation by reducing the number of intromissions required for ejaculation, ejaculation latencies, and post-ejaculation intervals [355, 356]. The use of oxytocin or vasopressin receptor antagonists may also have a role but there have been no reports of their efficacy in the treatment of PE [357].

Drug combinations of on-demand rapid acting SSRI and 5-HT1A receptor antagonist and/or oxytocin receptor antagonists, or single agents that target multiple receptors may form the foundation of more effective future on-demand medication.

**4. THE OFFICE MANAGEMENT OF PREMATURE EJACULATION: A BRIEF SUMMARIZATION**

Men with premature ejaculation should be evaluated with a detailed medical and sexual history, a physical examination, and appropriate investigations to establish the true presenting complaint, identify obvious biological causes such as medication or recent pelvic surgery, and uncover sufficient detail to establish the optimal treatment plan. **(Figure 10)**

Relevant information to obtain from the patient includes:

1. A basic medical history, including the use of prescribed and recreational medications
2. The cultural context and developmental history of the disorder, including whether the premature ejaculation is global or situational, lifelong or recent in its development,
3. Measures of the quality of each of the three phases of the sexual response cycle: desire, arousal, and ejaculation, since the desire and arousal phases may impact the ejaculatory response,
4. Details about the ejaculatory response, including the patient’s subjective assessment of his intravaginal ejaculatory latency time (IELT) and sense of ejaculatory control, the level of sexual dissatisfaction and distress, the frequency of sexual activity, and so on,
5. The partner’s assessment of the situation, including whether the partner suffers from female sexual dysfunction (FSD), and
6. Assessment of the sexual and overall relationship

**Level 3 evidence to suggest that evaluation of men presenting with self reported PE should include a full medical/sexual history, a focused physical examination, inventory assessment of erectile function and any investigations suggested by these findings**

**Grade C Recommendation**

Comprehensive and helpful decision trees that incorporate inclusion and exclusion criteria and that address most of the above points have recently been published in several sources [63, 358]. Several paper and pencil instruments that enable the health provider to tap into some or most of the specific domains above are also available [237, 359]. Although more typically used in the experimental study of PE, psychophysiological and/or electrophysiological evaluation can sometimes play a limited secondary role in the evaluation of early ejaculation. For example, visual sexual and penile stimulation administered in the laboratory elicits ejaculation in nearly 60% of men self-identified as having PE, compared with only about 8% of men having no ejaculatory disorder [69, 360]. The former group also reports a greater proximity to ejaculation and less ejaculatory control in response to such stimulation. In addition, PE men tend to exhibit stronger event-related potentials (ERP’s) to stimulation of the afferent pudendal nerves and shorter latencies in the efferent processes involved in bulbocavernosal contractions.
eliciting seminal expulsion [361-363]. Although most such evaluations can aid in the understanding of potential causes or mediators of PE, because they are time-consuming, labor intensive, and not yet reliably discriminating at an individual level, it is too early to assume a role for these procedures in the verification of a PE diagnosis.

Men with premature ejaculation secondary to erectile dysfunction, other sexual dysfunction, or genitourinary infection should receive appropriate etiology specific treatment. Men with lifelong premature ejaculation are usually best managed with pharmacotherapy. Men with significant contributing psychogenic or relationship factors may benefit from concomitant cognitive-behavioral therapy. [210-212] Recurrence of premature ejaculation is highly likely to occur following withdrawal of treatment. Men with acquired premature ejaculation can be treated with pharmacotherapy and/or cognitive-behavioral therapy according to patient/partner preference. [210-212] Restoration of ejaculatory control in men with acquired premature ejaculation is likely to occur following completion of treatment but this result appears to be the exception in men with lifelong PE. Cognitive-behavioral therapy may augment pharmacotherapy to enhance relapse prevention.

V. DELAYED EJACULATION, ANEJACULATION, AND ANORGASMIA: DEFINITION, EPIDEMIOLOGY, & PATHOPHYSIOLOGY

Any psychological or medical disease or surgical procedure which interferes with either central control of ejaculation or the peripheral sympathetic nerve supply to the vas and bladder neck, the somatic efferent nerve supply to the pelvic floor, or the somatic afferent nerve supply to the penis can result in delayed ejaculation, anejaculation and anorgasmia. As such, the causes of delayed ejaculation, anejaculation and anorgasmia are manifold (Table 16).

The progressive loss of the fast conducting peripheral sensory axons which begins to be apparent in the third decade of life, and the dermal atrophy, myelin collagen infiltration, and pacinian corpuscle degeneration observed in older men may result in a degree of age related degenerative penile hypo-anesthesia and difficulty in achieving the ejaculatory threshold. This is anecdotally exaggerated in men with ED treated with intracavernous pharmacotherapy and is often compounded by the loss of pelvic floor muscle tone seen in the similar aged, post-menopausal and often multiparous sexual partners of these men.

Figure 10. Management algorithm for premature ejaculation
1. DEFINITION, TERMINOLOGY, AND CHARACTERISTICS OF DELAYED EJACULATION

Delayed (DE), Retarded Ejaculation (RE), or Inhibited Ejaculation (IE) are probably the least common, least studied, and least understood of the male sexual dysfunctions. Yet its impact is significant in that it typically results in a lack of sexual fulfillment for both the man and his partner, an effect further compounded when procreation is among the couple’s goals of sexual intercourse.

Problems with “difficulty” in ejaculating may range from varying delays in the latency to ejaculation to complete inability to ejaculate (anejaculation). Reductions in the volume, force, and sensation of ejaculation may occur as well. At the extremes are anejaculation (time) and retrograde ejaculation (direction), but more commonly encountered is Inhibited or Retarded ejaculation (DE). Partially retarded ejaculation (PRE) is sometimes observed in men who attempt to control ejaculation by suppressing the muscular contractions associated with ejaculation. These men experience diminished pleasure and sensation as semen is released during emission, and the ejaculatory sensations are dulled through attempted suppression of striate muscle response. PRE is sometimes observed in men with PE as they first attempt to consciously delay their orgasm. A final disorder, anorgasmia, refers to a perceived absence of the orgasm experience, independent of whether or not any or all of the physiologic concomitants of ejaculation have taken place.

a) Terminology and definition

The terminology for difficulties achieving ejaculation is far from precise. Retarded ejaculation, delayed ejaculation, inadequate ejaculation, inhibited ejaculation, idiopathic anejaculation, primary impotence ejaculations, and psychogenic anejaculation have all been used synonymously to describe a delay or absence of male orgasmic response. If a distinction is to be made, usually inhibited ejaculation is characterized by the complete absence of ejaculation, although even here no clear consensus exits. In this review, the terminology Retarded Ejaculation (RE) or the preferred Delayed Ejaculation (DE) is meant to describe any and all of the ejaculatory disorders resulting in a delay or absence of ejaculation.

The DSM-IV-TR defines DE as the persistent or recurrent delay in, or absence of, orgasm after a normal sexual excitement phase during sexual activity that the clinician, taking into account the person’s age, judges to be adequate in focus, intensity, and duration. The disturbance causes marked distress or interpersonal difficulty; it should not be better accounted for by another Axis I (clinical) disorder or caused exclusively by the direct physiologic effects of a substance or a general medical condition [364]. Similarly, the World Health Organization 2nd Consultation on Sexual Dysfunction defines DE as the persistent or recurrent difficulty, delay in, or absence of attaining orgasm after sufficient sexual stimulation, which causes personal distress [75].

There are no clear criteria as to when a man actually meets the conditions for DE, as operationalized criteria do not exist. Given that most sexually functional men ejaculate within about 4-10 minutes following intromission [193], a clinician might assume that men with latencies beyond 25 or 30 minutes (21-23 min represents about two standard deviations above the mean) who report distress or men who simply cease sexual activity due to exhaustion or irritation qualify for this diagnosis. Such symptoms, together with the fact that a man and/or his partner decide to seek help for the problem, are usually sufficient for a DE diagnosis.

b) The prevalence of retarded or delayed ejaculation

The prevalence of ejaculatory disorders is unclear, partly because of the dearth of normative data for defining the duration of “normal” ejaculatory latency, particularly regarding the right “tail” of the distribution (i.e., beyond the mean latency to orgasm). Furthermore, larger epidemiologic studies have not subdivided various types of ejaculatory disorders (e.g., delayed vs. absent), further limiting our knowledge of the prevalence of DE. In general,
DE is reported at low rates in the literature, rarely exceeding 3% [85, 365, 366]. Since the beginning of sex therapy, DE was seen as a clinical rarity, with Masters and Johnson [224] initially reporting only 17 cases. Apfelbaum [367] reported 34 cases and Kaplan [368] fewer than 50 cases in their respective practices. However, based on clinical experiences, some urologists and sex therapists are reporting an increasing prevalence of DE [366, 369, 370]. The prevalence of DE appears to be moderately and positively related to age, which is not surprising in view of the fact that ejaculatory function as a whole tends to diminish as men age.

c) Characteristics of men with delayed ejaculation

Failure of ejaculation can be a lifelong primary event or an acquired or secondary problem. It may be global and happen in every sexual encounter or it may be intermittent or situational. Normative descriptive data from large samples of DE men have not been available, but a recent analysis identified 25% of a clinical sample suffering from primary DE, with the remainder reporting a secondary problem [365]. While coital anorgasmia is frequently the treatment driver (especially for extremely religious individuals referred for fertility problems), heterosexual men also seek treatment when distressed by their inability to achieve orgasm in response to manual, oral, or vaginal stimulation by their partner. Data available on homosexual men are limited, but distress/frustration associated with not being able to ejaculate by any desired/chosen mode of stimulation remains fairly constant across all men, regardless of sexual orientation [371].

Many men with secondary DE can masturbate to orgasm, whereas others, for multiple reasons, will or can not. Loss of masturbatory capacity secondary to emotional or physical trauma is also seen. Approximately 75% of one clinical sample [365] could reach orgasm through masturbation, while the remainder either would not or could not. Interestingly, correlational evidence suggests that masturbatory frequency and style may be predisposing factors for DE, since a substantial portion of men who present with coital DE report high levels of activity with an idiosyncratic masturbatory style [372, 373].

Similar to men with other types of sexual dysfunction, men with DE indicate high levels of relationship distress, sexual dissatisfaction, anxiety about their sexual performance, and general health issues—significantly higher than sexually functional men. In addition, along with other sexually dysfunctional counterparts, men with DE typically report lower frequencies of coital activity [373]. A distinguishing characteristic of men with DE—and one that has implications for treatment—is that they usually have little or no difficulty attaining or keeping their erections—in fact they are often able to maintain erections for prolonged periods of time. But despite their good erections, they report low levels of subjective sexual arousal, at least compared with sexually functional men [374].

2. PATHOPHYSIOLOGIES COMMONLY LEADING TO EJACULATORY DISORDERS, INCLUDING DE

a) Congenital disorders

1) Mullerian Duct Obstruction

As the male fetus develops, the Mullerian ducts normally disappear from above downwards under the influence of Mullerian inhibitory factor (MIF), which is produced by the Sertoli cells in the primitive testis. Failure of complete absorption may leave a small Mullerian duct remnant at the lower end that lies between the ejaculatory ducts. The Wolffian (mesonephric) ducts are composed of three distinct areas. The upper part forms the epididymis and distal vas deferens, while the proximal vas deferens, seminal vesicle, and ejaculatory duct are derived from the middle area. The most caudal part is the common mesonephric duct, from which the ureteric bud springs at approximately 4 weeks of development: this becomes the ureter and will induce the metanephric blastema to form the kidney. The urogenital sinus reabsorbs the lower end of this structure, and the ureteric orifices are thus separated from the vasa deferentia, seminal vesicles and ejaculatory ducts. Several complex anomalies may occur in this area leading to ectopic opening of the vas deferens and sometimes associated with anorectal anomalies [375]. If too much of the proximal vas precursor is absorbed, a variable amount of the proximal vas, seminal vesicle, and/or ejaculatory duct may be absent. There may also be coexisting abnormalities in the ipsilateral kidney or ureter.

Persistence of a small remnant of the Mullerian duct may lead to a cyst forming between the ejaculatory ducts which can become obstructed and cause diminution of the volume of the ejaculate and infertility. Haemospermia is not uncommon in these patients. Seminal analysis shows the changes characteristic of ejaculatory duct obstruction with a small volume (less than 1.5 ml), acid pH, and little or no fructose. Both vasa are palpable and the epididymes usually feel distended. The diagnosis is established by transrectal ultrasound scan (TRUS), and the lesion can be delineated by percutaneous puncture of the cyst with instillation of radio opaque medium. The cyst can be incised or deroofed endoscopically after delineating its extent by injection of blue dye (see below). Improvement in ejaculate volume and seminal quality follows in most cases [376].

2) Wolffian Duct abnormalities

Congenital anomalies may be either sporadic, with
a localized defect in the proximal part of the vas deferens, or a more generalized maldevelopment due to a systemic genetic abnormality. Local Wolffian duct abnormality involves loss of a variable amount of the vas deferens, seminal vesicle, and/or ejaculatory duct, and sometimes part of the ipsilateral urinary system as well. This may be associated with maldevelopment of the bladder neck and trigone, which fails to close effectively and thereby produces retrograde ejaculation. Bilateral abnormalities are often associated with carriage of the cystic fibrosis gene [377]. Unilateral absence of the vas deferens has been observed in 5%, and bilateral absence in 18% of 370 azoospermic males with normal serum FSH levels investigated by the author [378].

3) PRUNE BELLY SYNDROME

Patients with prune belly syndrome have normal libido, erections, and orgasms. Most have abnormal ejaculation and probably emission. In a study involving nine patients, seven had retrograde ejaculation and two produced ejaculates [379]. Five patients provided semen or urine passed after masturbation. Two produced ejaculated semen. One of the ejaculated specimens consisted of 4.5 cc of fluid indistinguishable from urine and one was 2.5 cc of fluid with the appearance of watery semen. Post masturbation urine specimens were of normal urinary appearance. None of the specimens contained sperm and no mention was made of the fructose content. Abnormal ejaculation thus appears to be present in the vast majority of patients with prune belly syndrome. Whether the primary abnormality is retrograde ejaculation or lack of emission is not clear.

b) Traumatic damage

1) IMPERFORATE ANUS

Ejaculatory duct obstruction may follow correction of imperforate anus. The pull through procedure passes close to the posterior aspect of the prostate, and damage is most likely if there has been closure of a recto urethral fistula. Analysis of 20 subfertile males who had repair of imperforate anus in infancy indicated that 7 had no ejaculate, 11 were azoospermic, 1 was severely oligozoospermic, and only 1 had a normal sperm concentration in a very small volume ejaculate [380]. Both vasa were blocked in 5 men and one vas in a further 8 patients, apparently as a result of the original operative procedure.

2) OPERATIONS ON THE PROSTATE

Antegrade (normal) ejaculation requires a closed bladder neck (and proximal urethra). Surgical procedures that compromise the bladder neck closure mechanism may result in retrograde ejaculation. Transurethral incision of the prostate (TUIP) results in retrograde ejaculation in 5% [381] to 45% [382] of patients and is probably related to whether one or two incisions are made and whether or not the incision includes primarily the bladder neck or extends to the level of the verumontanum. The importance of contraction of the urethral smooth muscle at the level of the verumontanum has been hypothesized to be important in preventing retrograde ejaculation [383]. Transurethral resection of the prostate (TURP) carries a higher incidence of retrograde ejaculation than does TUIP. The reported incidence of retrograde ejaculation following TURP ranges from 42% [384] to 100% [385]. Although these men may have some antegrade ejaculation and usually experience orgasmic sensation, both events may be reduced as part of the changes that occur in the male sexual response as a man ages. Retrograde ejaculation and failure of emission can be distinguished by examination of a post masturbatory specimen of urine for the presence of spermatozoa and fructose. After radical prostatectomy, ejaculation is bound to be lost since the seminal vesicles are removed with the prostate gland. Erectile impotence was common until detailed anatomical studies showed where the parasympathetic nerves ran on the surface of the prostate gland, and a nerve sparing operative technique was developed [386]. A sensation of orgasm is often preserved despite loss of ejaculation.

Retrograde ejaculation can be surgically treated with bladder neck reconstruction but results remain consistently poor [386]. Drug treatment is the most promising approach. As mentioned earlier, alpha-adrenergic sympathetic nerves mediate both bladder neck closure and emission. Several sympathomimetic agents have been described as useful with mixed results [387]. These drugs include pseudoephedrine and ephedrine, and phenylpropanolamine. These agents work by stimulating the release of noradrenaline from the nerve axon terminals but may also directly stimulate both alpha- and beta-adrenergic receptors. The most useful is pseudoephedrine which is administered at a dose of 120 mg 2-2.5 hours precoital. The tricyclic antidepressant, Imipramine, which blocks the reuptake of noradrenaline by the axon from the synaptic cleft, is also occasionally useful [388]. The usual dose is 25mg twice daily. Current thinking is that long-term treatment with imipramine is likely to be more effective. While medical treatment may not always produce normal ejaculation, it may result in some prograde ejaculation. In patients who do not achieve antegrade ejaculation with surgery or medication, sperm retrieval and artificial insemination is an alternative approach. The basic method of sperm retrieval involves recovery of urine by either catheter or voiding after masturbation, and then centrifugation and isolation of the sperm.

3) INFECTIVE DISORDERS

Genital infection such as gonorrhoea or non specific
urethral strictures can produce stricture formation in any part of the male reproductive tract, especially if treatment is delayed. Urinary infection, especially if complicated by epididymitis, can also produce obstruction that may be situated at ejaculatory duct level.

Routine vasography in subfertile men with azospermia and normal serum FSH levels revealed post-infective vasal blocks in 8% and acquired ejaculatory duct obstruction in 4% [378]. Schistosomiasis is endemic in large parts of Africa and is seen with increasing frequency in tourists returning from Africa who have contracted the disease while enjoying water sports: Lake Malawi has acquired an evil reputation in this respect. The disease may present with haemospermia [389], and fibrosis and calcification may lead to genital obstruction. Genito urinary tuberculosis can cause great damage to the male reproductive tracts, and since healing occurs with calcification, the lesions may be irreparable. Plain X ray will often show the extent of the disease.

Haemospermia is seldom as ominous a symptom as haematuria, but this complaint should not be ignored. Analysis of the findings in 81 patients revealed that an inflammatory cause could be defined in most men under 30 years of age; however, there were a few (8%) with more serious disease including carcinoma of prostate and bladder [390]. It should be remembered, also, that schistosomiasis and tuberculosis could present in this way. Routine investigation of haemospermia by TRUS not uncommonly reveals the presence of small stones in the ejaculatory ducts, which may be associated with obstruction and dilatation of the seminal vesicles. Such stones usually pass spontaneously.

c) Neurological disorders

1) **Spinal cord injury**

The ability to ejaculate is severely impaired by spinal cord injury (SCI). Bors and Comarr highlighted the impact of the level and completeness of SCI on the post-injury erectile and ejaculatory capacity (Table 17) [391, 392]. Unlike erectile capacity, the ability to ejaculate increases with descending levels of spinal injury. Less than 5% of patients with complete upper motor neuron lesions retain the ability to ejaculate. Ejaculation rates are higher (15%) in patients with both lower motor neuron lesions and an intact throracolumbar sympathetic outflow. Approximately 22% of patients with an incomplete upper motor neuron lesion and almost all men with incomplete lower motor neuron lesions retain the ability to ejaculate. In those patients capable of successful ejaculation, the sensation of orgasm may be absent and retrograde ejaculation often occurs.

Several techniques for obtaining semen from spinal cord injured men with ejaculatory dysfunction have been reported. The intrathecal administration of the anticholinesterase inhibitors neostigmine and subcutaneous physostigmine to induce ejaculation is more of historical interest and is no longer used due to a 60% risk of autonomic dysreflexia, especially in men with injuries above the T5 level [393, 394]. Vibratory stimulation is successful in obtaining semen in up to 70% of men with spinal cord injury [395]. This technique induces a reflexogenic ejaculation via the sacral roots and the ejaculatory coordination center in the upper thoracolumbar spinal cord. The use of electro-ejaculation to obtain semen by electrical stimulation of efferent sympathetic fibers of the hypogastric plexus is an effective and safe method of obtaining semen. Brindley et al have reported that 71% of men with spinal cord injury who underwent electro-ejaculation achieved ejaculation [396]. However, both are associated with a significantly higher risk of autonomic dysreflexia than electro-ejaculation. Pre-treatment with a fast acting vasodilator such as nifedipine minimizes the risk of severe hypertension, should autonomic dysreflexia occur with either form of treatment [397].

Several authors have reported the use of midodrine in spinal cord injured patients. In recent studies, antegrade or retrograde ejaculation occurred in 22-64.6% of spinal cord injured patients who had previously failed to respond to penile vibratory stimulation, following treatment with midodrine 30–120 min before a new stimulation. [398, 399]

If the spinal reflex arc is intact, a hypogastric plexus stimulator can provide ejaculation in the comfort and security of the patients’ home [400]. Percutaneous aspiration of semen from the vas deferens has also been reported as a means of harvesting semen for use with artificial reproductive techniques [401].

Semen collected from men with spinal cord injury is often initially senescent and of poor quality with a low sperm count and reduced sperm motility but may improve with subsequent ejaculations. This poor semen quality may be due to chronic urinary tract infection, sperm content with urine, chronic use of various medications, elevated scrotal temperature due to prolonged sitting, and stasis of prostatic fluid. Testicular biopsies in spinal cord injured men demonstrate a wide range of testicular dysfunction including hypospermatogenesis, maturation arrest, atrophy of seminiferous tubules, germinal cell hypoplasia, interstitial fibrosis, and Leydig cell hyperplasia. In addition, prostatitis secondary to prolonged catheterization, epididymitis, and epididymo-orchitis can precipitate obstructive ductal lesions and testicular damage. Ohl et al reported that sperm density and motility were higher in those with incomplete lesions [402]. In a recent collective analysis of 40 paraplegic patients, 22 successfully produced pregnancies by natural insemination or assisted reproductive techniques [403].

2) **Para-aortic lymphadenectomy**

This operation is usually done to clear lymph node me-
tastases from testicular tumors, when the sympathetic nerves and ganglia may also be removed leading to loss of ejaculation. Early studies showed that up to three quarters of patients lost antegrade ejaculation after full bilateral retroperitoneal lymph node dissection. As a result of careful anatomical studies, the technique of retroperitoneal lymph node dissection has been modified with nerve sparing so that antegrade ejaculation is now maintained in 70-90% of patients.

One quarter of the patients who complete chemotherapy for advanced testicular tumor have residual masses in the para aortic region [404]. Among 231 consecutive patients undergoing para aortic lymphadenectomy after chemotherapy at the Royal Marsden Hospital, there was persistent undifferentiated tumor in 21% [405]. In an experience of 186 patients, a nerve sparing operative technique introduced in 1984 led to a significant reduction in ejaculatory dysfunction from 37% to 19% [406]. Loss of ejaculation occurred significantly more often after bilateral (46%) compared to unilateral (14%) dissection, and was related to the size of the excised mass (<4 cm 4%; 4-8 cm 19%; >8 cm 60%).

It is important to anticipate this complication in young men with testicular tumors who may need chemotherapy or node dissection, and arrangements should be made for sperm storage before treatment commences. Excellent results can be obtained with artificial insemination using cryopreserved spermatozoa [407].

d) Functional disorders

1) Seminal Megavesicles

Adult polycystic kidney disease has been found in association with pathological dilatation of the seminal vesicles in 6 patients [408]. TRUS and percutaneous puncture of the seminal vesicles before and after resection of the ejaculatory ducts has revealed that the gross dilatation of the seminal vesicles was not caused by obstruction, but appeared to be due to atonicity (megavesicles). These ultrasonic appearances, when described previously, were incorrectly thought to be due to seminal vesicle cysts. Pathological dilatation of the seminal vesicles in the absence of obstruction has been described previously, although the etiology remains obscure [409].

e) Radiotherapy for male pelvic cancer

Quality of Life (QoL) in general and sexual functioning in particular have become very important in the well being of cancer patients. Due to modern surgical techniques, improved quality of drugs for chemotherapy, and modern radiation techniques, more patients can be successfully treated without largely compromising sexual functioning.

1) Prostate cancer

Prostate cancer (PC) has become the most common non-skin malignancy in men in Western countries. External-beam radiotherapy (EBRT) and brachytherapy (BT) are, together with the radical prostatectomy (RP), the most common and effective treatments for localized PC. Regardless of the introduction of very modern radiotherapy (RT) techniques, sexual functioning after PC treatment remains problematic for many patients. Self-administered questionnaires have widely been used to evaluate sexual functioning in patients after RT of PC. Nevertheless, such instruments are highly variable and largely unvalidated. These questionnaires elicit limited information about aspects of sexuality other than erectile function. Although a deterioration of sexual activity has been associated with the severity of ejaculatory dysfunction, particularly a decrease in volume or absence of semen [410], only a few questionnaires included items related to ejaculation and orgasm.

Already in the 1980s ejaculatory disturbances following RT of PC were reported [411]. (Table 18) In the 1990s more studies included items related to desire, ejaculation, and orgasm. After EBRT, a decline in sexual desire was reported by 43% of 64 patients and a decreased frequency of orgasm by 57%; all men reported a decrease in ejaculate volume[412]. Using a validated questionnaire, Borghede and Sullivan [413] reported a decrease in the ability to ejaculate in 56% of the patients. Good prognostic factors for sexual functioning preservation following RT were low age and higher frequency of intercourse.

Early BT studies also assessed sexual functioning. Herr [414] reported already in 1979 on 51 patients treated with retropubic iodium-125 seeds, with loss of ejaculate experienced by 6% of the patients. In a later study, dry ejaculation was reported by 16%

[Table 18]
of the patients after BT [415]. In both studies, all patients had previously undergone a trans-urethral resection of the prostate (TURP). For the first time a discomfort with ejaculation was mentioned in two studies (up to 25% of the patients) [416, 417]. This result is quite common in clinical practice after BT, due to edema of the prostate possibly reducing the elasticity of the urethra and inducing discomfort with ejaculation. In some patients discomfort with ejaculation did not disappear even 18-24 months after BT [418]. Also, decreased interest in sex, sexual desire, and libido was mentioned in up to 50% of the patients evaluated [413, 417-419].

Several studies on the etiology of post-RT decreased libido and ejaculatory disorders have been reported. Daniell et al [420] studied retrospectively levels of testosterone (TST) and other hormones after RT of PC. TST was found to be low 3 to 8 years after EBRT with lower levels found in older patients. Although testes are very sensitive to radiation, spermatogenesis is more easily affected than androgen productions. The radiation dose calculated in the testes of men irradiated for PC is only 3-8% of the dose that could possibly affect androgen production and explain a decrease in TST. A TURP carries a high incidence of retrograde ejaculation because it is thought to disrupt the closure mechanism of the vesical neck; this could explain ejaculatory disturbances in most patients following RT with previous TURP.

2) RECTAL CARCINOMA

Not much is known about sexual functioning following RT of rectal carcinoma. Pre-operative RT for rectal cancer has been associated with a reduction in the rate of local relapse and possibly an advantage in survival. Pre-operative RT with the total mesorectal excision (TME) in low stage rectal cancer has become a common procedure in Europe. A sharp dissection of the mesorectum associated with visualization and preservation of the pelvic autonomic nerve leads to excellent results regarding erectile and ejaculatory functioning. Only one study has specifically studied the effects of pre-operative RT for rectal carcinoma on male sexual functioning and concluded that it may impair male sexual functioning [421]. However, numbers were too small to draw final conclusion.

3) TESTICULAR CANCER

Germ cell tumors of the testis are relatively rare, accounting for about 1% of all male cancers. The long-term survival for early disease approaches 100%. Because testicular cancer affects mainly young men in their sexual and fertile life, sexual functioning and ejaculatory disorders are particularly important. The side effects of retroperitoneal lymph node dissection (RPLND) for residual mass after chemotherapy for non-seminomatous cancer are better documented than sexual sequelae of elective abdominal RT for seminoma. Dry ejaculation occurs in the majority of the patients in non-nerve sparing techniques. As a result of careful anatomical studies, the technique of RPLND has been modified with nerve sparing so that antegrade ejaculation is now maintained in 80 100% of patients [422]. Libido and orgasm seem to be normal in these patients.

Following RT, deterioration in sexual functioning has been reported between 1% and 25% of the patients [423-427]. Tinkler et al reported on 237 patients after orchiectomy and abdominal RT and compared these data to 402 age-matched controls [425]. In almost all parameters studied including erection, ejaculation, and libido, patients scored less than controls (reduction in orgasm, in libido, and interest in sex). Specifically, there was no difference in the ability to ejaculate during sexual activity but the RT patients reported a noticeable reduction in the amount of semen compared to before treatment [425]. Caffo et al evaluated toxicity and QoL of 143 patients treated for early-stage testicular cancer. Twenty-three per cent reported a decreased libido, 27% problems with getting an orgasm, and 38% ejaculation disturbances, including premature ejaculation. A decrease in sexual desire, in orgasm, and volume or semen was negatively correlated with age [423]. Jonker-Pool et al [424] reported on three groups of patients, after RT, wait and see, and chemotherapy. RT patients reported decreased libido in 22% compared to 12% in the wait and see group and 30% in the chemotherapy group. Decrease of absence of ejaculate was reported in 15%, 7% and 21% in the three groups, respectively; decreased orgasm in 15%, 12% and 30%, respectively. Although the differences were not statistically significant, in the RT group ejaculation and orgasm disturbances were higher than in the wait and see group. Similar results were reported by Arai et al [410]. PE was reported in up to half of the patients [410, 427], but it was the same as recalled before treatment [427].

The superior hypogastric plexus is responsible for ejaculation and it is mediated by the sympathetic system; it is a fenestrated network of fibers anterior of the lower abdominal aorta. The hypogastric nerves exit bilaterally at the inferior pole of the superior hypogastric plexus, and have connections with the S1-S2 roots. Normal emission requires integrity of this system. During RPLND these nerves are difficult to recognize and might be damaged, resulting in decreased semen volume or dry ejaculation. Pathways for ejaculation are included in the RT fields for rectal and prostate carcinomas. Damage of the sympathetic nerves could be caused by radiation, but the dose does not seem enough to completely explain the dysfunction. Orgasm is even more complex than ejaculation since it is also affected by cortical input. Drug treatment for loss of ejaculation is not very successful but electroejaculation can
produce spermatozoa for insemination. It is important to anticipate this complication in young men with testicular tumors who may need chemotherapy or node dissection. Arrangements should be made for sperm collection and storage at the earliest opportunity before treatment commences. Excellent results can be obtained with artificial insemination using cryopreserved spermatozoa [407].

3. PSYCHOLOGICAL ETIOLOGIES OF DELAYED EJACULATION

Like most other sexual dysfunctions, unless a clear pathophysiology has been identified, DE may be best understood as an interaction of organic and psychogenic factors. That is, a biological set point for ejaculatory latency is affected by multiple organic and psychogenic factors in varying combinations over the course of a man's life cycle. Appropriate assessment requires an appreciation of how these factors combine to determine the inhibited ejaculatory response for any particular individual.

Among those factors that are psychogenic and/or behavioral, a number of possibilities have been proposed. Although none has been identified or accepted as the primary determinant of DE, some explanations have received more support than others, and some appear more plausible than others.

a) Psychodynamic approaches

Psychodynamic interpretations emphasize psychosexual development issues and have attributed life-long DE to a wide range of conditions, including fear, anxiety, hostility and relationship difficulties [225, 428, 429]. Many different manifestations of anxiety and fear have been hypothesized, including fear of death and castration, fear of loss of self resulting from loss of semen, fear of castration by the female genitals, fear that ejaculation would hurt the female, fear of being hurt by the female, performance anxiety, unwillingness to give of oneself as an expression of love, fear of impregnating the female, and guilt secondary to a strict religious upbringing [430]. Although some of these factors may contribute to the etiologies of individual men with DE, no well controlled studies provide broad support, at this point, for any of the various hypotheses for mentioned above [430].

b) Religious/culture

Masters and Johnson were the first to suggest that DE was associated with orthodoxy of religious belief [224]. Beliefs may limit the sexual experience necessary for learning to ejaculate or may result in an inhibition of normal function. Regardless of specific religion involved (Muslim, Hindu, Jewish, etc.), many devoutly religious men have masturbated only minimally or not at all. Some of these men masturbated for a period of years like their secular counterparts, but guilt and anxiety about “spilling seed” may have led to idiosyncratic masturbatory patterns, which in turn resulted in DE. These men often had little contact with women prior to marriage (which may have been arranged after a few chaperoned dates) and, although these men may have dated, they were less likely than their secular counterparts to experience orgasm with a partner, especially through intercourse. Some of these men did sexually experiment with women who they did not marry; however, their cognitions about these women often reflected a «Madonna-whore» split.

c) Insufficient sexual arousal

An excellent critical review of the psychological etiology of DE has been provided by Apfelbaum [367], who first noted the sexual politic surrounding DE and female anorgasmia: “Like the woman who has inappropriately been castigated for willfully depriving her husband of the pleasure of bringing her to orgasm, the delayed ejaculator’s own belief that he is withholding is widely endorsed, understandably by his partners and less justifiably by most therapists” (p. 182). Not only psychoanalysts, but sex therapists and behavior therapists as well, seemed to assume the DE patient’s orgasm is blocked, rather than the patient’s level of arousal being insufficient.

Apfelbaum observed that some males appear able to achieve erections sufficient for intercourse despite a relative absence of subjective arousal [367]. He felt these “automatic erections” were taken as erroneous evidence by both the man and his partner that he was ready for sex and capable of achieving orgasm. This same process is the likely cause of increased anecdotal clinical reports of DE for patients using popular urologic-based treatments for ED [2, 431, 432]. Urologists received a few early complaints of RE secondary to successful penile prosthesis surgery and ICI. However, the introduction of sildenafil brought increased numbers of patients to physician’s offices, many of whom experienced restored erections and coitus with ejaculation. A subset of men on sildenafil, however, experienced erection without adequate psychoemotional arousal and, as a result, experienced difficulty achieving orgasm, as they did not experience sufficient erotic stimulation before and during coitus. These men confused their erect state as an indication of sexual arousal when it merely indicated vasocongestive success [2, 431].

d) Masturbation

Apfelbaum coined “autosexual” orientation to describe men with DE who prefer masturbation to partnered sex [367]. Many men with RE engage in self-stimulation that is idiosyncratic in the speed, pressure, duration, and intensity necessary to produce an orgasm, yet dissimilar to what they experienced with a partner. Thus, they precondition themselves to possible difficulty attaining orgasm with a partner and, as a result, experience secondary DE. Disparity between the reality of sex with the partner and the use of sexual fantasy (whether unconventional or not) during masturbation is another potential cause of DE. This disparity may take any number of forms: body type, orientation, and sex activity performed. Although many men and women are inhibited about using their masturbatory fantasies when with their partner, like their female counterparts, when men with DE integrate their masturbation fantasies into sex with their partner, orgasm is more likely attained [431].

In summary, delayed or absent ejaculation can be a lifelong (primary) or an acquired (secondary) problem. Many psychodynamic explanations have been offered for DE and these may account for the problem in specific individual cases. More likely, however, men with DE derive greater arousal and enjoyment from masturbation than from intercourse, an “auto-sexual” orientation that may involve an idiosyncratic and vigorous masturbation style that ultimately interferes with the ability to attain orgasm [372, 433-437]. In fact, masturbatory frequency and style may be predisposing factors for DE, since a substantial portion of men who present with coital DE report high levels of idiosyncratic masturbatory activity [372, 434-437]. Disparity between the reality of sex with the partner and the sexual fantasy used during masturbation may represent another contributor to DE [431, 438]. And finally, the evaluative/performance aspect of sex with a partner often creates “sexual performance anxiety,” a factor that may contribute to DE. Specifically, anxiety surrounding the inability to ejaculate may draw the man’s attention away from erotic cues that normally serve to enhance arousal [433].

VI: EVALUATION OF DELAYED EJACULATION, ANEJACULATION AND ANORGASMIA

1. EVALUATION AND ASSESSMENT OF DE

Treatment should be etiology specific and address the issue of infertility in men of a reproductive age. If a man has difficulty with ejaculation, or has a small volume or absent ejaculate, it must first be established whether the problem is congenital or acquired, and whether organic factors are implicated. Assessment begins by reviewing the conditions under which the man is able to ejaculate, for example, during sleep, with masturbation, with partner’s hand or mouth stimulation or infrequently with varying coital positions. The course of the problem is documented, and variables that improve or worsen performance are noted. Questions concerning the man’s ability to relax, sustain, and heighten arousal and the degree to which he can concentrate on sensations are posed [439]. If orgasmic attainment had been possible previously, the life events/circumstances temporarily related to orgasmic cessation are reviewed. The events in question maybe pharmaceutical, congenital problems, illness, trauma, or a variety of life stressors and other psychological factors, for example, following his wife’s mastectomy: the man is afraid of hurting her and therefore only partially aroused. Societal/religious attitudes that may interfere with excitement are noted, such as the spilling of seed as a sin. Finally, questions concerning the quality of the nonsexual relationship are posed and
problems explored. This assessment in conjunction with appropriate physical examination and laboratory results will provide understanding and determine an appropriate treatment path.

2. INVESTIGATING AND ALLEVIATING ORGANIC FACTORS IN DE OR ANEJACULATION

a) General investigation

A careful clinical history should be taken, and physical examination will establish whether the testicles and epididymes are normal, and whether the vasa are present or absent, on each side. Next, it is essential to establish whether there is retrograde or completely absent ejaculation, by examination of a deposit of urine after centrifugation. The presence of spermatozoa indicates retrograde ejaculation. These facts will allow the patient to be placed into one of several broad categories, after which more detailed evaluation can take place.

If the etiology is unclear, organic factors such as haemospermia may require full investigation. Culture of expressed prostatic secretion and urine will define the nature of an infective process such as prostatitis [440] and urine cytology and serum prostate specific antigen should be assayed to exclude bladder or prostatic cancer. Ultrasound scan of the testicles and epididymes should define any local disease. TRUS will demonstrate structural abnormality in the prostate or seminal vesicles, or may show up a stone in the ejaculatory duct or even a Mullerian duct cyst. Cystoscopy is seldom helpful.

Patients with ejaculatory duct obstruction usually present with infertility. Seminal analysis may simply be reported as showing azospermia or oligospermia, but the characteristic biochemical changes should be sought. There should be absence of part or the entire component of the ejaculate that comes from the vasa and seminal vesicles via the ejaculatory ducts. The volume is low (usually less than 1.5 ml), the pH is low (less than 7) and the fructose content is either low (less than 120 mg/100ml) or absent. If both vasa are palpable, a diagnosis of ejaculatory duct obstruction is very likely.

When there is absence of the vasa, it is important to establish whether the condition is unilateral or bilateral. With unilateral absence of the vasa deferens, the urinary system must also be checked by ultrasound scanning, as coexisting renal anomalies may be present [441]. With bilateral absence or malformation of the vasa, it is essential to consider whether the anomaly may be part of a genetic defect associated with carriage of the potentially harmful cystic fibrosis chromosome anomaly [377].

b) Imaging in ejaculatory duct obstruction

A lesion or obstruction may be suspected by finding distended seminal vesicles on transrectal ultrasound scanning. However, the exact site of obstruction should be defined radiologically by vasography or percutaneous puncture of the seminal vesicles. Subsequently, methylene blue dye may be instilled to outline the ejaculatory system so that it can be recognized after it has been entered at transurethral resection [442].

c) Electrophysiological evaluation of the nervous pathways controlling ejaculation

Neurophysiological tests allow objective evaluation of the nervous pathways controlling ejaculation and are occasionally of use in the evaluation of delayed ejaculation or anejaculation. Four tests are routinely used.

d) Pudendal Somatosensory Evoked Potentials (Pudendal SEPs)

Somatosensory evoked potentials (SEPs) are defined as a transient alteration of the EEG following peripheral nerve stimulation. They provide objective information concerning the afferent volley from the dorsal nerve of penis to the cortex. The technique consists of electrical stimulation of the dorsal nerve of penis with recording of the evoked responses over the spine and the scalp (2 cm behind the central vertex). First the sensibility threshold is measured. By definition, the sensibility threshold is the lowest perceivable sensation of the electrical current at the point of stimulation. The latency of the response is measured both at the onset of the response and the peak of the first reproducible deflection. By recording the response at two different levels, three different transit times are obtained: a total transit time (from penis to brain), a peripheral transit time (from penis to spine), and a central transit time (which is obtained by subtracting the peripheral from the total transit time). The peripheral transit time is approximately 13.5 msec. The total transit time is approximately 34 msec (onset) and 43 msec (top of P1 deflection) [443, 444].

e) Pudendal Motor Evoked Potentials (Pudendal MEPs)

Motor Evoked Potentials (MEPs) explore the efferent pathways (pyramidal tracts) from brain to target muscle (bulbocavernosus muscles). This technique consists of stimulating the motor cortex and sacral roots by means of a magneto electric stimulator. For brain stimulation, the coil is applied 2 cm behind the vertex. For sacral root stimulation, the coil is applied laterally to the spine. The response is picked up from the bulbocavernosus muscles with co axial EMG needle electrodes. Brain stimulation is performed, first at rest, and then during a voluntary contraction of the pelvic floor (facilitation procedure). Sacral root stimulation is performed only at rest. The response is measured at the onset of the first reliable deflec-
tion. By stimulating the central nervous system at 2 levels, 3 different transit times will be obtained: a total transit time (from brain to target muscle), a peripheral transit time (from sacral roots to target muscle) and a central transit time (obtained by subtracting the peripheral from the total transit time). The total transit time measured in the bulbocavernous muscles is respectively 28 msec (brain stimulation patient at rest) and 23 msec (brain stimulation patient contracting the pelvic floor). The peripheral transit time is 7 msec (sacral root stimulation) [445].

f) Sacral Reflex Arc Testing: the Somatic somatic Reflex Arc

This test allows the investigation of the sensory and motor branch of the pudendal nerve and of the sacral segments S2, S3, S4. The technique consists in stimulating the dorsal nerve of the penis and recording the response from the bulbocavernous muscles. The response consists usually of 2 deflections. The mean latency of the first deflection is 35 msec, although a late deflection is often observed at 80 msec [444, 446].

g) Sympathetic Skin Responses (SSRs)

Electrical activity from the sympathetic nerve terminals controlling the sweat glands of the skin can be recorded following electrical stimulation of any peripheral nerve trunk. The test allows evaluation of the sympathetic efferent outflow to the skin of the genital organs which may impact ejaculatory function. The dorsal nerve of the penis is stimulated using 2 ring electrodes wrapped around the penile shaft, the cathode being proximal. The stimulation consists of single electrical pulses applied at a rate of 0.05 Hz. Sympathetic skin responses are recorded from hand, foot, and perineum using disc electrodes affixed to the skin. Two tracings are superimposed to check the reproducibility of the response. The right median nerve is then stimulated, and SSRs are recorded from the hand, foot, perineum, and penis. The mean latency of hand, foot, and perineum SSRs following dorsal nerve of the penis stimulation are, respectively, 1.40 sec, 2 sec, and 1.4 sec. Following median nerve stimulation, the latency of penile SSRs is 1.50 sec [447, 448].

VII: TREATMENT OF DELAYED EJACULATION, ANEJACULATION AND ANORGASMIA

1. PSYCHOLOGICAL STRATEGIES IN THE TREATMENT OF DELAYED EJACULATION

a) General considerations and approaches

As indicated above, before considering a psychological/behavioral approach toward the treatment of DE, clinicians first need to exclude probable iatrogenic and pathophysiological causes. They should, for example, be alert to various medical conditions as well as medications that might delay ejaculation and, in the case of antidepressants, consider a reduction in dose or use of antidote [449]. Vascular or neuropathic damage that causes DE is usually irreversible and therefore the patient might be counseled to seek alternative methods to achieve mutual sexual satisfaction with his partner. Androgen deficiency—another potential cause for DE—requires appropriate testosterone replacement therapy. Whether a clear pathophysiological cause is present or absent, patients might be counseled to consider lifestyle changes, including enjoying more time together to achieve greater intimacy, minimizing alcohol consumption, making love when not tired, and practicing techniques that maximize penile stimulation such as pelvic floor training [430]. Patient education regarding existing factors that can exacerbate their delayed ejaculation is an important first step and may represent a segue into either short-term or long-term counseling.

Beneficial effects through psychotherapy depend on the severity of the DE and the individual's receptiveness to engage in counseling and adhere to the counselor's recommendations. Indeed, for DE that has its probable roots in psychological and behavioral issues, psychotherapy appears to be the only effective treatment, as effective drug treatment is limited and poorly tested. The man who presents with DE, in whom organic and pharmacologic causes have been eliminated, requires thorough psychosocial assessment. His partner and the quality of the relationship also warrant exploration. Numerous psychotherapeutic processes are described for the management of delayed or inhibited ejaculation [224, 225, 367, 450] and some appear to be effective, but none has been properly evaluated in large scale samples [451]. Among these strategies are: (1) sex education; (2) reduction of goal-focused anxiety; (3) increased, more genitally-focused stimulation; (4) patient role-playing an exaggerated ejaculatory response on his own and in front of his partner; (5) masturbatory retraining; and (6) re-alignment of sexual fantasies and arousal strategies.

Treatment strategies for DE have typically been based upon the etiologies previously described, and most benefit from cooperation of the sexual partner. Successful treatment approaches typically begin by recognizing the importance of de-stigmatizing the dysfunction, providing appropriate sex-response education to the couple, and defusing dyadic tension that might have evolved in response to the dysfunction. For example, discussion of a potential biologic predisposition is often helpful in reducing patient and partner anxiety and mutual recriminations, while simultaneously assisting the formation of a therapeutic alliance with the health care professional [365].

Most current sex therapy approaches to DE empha-
size the importance of masturbation in the treatment of DE, with most of the focus on “masturbatory retraining” integrated into sex therapy [365, 368]. Masturbation retraining is, however, only a means to an end, and the true goal of most current therapeutic techniques for DE (either primary or secondary) is to both provide more intense stimulation and induce higher levels of psychosexual arousal so the man can attain orgasm within the framework of a satisfying partnered experience. A number of strategies have been utilized to achieve the endpoints of increased arousal and satisfaction.

Men with primary anorgasmia (a complete lack of ejaculatory response), like their female counterparts, typically need help determining their sexual arousal preferences through self-exploration and then in communicating that knowledge to their partner. Masturbation training may use a modification of the model described by Barbach [452] for women, although the use of vibrators, sometimes recommended by urologists, is rare. Progressing from neutral sensations to the ability to identify and experience pleasurable sensations is encouraged whether or not ejaculation should occur.

Typically, self-stimulation techniques incorporating fantasy can be used to achieve incremental increases in arousal that eventually enable orgasm. Fantasy can serve the purpose of increasing arousal and blocking inhibiting thoughts that might otherwise interfere. Once the man’s ejaculatory ability is established through masturbation, the same skill set can be incorporated into sex with the partner. Although some cultures and religions forbid masturbation, temporary religious dispensation is sometimes available, especially when procreation is a goal of treatment.

An important component in the treatment of any type of DE is the removal of the “demand” (and thus anxiety-producing) characteristics of the situation [367]. "Ejaculatory performance” anxiety can interfere with the erotic sensations of genital stimulation and may result in levels of sexual excitement insufficient for climax (although they may be more than adequate to maintain an erection). To reduce anxiety, treatment may include recognition of DE men’s over-eagerness to please their partners, validation of (though not necessarily encouragement of) the man’s autosexual orientation, removal of stigmas suggesting hostility or withholding toward their partner, and general anxiety reduction techniques such as relaxation and desensitization. By normalizing the anorgasmia, therapy can then explore factors that increase the man’s arousal (similar to treatment of anorgasmia in women). Finally, like a previously anorgasmic woman, the man is taught to effectively communicate his preferences to his partner so that both their needs are incorporated into the sexual experience.

b) Issues related to counseling
As with counseling for other kinds of problems, men with DE may resist the recommendations of the therapist. For example, a therapeutic suggestion to temporarily discontinue masturbation may be met with resistance by the patient. Nevertheless, the therapeutic benefit of temporarily discontinuing self-stimulation can be an important part of the therapeutic process to increase overall sexual arousal, when it does occur. Such recommendations must be balanced with maintenance of a therapeutic rapport and alliance with the patient, and therefore the issue of masturbation interruption may be negotiated. For example, a man who continues to masturbate may be encouraged by the therapist to alter the style of masturbation to approximate (in terms of speed, pressure, and technique) the stimulation likely to be experienced through manual, oral, or vaginal stimulation by his partner [371].

In addition to suspending masturbation, the patient might be encouraged to use fantasy and bodily movements during coitus that help approximate the thoughts and sensations previously experienced in masturbation. This process is facilitated and resistance minimized when the man’s partner is supported by the practitioner and understands that the alteration in coital style is part of a series of steps designed to reach a long term goal of coital harmony and satisfaction for them both.

The partner also needs to collaborate in the therapeutic process, finding ways that not only enhance the man’s arousal, but to accept the use of erotica and various (harmless) sexual fantasies that also might be incorporated into the couple’s lovemaking. Because fantasy plays an important role in arousal, sexual fantasies may have to be realigned so that thoughts experienced during masturbation better match those occurring during intercourse with the partner. The attractiveness and seductive/arousing capacity of the partner might also be increased to reduce the disparity between the man’s fantasy and the actuality of coitus with his partner.

Because interventions used in the treatment of DE may be experienced by the female partner as mechanistic (e.g., using a step wise program) and insensitive to her sexual needs, many women may initially respond negatively to the impression that the man is essentially masturbating himself with her various body parts, as opposed to engaging in connected lovemaking. This response may be exacerbated for the female when her partner needs actual pornography/erotica instead of mere fantasy to distract himself from negative thoughts and emotions that might interfere with arousal. The therapist must help the partner accept postponement of her
needs until the patient has progressed to a level of functionality, which then allows for encouragement and development of a greater sensitivity and sharing between them. The therapeutic challenge is to facilitate the rapport between the partners, while maintaining a therapeutic alliance with both partners and simultaneously optimizing his response to her manual, oral, and vaginal stimulation.

Finally, issues surrounding reproduction/conception may need to be addressed, as this issue is often an initial driver for treatment. This issue may require special sensitivity, particularly if the couple’s stated or unstated goals regarding family size and constitution (boys, girls, or no children at all) do not coincide. In such instances, the practitioner must find an acceptable way to refocus the treatment, at least temporarily, on the underlying issues responsible for the discordant goals of the couple in order for DE treatment to succeed. This process may require individual sessions with the man and occasionally with the partner as well.

Patients with psychogenic inhibited ejaculation (IE) are a challenging to treat population. Level 4 evidence to support that all require patient/couple psycho-education and/or psychosexual therapy which may be long term.

**Grade C Recommendation**

c) Treatment efficacy

The success of treating DE is difficult to assess from the literature [451] as the available evidence on the effectiveness of various treatments is limited [220, 430], and both successful and unsuccessful case reports have been cited [367, 372]. Heiman and Meston’s summary of sex therapy treatments concluded that “inadequate data” on the topic of delayed orgasm in men prevented any conclusion regarding efficacy of treatment [220]. Although many treatments for DE have been suggested in the psychotherapy literature, including early psychodynamic and sex therapy approaches [224, 225, 442, 453-456], few have been subject to rigorous testing. Masters and Johnson[224] reported a low failure rate of 17.6% using a treatment combination of sensate focus, vigorous non coital penile stimulation and modifications of intercourse technique. In the Ohl et al. study [457], 81% of men who were anorgasmic prior to fertility treatment were successful in reaching orgasm through vibrator stimulation. Apfelbaum treated almost all of his DE cases with «body work» using sexual surrogates [367]. And Perelman reported retrospective chart review success rates of over 80% in treating DE using various forms of cognitive-behavioral sex therapy [431]. However, these analyses represent, for the most part, uncontrolled reports with treatment ranging from a few brief sessions of sex education to nearly two years of multiple-modality treatment in more complex multiple etiologic cases.

2. DRUG TREATMENT FOR DELAYED AND INHIBITED EJACULATION

Treatment of delayed or inhibited ejaculation with pharmaceuticals has met with limited success. No drugs have been approved by regulatory agencies for this purpose, and most drugs that have been identified for potential use have limited efficacy, impart significant side effects, or are yet considered experimental in nature. (Table 19) In some instances, the drugs may only indirectly affect ejaculatory latency by affecting other components of the sexual response cycle; in other instances, the drugs have been used primarily to counter effects of other pharmaceuticals that iatrogenically induce delayed or inhibited ejaculation.

There are multiple reports in the literature of the use of a variety of drugs in the treatment of delayed ejaculation or anejaculation. Typically, these drugs facilitate ejaculation by either a central dopaminergic or anti-serotonergic mechanism of action. Most studies do not use placebo controlled designs and most are anecdotal case reports/series dealing with the treatment of SSRI induced ejaculatory dysfunction. (Table 20)

Several authors have reported that the cerebral serotonergic system exerts an inhibitory role on ejaculation and male sexual activity in the rat model and that the dopaminergic system, particularly that in the anterior hypothalamus, has a facilitatory role [458, 459]. The ejaculatory dysfunction commonly associated with the anti-hypertensive alphamethyl dopa which reduces cerebral monoamine levels by suppressing the cerebral dopaminergic system is consistent with these reports. The occurrence of paradoxical hypersexuality, for example, spontaneous orgasm with clomipramine and fluoxetine, however, suggests that this balance is more complex and that different 5-HT receptor subtypes may have opposing effects on sexual function [460-462].

a) Alpha-1 Adrenergic Receptor Agonists

Alpha-1 adrenergic receptor agonists such as imipramine, ephedrine, pseudoephedrine and midodrine may have a role in the pharmacological treatment of inhibited ejaculation. Midodrine is used in the treatment of various hypotensive disorders and is associated with causes less frequent and less severe adrenergic effects than ephedrine and other sympathomimetic agents. Midodrine is used in the treatment of various hypotensive disorders and is associated with causes less frequent and less severe adrenergic effects than ephedrine and other sympathomimetic agents. Several authors have reported the use of midodrine in spinal cord injured patients. In recent studies, antegrade or retrograde ejaculation occurred in 22-64.6% of spinal cord injured patients.
who had previously failed to respond to penile vibratory stimulation, following treatment with midodrine 30–120 min before a new stimulation. [398, 399]

Safarinejad recently reported that midocrine reverses organic anejaculation in non-SCI subjects in more than 50% of patients. In a placebo controlled study of 128 patients, stepwise titration of oral midodrine 7.5–15mg/day resulted in antegrade, retrograde and combined antegrade/retrograde ejaculation occurred in 18 (29.5%), 8 (13.1%) and 9 (14.8%) patients respectively. [463]

b) Cyproheptadine

The antihistamine cyproheptadine, which increases cerebral serotonin levels, has been shown to increase male sexual activity in the rat [458]. The literature contains several anecdotal case reports and other small case series of the use of cyproheptadine to reverse the anorgasmia induced by the SSRI antidepressants but no controlled studies are known [464-469]. These studies suggest an effective dose range of 2-16mg., with administration on a chronic or «on demand» basis. McCormick reported the use of cyproheptadine to reverse the anorgasmia induced by the SSRI luoxetine in 2 patients [464]. Ashton et al also reported improvement in 12 of 25 men with SSRI induced sexual dysfunction with a mean dose of 8.6 mg, with efficacy limited by sedation and potential reversal of antidepressant effect [465]. A role for cyproheptadine in the treatment of both delayed ejaculation and anejaculation may be limited to a degree by its sedative effect.

c) Amantadine

Central dopamine activity can be increased by a variety of mechanisms ranging from the provision of dopamine synthesis precursors, for example, L-dopa, to use of substitute neurotransmitters to directly stimulate central dopamine receptors (Table 21). Amantadine, an indirect stimulant of dopaminergic nerves both centrally and peripherally which is used in the treatment of Parkinson’s disease and has a limited role as an anti-viral agent, has been reported to stimulate sexual behaviour, ejaculation, and other sexual reflexes in rats [470, 471]. Several authors have reported a place for amantadine in the reversal of SSRI antidepressant induced anorgasmia [465, 472-476]. Ashton et al reported improvement in SSRI induced sexual dysfunction in 8 of 19 men with mean dose of 200mg [465]. Balon reported some efficacy with «on demand» amantadine (100mg) administered 5-6 hrs before coitus in a similar group of patients [472].

d) Yohimbine

Several authors have reported their experience with Yohimbine, a derivative of the bark of the Yocon tree, in the management of SSRI induced sexual dysfunction [477-479]. Yohimbine is an alpha-2 antagonist, an alpha-1 agonist, and a calcium channel blocker that inhibits platelet aggregation. Price and Grunhaus reported reversal of clomipramine-induced anorgasmia with a dose of 10mg administered 90 minutes prior to coitus [477]. In a placebo-controlled study of 15 patients with fluoxetine-induced anorgasmia, Jacobsen reported a 73% response rate to yohimbine [478]. Hollander reported that yohimbine reversal of anejaculation in 5 of 6 men with intercourse and/or masturbation [479]. The response to yohimbine is typically delayed, taking up to 8 weeks, and is often associated with adverse effects including nausea, headache, dizziness, and anxiety. Careful dose titration is important as the extremes of dose have less pro-sexual effect.

e) Buspirone

Buspirone is a benzodiazepine class anxiolytic which possesses 5HT-1A receptor agonist activity [480]. Othmer et al reported normalization of sexual function in 8 of 10 men with a generalized anxiety disorder and associated sexual dysfunction using a dose range of 15-60mg daily [481]. Bupropion is a novel antidepressant which prolongs the action of dopamine by reducing its uptake from the synaptic cleft [482]. Ashton and Rosen described reversal of SSRI induced anorgasmia in 66% of patients studied. [483]

f) Apomorphine

Several authors have reported induction of «early ejaculation» in rats following administration of apomorphine, a central and peripheral DA-2 receptor agonist, at a dose of 50 mg/kg. DA receptor antagonists block this effect [44, 484]. Aizenberg et al examined the effect of the 5-HT2a/2c and alpha 2 antagonist mianserin in the treatment of patients with sexual dysfunction induced by serotonin reuptake inhibitors (SSRIs) [485]. Nine of the 15 subjects reported a marked improvement in their sexual functioning in the areas of orgasm and satisfaction usually within the first and second week of mianserin treatment. The authors suggested that co-administration of low-dose mianserin might be an additional option in the treatment of sexual dysfunction induced by SSRIs.

g) Quinelorane

Quinelorane is a highly selective, potent DA-2 agonist which was extensively studied in animals in the early part of this decade. Foreman and Hall observed increased mounting, intromission and ejaculation in both sexually inactive and sluggish rats following administration of quinelorane [486]. Prior administration of a dopamine antagonist eliminated these stimulatory effects, confirming that these sexual effects were due to stimulation of DA receptors. These investigators reported that many rats failed to ejaculate at the extremes of doses, with low doses causing sedation and high doses causing hyperactive behaviour such as chewing or sniffing. Animals appear to become more sensitive to dopamine agonists with increased use, suggesting that abuse may eliminate any sexual benefits. Eaton et al. injected quinelorane directly into the rat paraventricular nucleus and medial preoptic area and reported different response with different doses [487]. At extremes, quinelorane could cause paradoxical PE, reduced sexual desire, and ED. The reduced sexual response observed at low doses is due to stimulation of dopamine «auto-receptors» which decrease dopamine activity and respond to lower doses than do dopamine

the stimulatory DA-2 receptors. In theoretical clinical use, lowering the dose to avoid excess excitement may result in worse sexual dysfunction than prior to treatment. Human double blind placebo controlled clinical studies of quinelorane were commenced in the late 1980s involving multiple sites and more than 500 men and women with ED, reduced sexual desire, and reduced arousal. The United States Food and Drug Administration review of the trial data was inconclusive and concern was expressed over the more than 50% incidence of nausea and hypotension and the indirect negative sexual adverse effects. Clinical studies were terminated and the results remain confidential and unpublished.

**h) Oxytocin**

Oxytocin is a peptide hormone made of nine amino acids. It is released by the human posterior pituitary gland, and has been associated with the Letdown reflex in lactating mothers, uterine contractions during the second and third stages of labor, in addition to increased levels at orgasm in both men and women. [488] Oxytocin has been used to facilitate labor induction, for initiation of lactation in women after delivery [489], and more recently in the treatment of autism [490]. More recently, a study on humans published in Nature has shown its value in social bonding, increasing trust, and enhancing the sense of well-being. Studies on attachment, social bonding, and sexual behaviors in the animal models have pointed to oxytocin as an important mediator [491]. Animal studies pointed to the role of oxytocin receptors in selective serotonin reuptake inhibitors-induced ejaculation delays [492], with evidence of successful reversal using oxytocin in the male rat [493].

Ishak et al recently reported a single case effectiveness of administering intranasal oxytocin intracoitaly in a case of treatment-resistant anorgasmia. Oxytocin (20–24 IU) was effective in restoring ejaculation at the point when ejaculation was sought. Following its use, the patient ejaculated regularly (multiple times per week) after sexual intercourse, an effect that is persisting consistently for 8 months until the time of submission of this report. Both the patient and his wife reported a high degree of satisfaction with this intervention. [494] Whether oxytocin works in anorgasmia by increasing the ability to “fully share oneself” or more plausibly through promoting rhythmic contracility of the penile and pelvic musculature, the exact mechanism of action is awaiting to be discovered.

Finally, some men may exhibit retrograde ejaculation rather than delayed ejaculation or anejaculation. Retrograde ejaculation can be surgically treated with bladder neck reconstruction, although no surgical procedure exists for the treatment of failed emission. Drug treatment also offers a promising approach for retrograde ejaculation. Thus, while medical treatment may not always produce normal ejaculation it may convert a patient with lack of emission into one with retrograde ejaculation and may result in small amounts of viable sperm both of which can be combined with standard artificial insemination techniques to produce a pregnancy.

**Level 4 evidence to support the treatment of DE/anejaculation with pharmacotherapy**

**Grade D Recommendation**

**3. OFFICE MANAGEMENT OF DELAYED EJACULATION AND ANEJACULATION: A SUMMARY**

Men with delayed ejaculation, anejaculation and/or anorgasmia should be evaluated with a detailed medical and sexual history, a physical examination, and appropriate investigations to establish the true presenting complaint, identify obvious biological causes such as medication or recent pelvic surgery, and uncover sufficient detail to establish the optimal treatment plan (Figure 11).

Relevant information to obtain from the patient includes:

1. A basic medical history, including use of prescribed and recreational medications
2. The cultural context and developmental history of the disorder, including whether the ejaculatory dysfunction is global or situational, lifelong or recent in its development,
3. Measures of the quality of each of the three phases of the sexual response cycle: desire, arousal, and ejaculation, since the desire and arousal phases may impact the ejaculatory response,
4. Details about the ejaculatory response, including the presence or absence of orgasm, the prodromal sensation of ejaculatory inevitability and prograde ejaculation, the level of sexual dissatisfaction and distress, the frequency of sexual activity, and so on,
5. A careful physical examination to establish whether the testicles and epididymes are normal, and whether the vasa are present or absent, on each side
6. The partner’s assessment of the situation, including whether the partner is suffers from female sexual dysfunction (FSD), and
7. Assessment of the sexual and overall relationship

**Level 4 evidence to suggest that evaluation of men presenting with DE/anejaculation should include a full medical/sexual history, a focused physical examination, determination of serum testosterone levels and any investigations suggested by these findings**

**Grade C Recommendation**
Treatment should be etiology specific and address the issue of infertility in men of a reproductive age. Men, who never achieve orgasm and ejaculation, are suffering from either a biogenic failure of emission and/or psychogenic inhibited ejaculation may require fairly extensive medical evaluation. Men who occasionally achieve orgasm and ejaculation are usually suffering from psychogenic inhibited ejaculation or penile hypoanaesthesia secondary to age related degeneration of the afferent penile nerves and may respond well to various cognitive-behavioral strategies that include education and sexual techniques designed to maximize arousal.

Level 4 evidence to suggest that treatment of DE/anejaculation should be etiology specific, and may include patient/couple psycho-education and/or psychosexual therapy, pharmacotherapy or integrated treatment. Men/partners of reproductive age should be informed of the risk of infertility due to anejaculation following pelvic surgery and the need for sperm harvesting and assisted reproductive techniques.

**Grade C Recommendation**

The majority of men who always achieve orgasm but never experience prograde ejaculation or have a greatly reduced prograde ejaculatory volume should be investigated for retrograde ejaculation. The presence of spermatozoa and fructose in centrifuged post-ejaculatory voided urine confirms the diagnosis. Management involves education and reassurance of the patient, pharmacotherapy or, in rare cases, bladder neck reconstruction. The absence of spermatozoa suggests congenital absence or agenesis of the testis or vas/vasa or acquired ejaculatory duct obstruction. Management involves investigation by ultrasonic or radiological imaging to identify the site of obstruction and disease specific treatment.

**4. THE FUTURE**

Combined treatment—need for integrated pharmacotherapy and sex therapy approaches—has been gaining acceptance within both medical and counseling circles, and although evidence is yet limited, preliminary research suggests that the patient has much to gain from this more holistic approach.[4] It seems likely that the most effective treatments for PE and DE will follow the pattern seen in the treatment of ED, where an integration of pharmacotherapy and sex therapy is becoming the treatment of choice [462, 495-505]. These recent articles by urologists and sex therapists have advocated a multidisciplinary approach for the treatment of ED; emphasizing the importance of follow-up in providing opportunity for necessary patient education and counseling. Additionally, the integration of sexual counseling and pharmacotherapy is likely to be of assistance to patients seeking adjustment and rehabilitation from multiple medical conditions (e.g., retrograde ejaculation secondary to prostatic surgery). Furthermore, couples presenting multiple sexual dysfunctions are likely to benefit from a model incorporating additional sex therapy with pharmacotherapy. An integrated model allows for resolving and balancing significant intra and interpersonal psychological issues which otherwise may destabilize treatment success. There are published case reports integrating sex therapy and pharmacotherapy when treating a couple’s multiple dysfunc-
tions (including DE), but large controlled prospective studies are needed in order to define an appropriate treatment algorithm [506]. The development of new pharmaceuticals will only refine such an algorithm and improve our opportunity for enhancing orgasmic function.

Implants, Mechanical Devices, & Vascular Surgery for Erectile Dysfunction

WAYNE JG HELLSTROM, DROGO K. MONTAGUE, IGNACIO MONCADA, CULLEY CARSON, SUKS MINHAS, GERALDO FARIA, SUDHAKAR KRISHNAMURTI,

1. INTRODUCTION

A satisfactory erection has been the pursuit of mankind for millennia. Historically, numerous potions and superstitions have been employed to improve erectile function, often with a placebo benefit.

The introduction of penile prostheses for the treatment of men suffering with erectile dysfunction (ED) has opened new avenues of basic research, introduced the concept of related medical comorbidities, established an epidemiology for this condition, and stimulated a variety of successful less-invasive treatment options. Indeed, recent advances in the science and clinical management of sexual dysfunction can largely be attributed to the introduction of the modern day penile prosthesis.

Early implants were wooden splints that supported the penis in a semi-rigid state. The French surgeon Ambrose Pare’ suggested an “artificial penis” made of a wood pipe constructed for patients after traumatic penile amputation in order to facilitate urination in the standing position. Although not intended for sexual intercourse, one may refer to this 16th century device as an early “penile prosthesis.”

The first real implant using autologous materials was the use of rib cartilage in conjunction with a tubed phalloplasty by Russian surgeon Bogoraz in 1936 [2]. Future endeavors by this far-sighted surgeon utilized rib cartilage in morphologically intact penises in men suffering from ED. Unfortunately, long term success with this method was limited by natural resorption.

The use of alloplastic materials originates from experimental materials developed in laboratories and resulted in the first acrylic subcutaneous penile implants in 1949 [3]. Another major innovation was the intracavernosal implantation of acrylic rods by Egyptian surgeon G.E. Beheri [4]. After the clinical acceptance of malleable and semi-rigid implants, Scott et al introduced the 3-piece inflatable device in 1973 [5]. Besides progress in the design and durability of the penile implant, a whole industry focusing on ED diagnosis and treatment has evolved. Diagnostic measurement devices became more sophisticated, but with time have largely been supplanted by more specialized validated subjective questionnaires.

While the newer medical treatments are considered first and second lines of therapy, penile implants still remain a popular and important option for men with medication-resistant ED. Additionally, implants are appropriate when medical therapy is contraindicated, causes severe side effects, vacuum erection therapy has proven unsatisfactory or unacceptable, and/or in men with end organ failure (e.g. diabetes mellitus), severe structural abnormalities (e.g. Peyronie’s disease), or cavernosal fibrosis (e.g. after prolonged priapism or infection).

2. INDICATIONS FOR SURGERY

A variety of penile prosthesis designs are currently available for implantation, but not all patients with ED are candidates for penile prosthesis implantation. Penile prostheses are indicated for the treatment of organic erectile dysfunction in men who fail or reject more conservative measures, such as oral PDE5 inhibitors, vacuum erection devices (VED), urethral alprostadil suppositories, and intracavernosal injection therapy. For those men, in whom penile prostheses are suggested, careful counseling before penile implant procedures will limit many of the problems with postoperative dissatisfaction. Once the discussion and demonstration of penile implant varieties has been carried out, patients may
then choose a specific prosthetic type based on their needs and preferences [6]. Younger patients with normal manual dexterity and patients who wear form-fitting clothing or who shower in public (e.g., health club) often choose a three-piece inflatable penile prosthesis because appearance in the flaccid position is better than other designs. For these patients, implantation of a semirigid rod penile prosthesis requires a significant lifestyle change and they are better served with an inflatable-type prosthesis.

Similarly, patients with Peyronie’s disease, secondary implantation, or neurological disease are best served with an inflatable penile prosthesis considering interior tissue pressures are diminished between uses and the possibility of extrusion is diminished [7]. For patients in whom the convenience of inflation and deflation are not important, the risks of mechanical malfunctions may outweigh the concealment disadvantage of a malleable penile prosthesis. Such patients as paraplegics – who require external urinary collection device, those with inadequate manual dexterity, or those with significant obesity may be better served with a malleable penile prosthesis.

3. TYPES OF PENILE IMPLANTS

There are three classes of penile implants, hydraulic, semi-rigid, and soft silicone (Table 1) [5, 8, 9]. The hydraulic consists of two types, the three-piece inflatable and the two-piece inflatable. Two companies manufacture the three-piece variety; American Medical Systems (AMS) (Minnetonka, MN) and Coloplast (Minneapolis, MN).

Both companies market two widths of inflatable cylinders. AMS calls its standard cylinder the CX and its narrow cylinders the CXR. Coloplast titles its standard cylinder the Titan and its narrow-base model the Titan NB. The narrow cylinders are appropriate for the thin penis and for the penis with scar tissue where dilation to a large caliber corporal body is not easily accomplished. All of these cylinders expand in girth, but not in length. AMS also manufactures the LGX cylinder that expands in girth and length. Cylinder construction is quite different for the two manufacturers. AMS cylinders are composed of three layers. The inner layer is silicone, the middle layer is a fabric of woven Dacron and Lycra, and the outer layer is silicone. The CX and CXR have a unidirectional weave to their fabric allowing only girth expansion, whereas the LGX has a bidirectional weave permitting expansion both in length and girth. In late 1999 AMS added a Parylene coating to the surfaces of the silicone not in contact with the body tissues. This micropolymer increases the lubricity of the silicone and in bench testing by the manufacturer makes the silicone much more wear-resistant. The AMS pump and reservoir are also made from silicone and Parylene has not been added to their construction at this time.

The Coloplast cylinders and reservoir are made of Bioflex, a material similar to polyurethane, and silicone is used for the pump and the tubing to connect the components. Bioflex and silicone do not bond to each other chemically and the process used to bond the components to the silicone tubing is proprietary and undisclosed by Coloplast. Coloplast Bioflex cylinders in lab testing are more abrasion-resistant than silicone cylinders and clinical studies prior to Parylene introduction bore this out, as the studies of non-Parylene AMS devices had worse 5-year freedom from mechanical revision than did the Coloplast implants [10]. It is notable that a very large series of Coloplast devices had virtually no failures from the Bioflex component; most revisions were necessitated by silicone tubing failure adjacent to the pump [11].

Coloplast devices are all pre-connected between the cylinders and pump (Figure 1). The cylinders are available in 2 cm increments from 10-22 cm – longer lengths are available by special order. Reservoir sizes are 75 cc and 100 cc. AMS devices are available pre-connected and also as separate components. Cylinder length for AMS is in 3 cm increments from 12-21 cm for the standard size CX and LGX, but 2 cm increments for the downsized CXR. Reservoir sizes available are 65 and 100 cc. Rear tip extenders (RTE) are 1-3 cm for the Coloplast implants and are stackable to allow rear tips to equal 6 cm in total. RTE for AMS CX and LGX are similar except that a 0.5 cm is also available. The CXR has non-stackable, snap-on RTE available from 0.5 cm to 6 cm.

**FIGURE 1: Coloplast Titan Alpha 1**
Infections are the most disastrous complications of any implantable device. Both companies have taken steps to decrease the incidence of these problems by applying coatings to the prosthesis designed to retard bacterial growth. In May 2001 AMS introduced InhibiZone™, a patented antibiotic surface treatment that impregnates minocycline and rifampin into the external silicone surfaces of all the components, except the RTE, resulting in a mottled orange external appearance (Figure 2).

FIGURE 2 – AMS 700CX InhibiZone Device

The antibiotics elute into the implant space over 7-10 days and all traces are gone by 12 days. Concentrations of the antibiotics represent less than a common oral dose, but seem effective in preventing early colonization and the development of a bacterial biofilm layer [12]. The mechanism of minocycline (inhibits protein synthesis) and rifampin (inhibits DNA-dependent RNA polymerase) may help reduce the likelihood of developing bacterial resistance to either agent [13]. In-vitro and in-vivo studies have demonstrated minocycline’s effectiveness in retarding the emergence of staphylococcal strains that are resistant to rifampin [14]. Short-term follow up for this prosthesis enhancement shows statistical improvement in infection reduction for first time implant patients by a single surgeon [15] and the manufacturer’s data bank studies [16].

Coloplast also coats their Alpha 1 and Alpha NB with a hydrophilic coating. Initially this coating was called Resist; this title was subsequently dropped in the United States and the prosthesis was renamed Titan and Titan NB. The hydrophilic coating absorbs 23 times its weight in water and the theory is that when a coated implant is soaked in an antibiotic-containing solution, the antibiotics adhere to the surface of the device. No clinical studies are available as of yet, however, a manufacturer data bank study shows a decreased rate of implant infection when compared to non-coated Coloplast devices [17]. Coincident with the introduction of the new-coated Titan prosthesis, the tips of the cylinders were changed to a more physiologic tapered shape rather than the former blunt appearance.

The only two-piece device presently available in the United States is the AMS Ambicor (Figure 3). This device has cylinders similar to the obsolete AMS self-contained implant, the Dynaflex. In this 2-piece model the pump mechanism has been moved from the tip of each cylinder to a separate scrotal pump attached to the two cylinders. Depression of the pump causes fluid to move from a 3-5 cc reservoir in the base of the cylinder to the middle of the penile shaft achieving marked rigidity. Detumescence is obtained by bending the penis 90° from the horizontal position for 12 seconds. Flaccidity and erection are compromised with this model when compared to the 3-piece multi-component device, mainly because the reservoir volume is so severely restricted. The device is not available with Parylene or InhibiZone™ coatings as of yet, but has a popular following and good short-term mechanical reliability [18].

FIGURE 3: AMS Ambicor

Coloplast previously marketed a two-piece device as the Mentor Mark II. This device had a pump/reservoir (Resipump) that contained 25cc but delivered approximately 15-20 cc to Bioflex standard sized cylinders. The device was not popular and Coloplast withdrew it from the marketplace. Coloplast developed a similar device called the Excel that has narrow based cylinders attached to a smaller (20cc) combined pump reservoir. This device is currently approved in a number of markets outside the USA.

There are two types of semi-rigid rod prostheses, the malleable and the mechanical. Coloplast’s Genesis is a malleable device composed of a braided silver wire surrounded by a silicone hydrophilic coat. The AMS 650 and 600 implants have similar construction of silicone surrounding a stainless steel woven core (Figure 4).
The Jonas prosthesis manufactured in Germany for over 20 years also has a silver core and silicone covering [19]. The AMS Dura II is a unique semi-rigid rod that features articulating segments of polyethylene held together by a central spring (Figure 5). The articulating segments resembling a ball and socket are covered by a polytetrafluoroethylene sleeve and surrounded by a silicone jacket to prevent ingrowth of tissue into the mechanical parts.

Finally there are soft silicone rods that were originally manufactured in France by Subrini [20]. Currently, these inexpensive devices are sold under various names in several countries, mostly in Europe and Mainland China. This implant has been promoted to aid the partially impotent man who has tumescence, but not rigidity. The soft silicone implants are used less often because many of these men with partial ED now respond to oral medication. There are other rods manufactured locally throughout the world, but few of these find their way out of their native countries (Table 2). Currently only one semi-rigid rod model is available with a coating to retard infection, the Mentor Genesis.

For patients with complex anatomic issues such as kidney transplant or neobladder, the surgeon might consider placing a more simple prosthesis than the 3-piece. Another solution might be to place the reservoir outside of its usual location behind the pelvic bone in the space of Retzius. Coloplast manufactures a reservoir suited for these complicated patients. The reservoir has a lock-out valve that prevents transfer of fluid from the reservoir into the cylinders (Figure 7). Fluid is only transferred from the reservoir to the cylinders upon creation of negative pressure from the pump, not in response to positive pressure on the reservoir.
The reason the space of Retzius is chosen for reservoirs without this auto-inflation modification is due to its potential capacity. Three months after reservoir implantation the new capsule formation around the reservoir usually prevents increased abdominal pressure from milking fluid from the reservoir into the cylinders. The Coloplast reservoir with lockout valve allows placement of the reservoir in locations that would normally cause auto-inflation (e.g. anterior to the transversalis fascia, but posterior to the abdominal wall muscles) [23]. Many skilled surgeons continue to use the traditional reservoir position, even in anatomically compromised patients, but others resort to ectopic locations, such as mentioned above, or even place the reservoir in an intraperitoneal location. The tubing caliber for the AMS and Coloplast products is similar. This permits the surgeon in specialized situations to combine manufacturer’s components.

4. PATIENT SELECTION

When selecting a prosthesis for a particular patient the surgeon considers the three choices of semi-rigid, 2-piece inflatable, and 3-piece inflatable. All things being equal and cost not being a factor, the 3-piece is considered the gold standard in most industrialized countries. The semi-rigid rod implants are easy to insert and usually easy to manipulate. The rods are especially bendable and with minimal exertion can easily be maneuvered in the upward or downward position. The wire devices will sometimes spring back and may not be perfectly positionable for erection or in a straight downward position [24]. Sitting and standing may require surreptitious manipulation of the device to promote concealment. Cystoscopy with a rigid instrument was formerly a problem, but flexible cystoscopy has eliminated this problem with semi-rigid rod implants. Patients with spinal cord injury have been more prone to have erosion of semi-rigid rod cylinders through the glans because of cylinder pressure and the absence of sensation. The patient lacking cutaneous sensation may not appreciate when rods are eroding through the tissues of the penis. Most authorities recommend inflatable implants for spinal cord injury patients even if the implant is used only to facilitate condom catheter urinary drainage [25]. When considering choices of semi-rigid rods, the mechanical model, AMS Dura II, is more expensive than the devices using internal wires, but is “the prosthesis of choice for patients lacking manual or mental ability to manipulate other devices” [26]. The two-piece prosthesis is advantageous if the surgeon desires to avoid intra-abdominal reservoir placement since the functional result is better than a rod implant. The Ambicor can deliver good rigidity and fair flaccidity, or fair rigidity and good flaccidity, but rarely good rigidity and flaccidity simultaneously. There are other compromises when compared to the three-piece prosthesis. The long proximal segment between the proximal end of the implant and the input tube (5 cm) tends to make this tube palpable on the shaft of the penis in thin patients resembling what some call “tailpipe penis.” Finally, as mentioned above, deterioration in erection with time may occur. The three-piece “gold standard” accounts for 70% of implants implanted in the United States, while 20% are two-piece inflatable (Ambicor) devices. The remaining 10% are semi-rigid rods. Outside the United States, where reimbursement by third parties is less frequent, and the cost of the rods is considerably less, the split is 50% inflatable and 50% rods.

Outcome studies published in the medical literature indicate higher satisfaction from implants than pills, injections, or VEDs [27]. In 2005 the majority of well-informed patients elected surgical correction rather than pursing a trial of intracavernosal injections or VED. Many educated individuals seek out an urologist who specializes in prosthetic urology [28]. It is imperative that physicians with a focus on prosthetic urology profess their qualifications on internet search sites to enable patient connection with qualified implanters.

Today a patient would be considered a good candidate for a penile prosthesis if he had failed medical therapy or if medical therapy were contraindicated and the other therapies such as penile injections, intraurethral therapy, and VED have also failed or do not satisfy the patient. Patients who eventually opt for an implant are usually highly motivated to continue with sexual activity.

In many instances, the physician helps the patient decide which prosthesis type to choose. This decision is usually based on the physician’s comfort with the surgical approach, assessment of body habitus, and manual dexterity of the patient and overall cost. Patients with a larger penis will be best served by a three-piece inflatable device, as these devices deliver the best rigidity. Similarly, patients with shorter penises often choose the three-piece device, since semi rigid rods and two-piece implants are more difficult to conceal. Patients with limited manual dexterity or those who have difficulty manipulating hydraulic devices are directed towards a semi-rigid rod. An exception to this rule is when a motivated partner manipulates the hydraulic device for the patient.

It is important for the patient receiving a 3-piece inflatable implant to understand that the post implant size of his penis will invariably be slightly shorter than his natural erection when he was fully potent. Also, unlike a normal erection, the prosthetic erection does not result in an increase in the size of the glans. Preoperative consultation with the implant candidate should explain this loss of length, but emphasize that girth of the penis may be greater than a natural erection, and girth, not length is responsible
for penile rigidity. To continue along this line of reasoning, rigidity is what produces maximum sexual satisfaction in the female, as the area for maximal female stimulation resides just inside the introitus.

Sensitivity of the penis, ejaculatory abilities, and sexual drive are for the most part unchanged following placement of a prosthesis. The patient needs to clearly understand that penile implants only restore the ability to penetrate. They do not restore any special sensitivity or sexual drive that may have been present in earlier years. If the cylinders are removed at a later date, the capsule remains and the empty space will partially fill with proliferating scar tissue. This may make it difficult for the patient to respond adequately to other treatments such as medication or a VED. It is important that the patient have a realistic expectation of his penile prosthesis.

There are a number of possible complications associated with penile prosthesis implantation, as with any surgical procedure. The most common complications necessitating reoperation are infection (1-4%) [12] and mechanical dysfunction (5-13% in first 5 years) [10, 11]. A preoperative consultation needs to include a discussion of these potential causes of a return to the operating theatre. The patient and his physician need to be mutually satisfied they have covered the major risks and rewards of the surgical event and this needs to be noted in the clinical record.

5. PRE-OPERATIVE PREPARATION AND POSTOPERATIVE CARE

Most penile implants are placed in patients with an organic etiology to ED, and have failed to respond, did not tolerate, or are unwilling to consider more conservative options [29]. Oral therapy often fails in men with severe ED due to diabetes mellitus or after radical pelvic surgery. Men with severe Peyronie's disease associated ED, severe penile fibrosis, or cases of post-priapism are more likely to be considered for implantation of a penile prosthesis. In the pre-sildenafil era it was the norm to diagnose the precise etiology of a patient's ED. Comprehensive blood testing (including cholesterol, glucose and hormone studies), vasoactive injection testing, color duplex Doppler ultrasound, and nocturnal penile tumescence studies were all routinely obtained. This extensive evaluation process is now thought to be unnecessary in the day of effective oral therapy. Many third party payers have recognized that many of these diagnostic tests do not influence ultimate patient outcome and refuse to reimburse ancillary test expenses.

Diabetes mellitus is known to be a risk factor for severe ED and the need for penile prosthesis implantation [30]. In 1992 Bishop et al suggested that patients with diabetes mellitus whose blood sugar was in better control for a period of time preoperatively, as manifested by a normal hemoglobin A1C, were less prone to develop a penile implant infection versus a group whose Hgb A1C was elevated [31]. Other larger series repeated this study and found no difference in infection rates in patients with normal or elevated Hgb A1C [32]. The presence of diabetes raises the risk of prosthetic infection from 3% to 8%, but the level of glycosylated hemoglobin, the fasting blood sugar (FBS) on day of surgery, and whether the patient was insulin-dependent were not predictive for increased rate of infection [32]. Another study, however, showed no difference in infection rates between diabetic and non-diabetic men receiving penile prosthesis [33].

Current work up consists of a history and physical, with some focus on sexual desire and enjoyment. Failure or intolerance to oral drug therapy and knowledge of penile injections, intrarethral agents, and VED is ascertained during initial history taking. If the history and physical is uncertain, further diagnostic testing may be warranted. If the patient indicates an interest, one can prescribe oral therapy, intracorporal injections, intrarethral pellets, or VED. If disinterested, or a history of unsatisfactory results with second line therapies exists, the surgeon can explain the surgical benefits of penile prosthesis surgery. Many high volume implanters are tertiary referral centers for prosthetic surgery with patients travelling from considerable distances. These patients are often seen for the first time one day and undergo surgery the next. The expedited work up consists of history, physical, and assessment of the lower urinary tract.

It is important that the lower urinary tract be evaluated prior to penile prosthesis surgery in order to avoid untoward events such as urinary tract infection, difficulty inserting a catheter, or urinary retention. It is customary to perform a urinalysis, post-void residual check, and if indicated a cystoscopy. Urinary tract infections are treated and patients who are prone to develop urinary infections (such as those with neurogenic bladders) are placed on prophylactic antibiotics preoperatively to maintain sterile urine for the day of surgery. If prostate obstruction is detected, this is treated prior to prosthesis implantation by either medication, or surgical therapy. Post-radical prostatectomy patients may have a bladder neck contracture that would prevent easy Foley catheter placement or post-operative urination. Such patients are dilated or undergo transurethral bladder neck incision. If significant urinary incontinence is encountered, prosthesis insertion is delayed to determine if concurrent artificial urinary sphincter (AUS) placement or a male sling procedure is recommended.

Patients shower with antibacterial soap for a few days prior to surgery. Shaving of the genital area
is performed in the holding area or operating room to minimize the chance of bacterial colonization. Antibiotics are initiated prophylactically one hour prior to surgery. The antibiotic choice is made by the surgeon and this decision should cover the possibility of infection by skin contaminants. There have never been any controlled studies in penile prosthesis recipients demonstrating that postoperative antibiotics decrease the incidence of surgical infections. If a scrotal incision is utilized, a catheter is inserted to facilitate urethral identification and to empty the bladder completely before reservoir placement. The catheter may be discontinued when the patient has recovered from anesthesia or remains until the following morning. Some surgeons opt to use drains at the conclusion of the procedure to reduce edema and provide an exit for corporal bleeding in the postoperative period. Such a drain is removed the following morning and has not demonstrated an increased incidence of prosthesis infection [34].

Pain following placement of a penile prosthesis is variable and individual. The pain is usually more prolonged than genital procedures without prosthetic components.

Some scrotal ecchymosis and swelling is common and a scrotal hematoma, if it forms, usually slowly resolves without operative intervention.

Patients are instructed at discharge to wear brief-type underwear for the first month and direct their penis upward if possible. Coloplast implants with a lockout valve prevent fluid transfer from the reservoir to the cylinders. A capsule has not formed around the reservoir fully until three months postoperatively and in the early period in patients without a lockout valve, any increase in intrabdominal pressure may cause fluid to leak from the reservoir into the cylinders causing partial tumescence. In such cases, the patient should either deflate his device or return to the office for deflation. Generally at three months a capsule has formed around the reservoir and protects the patient from future auto-inflation. A new pump from AMS for the three-piece prosthesis that prevents auto-inflation has been recently introduced into the market.

Patients are taught how to operate their hydraulic devices at approximately four to six weeks. Some surgeons prefer to begin cycling of devices earlier, but in most patients pain will be a limiting factor to early cycling. At three months most patients are pain free. In some cases (e.g. diabetes mellitus) neuropathic pain may persist for longer periods of time. If prolonged pain does occur, the surgeon should suspect the possibility of a subclinical infection associated with the prosthesis.

After patients are instructed in the operation of their device they are advised to cycle regularly. When the cylinders are left semi-inflated for prolonged periods of time, a capsule forms over the reservoir in the less-than-full state that thereby restricts its expansion. Patients particularly dislike auto-inflation if they are attempting to achieve complete flaccidity. After three months it is usually no longer possible to influence reservoir capacity, and corrective capsulotomy may be necessary to correct bothersome auto-inflation [35].

6. ANESTHESIA

Three-piece penile implants are placed under general or regional anesthesia. A short acting spinal is ideal for the procedure. Local anesthesia is inadequate for reservoir placement. On the other hand, semi rigid rods may be placed with local anesthesia only. A penile block with 1% lidocaine is utilized before a tourniquet is placed around the base of the penis and approximately 25 cc of anesthetic is instilled into either corpus cavernosum and held in place for one minute. The tourniquet is released allowing the local anesthetic to diffuse into the proximal portion of the corpora. Infiltration of the skin incision site completes the anesthetic block. Some surgeons inject the corpora with a small amount of long acting anesthetic such as marcaine to keep the patient pain-free in the immediate post-operative period.

7. OPERATIVE TECHNIQUE

Surgical implantation of penile prostheses can be carried out using a variety of surgical approaches and incisions. Semirigid and malleable prostheses can be implanted through a distal penile approach. Multiple-component prostheses, however, can be implanted by the infrapubic or penoscrotal approach. While individual surgeons have a variety of rationales for each of these approaches, there does not appear to be any clear advantage in patient satisfaction or outcome of the two approaches. There is no difference in infection rates between either infrapubic or scrotal incisions [30]. Patient anatomy may dictate appropriate choice. Patients with previous abdominal surgical procedures where reservoir placement is difficult may be better served with an infrapubic approach while patients with massive obesity may be better approached through a penoscrotal incision. Two-piece devices, because there is no separate reservoir, are best implanted through a penoscrotal incision.

a) Distal Penile Approach

A distal penile approach is usually the best approach for insertion of a semirigid or malleable penile prosthesis. This incision heals well, allows complete corporeal dilation, and facilitates rod placement. After placement of a Foley urethral catheter, a circumcoronal incision is carried out over 180 degrees of the subcoronal region of the penis. Dissection is carried down to the layer of Buck’s fascia, taking care to avoid the dorsal penile nerves, which course within Buck’s fascia. After Buck’s fascia is identified, stay
sutures are placed in the two corpora through the tunica albuginea lateral to the penile nerves. These longitudinal incisions can be extended as much as is necessary for dilatation and cylinder insertion. The corporal dilatation is commenced with large scissors to establish a track in the corporal tissue. Dilation then follows with Hagar, Brooks, or dilamezinsert dilators from 9 to 14 depending upon required cylinder girth (Figure 8). Once the corpora are sized using a Furlow or other dilator, the cylinders can be placed (Figure 9 and 10). A small vein retractor can be used to facilitate placement of the distal end of the cylinder. The corporotomy is closed with 2-0 absorbable, synthetic sutures. With noninlatable cylinders, a penile block can be performed and a noncompression dressing is applied.

b) Infrapubic Approach

The infrapubic approach allows better visualization of the reservoir placement than the penoscrotal approach. However, due to the proximity of the dorsal neurovascular bundle in the infrapubic approach, nerve injury is possible, resulting in decreased distal penile sensation in some patients. The infrapubic approach is carried out with a horizontal or vertical incision approximately one finger breadth below the symphysis pubis, allowing implantation with an easily concealed incision once the pubic hair regrows (Figure 9 and 10). After incision of the subcutaneous tissue, the dissection is continued to the rectus fascia. The rectus fascia is incised and dissected cephalad for approximately 2 to 3 cm. A midline separation of the rectus muscles is carried out using sharp and blunt dissection. A pouch is created bluntly beneath the rectus muscles to comfortably insert the inflatable reservoir without compression.

Dissection is then carried out over the corpora cavernosa. Sharp and blunt dissection is performed on either side of the fundiform ligament, identifying the dorsal neurovascular bundle. Note that the dorsal nerves of the penis lie approximately 2 to 3 mm lateral to the deep dorsal vein. Once Buck’s fascia has been dissected free from the tunica albuginea, the shiny white tunica albuginea is fixed with longitudinal traction sutures. A corporotomy incision is then carried out between the traction sutures and the corpora cavernosa is entered (Figure 12). The corporotomy incision can be carried out with scalpel or electrocautery. Large scissors are then used to carefully initiate the tunneling of the corpora cavernosa. Hagar dilators from size 9 to 14 or alternatively Brooks, Pratt, or dilamezinsert dilators can be used. If corporeal fibrosis is encountered, Rossillo cavernotomes can be used to dilate to size 12. Once dilation has been adequately carried out bilaterally, the Furlow introducer or dilamezinsert is used to measure the corpora cavernosal length using a traction suture as a central point of reference. The proximal and distal measurements are added to give total corporal length and choose appropriately sized inflatable cylinders. A length slightly less than the total measurement is usually used to permit comfortable positioning of the cylinders. Rear tip extenders of size 0.5, 1, 2, 3 cm, or combinations thereof are placed on the proximal cylinder end to adjust length. Once measurement has been obtained, interrupted sutures can be placed for later corporotomy closure. The advantage to this technique is the elimination of suture needles close to the area of the inflatable cylinder, diminishing the possibility of cylinder damage during corporotomy closure. Other methods of corporotomy closure include running sutures with or without a locking technique. Once the corporotomy sutures are placed, cylinders are positioned in the dilated straight corpora cavernosa using the Furlow inserting tool with distal needle to pull the cylinders into position. Once positioned, it is essential to ensure that there is no kinking and complete proximal and distal seating of the cylinders has taken place. The corporal incision should be placed proximal enough to allow easy exit of the input tube and minimize cylinder/input tube contact. Closure of the corpora cavernosum is carried out with traction on the cylinder placement suture to maintain it in a flat, nonkinking position and ensure adequate seating. Following placement of cylinders and closure of the corporotomy incision, cylinder inflation can be tested by pumping fluid to identify any abnormalities in position, curvature, or related problems.

A finger is placed beneath Scarpa’s fascia down into the scrotum on one side to develop a sub dartos pouch for the pump. The pump is then positioned in the previously constructed subrectus pocket and filled with an appropriate volume of normal saline or water/radiographic contrast media. Before connection, it is important to release pressure on the filling syringe and determine if any backfilling is observed. This backfilling or backpressure may predict an autoinflation problem in the future. Tubing connection is then carried out using quick connectors or suture tie plastic connectors. Snap-on connectors are used for Coloplast prostheses. The tubing is tailored to eliminate excessive length but to allow for adequate pump positioning. Shodded clamps are used to compress the tubing and the ends of the tubing, once tailored, are flushed with inflation fluid to eliminate small particles and blood clots. After the tubing is connected, the adequacy of the connection is tested by gently pulling on the connectors. All shodded clamps are removed and the device is inflated and deflated on multiple occasions to ensure adequate location, placement, and erection.

Following testing, thorough irrigation with antibiotic solution is carried out and the rectus fascia closed with interrupted sutures. The wound is then closed in
the standard fashion with two layers of subcutaneous tissue and a subcuticular skin suture. A dry sterile dressing is applied, a Foley catheter placed if necessary, and an ice pack applied. Suction drains may be used at the surgeon’s discretion.

Postoperatively, patients are instructed to maintain their penis in a dependent position for 4 to 6 weeks. Tight underwear and athletic supporters are not used in an effort to maintain the pump in its most dependent position.

c) Penoscrotal Approach

Three-piece inflatable penile prostheses, as well as, semirigid and two-piece prostheses can be implanted by a transverse or vertical penoscrotal incision. This approach has distinct advantages in obese patients and is the most common approach for routine penile prosthesis implantation. Because the penoscrotal approach requires differentiation of corpora cavernosa from the corpus spongiosum during resection, initial placement of a Foley catheter is preferred for this approach. The incision, usually horizontal, is placed in the upper portion of the scrotum one finger breadth below the penoscrotal junction. The Scott/Lone Star retractor (Lone Star Medical Products, Stafford, TX) facilitates exposure with this incision. Once the skin incision has been carried out, dissection is continued lateral to the corpus spongiosum and urethra to expose the corpora cavernosa. Incision, dilation, and closure of the corpora cavernosa are similar to that described previously for the infrapubic incision, but synthetic absorbable sutures should be used with this approach because the suture line may be palpable postoperatively (Figure 15). Cylinder sizing and placement are as described above. Pump placement is likewise in the most dependent portion of the scrotum just below the dartos fascia.

Dissection for reservoir placements can be carried out with a second separate infrapubic incision, but is more commonly performed through the penoscrotal incision (Figure 16). The scrotal skin incision is retracted to the area of the external inguinal ring and dissection is carried out medial to the spermatic cord. It is important to drain the bladder completely at this point. The transversalis fascia is then identified and incised sharply using large scissors pushed firmly through the medial aspect of the external inguinal ring. Dilation is carried out with the index finger after incision of the transversalis fascia. The reservoir balloon is then positioned over the index finger and placed in the perivesical space. Inflation of the reservoir is carried out with care that no backpressure is observed. If refilling of the syringe occurs, pocket enlargement must be carried out to help prevent autoinflation occurring down the line. Once the reservoir is placed, inflated, and tubing connected as previously described, the device is tested in inflation and deflation modes (Figure 17).

Closure is carried out with a subcuticular suture in the standard fashion. In men with a penoscrotal skin web, the horizontal skin incision can be closed in a midline fashion or employing a Z-plasty technique to enhance functional penile length.

8. PENILE PROSTHESIS COMPLICATIONS

a) Infection

Periprosthetic infection, infection in the space around a penile prosthesis, is the bane of genitourinary prosthetic surgery. While men with these infections are seldom seriously ill, eradication of the infection invariably requires complete device removal. Subsequent penile prosthesis reimplantation is difficult due to scarring of the corporeal smooth muscle, which leads to decreased penile length and girth as well as difficult cylinder implantation.

The use of prophylactic broad spectrum antibiotics is widespread in penile prosthetic surgery; however, the timing of the administration of these antibiotics varies. Guidelines suggest that “infusion of the first antimicrobial dose should begin within 60 minutes before surgical incision and that prophylactic antimicrobials should be discontinued within 24 hours after the end of surgery [36].”

Traditionally infection rates in revision penile prosthesis have been higher than with primary implant surgery. When at the time of revision surgery the entire device is removed and the implant spaces are lavaged with a series of antiseptic solutions before implantation of a new device, the infection rate is similar to that with first time (primary) penile prosthesis implantation [37]. Earlier however, it had been shown that when the old implant is entirely removed and replaced with a new device, lavage with only one antibiotic solution was enough to achieve an infection rate equivalent to that seen with primary penile prosthesis implantation [33].

In 1996 Brant and Mulcahy introduced the concept of penile prosthesis salvage for infected implants [38]. With this procedure, the entire infected device is removed and the implant spaces are lavaged with a series of antiseptic solutions. A new prosthesis is then implanted. This series was updated in 2000 [39] and again in 2003 at which time the success rate of salvage in a series of 101 infected implants was 84% [1]. After inflatable penile prosthesis implantation, infection usually first becomes evident by tissue changes around the pump. It is now generally accepted that the entire penile prosthesis is infected. Whether a salvage procedure is performed or the device is removed with planned later reimplantation, it is mandatory to remove all the prosthetic material including, if present, polytetrafluoroethylene tubing coverings and rear tip extenders (Table 3) [1].

Unfortunately some surgeons still remove only the
pump; with subsequent removal of the rest of the device becoming necessary because of infection. Superficial wound separation and / or infection is more common than periprosthetic infection. If the entire penile prosthesis is implanted below the fascia, routine wound care will result in wound healing without device infection. With inflatable penile prostheses, where the pump and cylinders are often available as a unit, surgeons using a penoscrotal approach often employ a technique that results in tubing being present under the scrotal skin and subcutaneous tissue. This is not only undesirable from a cosmetic standpoint but it also greatly increases the chance of device infection should a superficial wound infection or separation occur. Routing the pump through an opening in the back wall of the scrotal pouch for the pump buries the tubing beneath the fascia, thus avoiding these problems.

In 2001 American Medical Systems (Minnetonka, MN, USA) introduced a dual antibiotic coating, minocycline and rifampin, for their three-piece inflatable penile prosthesis product line. This was shown to decrease the infection rate 180 days after implant from 1.61% to 0.68% [16]. Mentor Corporation (now Coloplast) soon after introduced a hydrophilic coating, polyvinylpyrrolidone (PVP), for their three-piece inflatable penile prostheses. This coating allows the implanting surgeon to immerse the device in an antibiotic solution of his or her choosing. This resulted in a decrease in the infection rate one year after implant from 2.07% to 1.06% [17].

b) AUTO-INFLATION

Partial spontaneous inflation of a three-piece inflatable penile prosthesis sometimes occurs and may be bothersome to the patient. In one study the rates of auto-inflation in men implanted with three-piece inflatable prostheses after prostatectomy was 3% and in men with erectile dysfunction due to other causes it was 5%. (p>0.99) [40] Mentor introduced a lock-out valve in the reservoir stem which resulted in a 1.3% rate of auto-inflation compared to an 11% rate in historical controls [23]. American Medical Systems recently introduced a lock out valve in the top of the pump of their AMS 700MS™ device; published rates of auto-inflation with this prosthesis are not yet available.

c) GLANS PROBLEMS AFTER PENILE PROSTHESIS IMPLANTATION

Patients who are considering penile prosthesis implantation should be told about the lack of glans tumescence and that their erection may be shorter than their former natural erection. Some men who complain of lack of glans tumescence or coolness after penile prosthesis implantation may benefit from the use of a phosphodiesterase type 5 inhibitor or from the use intrarethral alprostadil (MUSE, Vivus, Mountain View, CA) [41].

Other patients may complain of poor support of the glans penis by the tips of the prosthesis. This downward drooping of the distal penis is referred to as the SST deformity because of the similarity of its appearance to the supersonic transport or Concord aircraft. If the SST deformity is due to cylinders which are too short, revision with implantation of longer cylinders will correct the deformity and result in a somewhat longer penis. Sometimes this deformity occurs because of anatomic variations in the relationship of the glans penis to the corporeal tips. In this case a glanulopexy modified after that originally described by Ball [42] may be helpful [43].

d) RESERVOIR DISPLACEMENT

In three-piece inflatable penile prosthesis implantation by the penoscrotal approach, the empty reservoir is inserted blindly into the retropubic space by perforating the fascia on the medial side of the external inguinal ring or through the fascia just above the pubic tubercle. This is safely done by insure complete bladder emptying through a urethral catheter. The fascial defect created should be tight to the surgeon’s finger. Filling the reservoir with saline after placement helps maintain its retropubic position. Reservoir displacement or herniation into the inguinal canal or upper scrotum will rarely occur. One survey

found an incidence of this complication of 0.7% [44]. Correction of this complication is by revision through an inguinal incision with placement of the reservoir in its proper position and repairing the defect.

e) Distal Cylinder Erosion or Extrusion

Because of loss of sensation, erosion of a penile implant into the urethra occurs more commonly in paraplegic or quadriplegic recipients. This erosion rate was 18.1% (15 of 83) for cases of semirigid rods, 2.4% (2 of 84) for self contained inflatable prostheses, and 0% (0 of 28) for 3 piece inflatable devices [7]. Three-piece inflatable prostheses appear to be associated with less risk of this complication in these recipients. Distal cylinder extrusion laterally can be repaired by creating a new cavity for the distal cylinder behind the back wall of the fibrotic sheath containing it [45]. An alternative technique is to perform distal corporoplasty using synthetic material [46]. Proximal perforation of the cura during the implant procedure can be repaired by the constructing wind sock of vascular prosthetic material and anchoring this to the prosthesis [47].

However, perforation of the crus during dilation usually occurs with the use of narrow dilators and is recognized by the sudden passage of the dilator into the soft tissue of the perineum. When this occurs, it is usually possible to use large scissors to establish the true plane of dilation down to the attachment of the crus to the pelvic bone.

Larger dilators follow this plane, thus avoiding further dilation of the false passage. The rear tip of the cylinder can then be implanted within the crus. The small false passage heals over the tip of the cylinder. These steps eliminate the need for wind sock repair.

f) Carvernosal Fibrosis

Smooth muscle fibrosis occurs in men with ED following prolonged ischemic priapism and in men who have had removal of an infected penile prosthesis.

Dilation of the corpora can be quite difficult and limited dilation may be all that can be achieved. Smaller diameter penile prostheses are useful in these cases. If primary closure of the tunica albuginea over the prosthesis is not possible, the device may be covered by graft material. The following graft materials have been used for this purpose: human cadaveric dura mater [48], polytetrafluorethylene [49], human cadaveric pericardium [50], and porcine small intestinal submucosa [51]. The results of prosthetic surgery using narrow diameter cylinders are often satisfactory. When they are not, future upsizing to wider and sometimes longer cylinders may be helpful [52].

In cases of severe cavernosal fibrosis, corporeal excavation through extended corporotomies has been successfully performed with most of the fibrotic contents of the corpora being removed [53]. This leaves a tunica albuginea shell into which the prosthetic cylinders can be laid. Primary closure of the tunica albuginea over the cylinders is then easily accomplished without graft materials.

9. Penile Prosthesis Survival

Mechanical failure of penile prosthesis can include leakage from the cylinders, tubing fracture, reservoir malfunction, connector disruption, tube kinking, and cylinder aneurysm. Failure rates among inflatable penile prostheses (IPP) have historically been low (Table 4). A recent study from the University of Arkansas assessed the long term survival of IPP, covering both AMS and Mentor/Coloplast models (n = 2,384), and documented the overall 15 year freedom from reoperation to be about 60%, with no significant difference between models [54]. Another study evaluated the efficacy and survivability of the two-piece Ambicor inflatable penile prosthesis, finding that, due to recent revisions in rear tip extenders and pump tubing reinforcement, freedom from reoperation was 99.2%, 99.2% and 91% at 12, 36 and 48 months, respectively (n = 146). Corresponding patient and partner satisfaction were similarly 85% and 76% [55]. The AMS three-piece 700 CX was evaluated for long-term survival in a recent study including 455 patients and was found to have an overall freedom from reoperation of 74.9% and freedom from mechanical failure of 81.3% after ten years [56].

10. PATIENT AND PARTNER SATISFACTION

Numerous studies have reported high satisfaction rates for both patients and partners after penile prosthesis implantation for the treatment of ED. In a series of 185 patients from a group of European institutions, authors reported a 98% patient and 96% partner satisfaction rate [61]. The rapid ability to produce an erection and consistent excellent rigidity with the prosthesis were two major factors contributing to this high level of satisfaction for this modality of ED treatment. Lower satisfaction rates have been noted when there is an overall loss of penile length, such as in revision surgery after infection and in prosthesis implantation for Peyronie's disease with penile shortening [62, 63]. Patient satisfaction is a complex and multifactorial issue that may include the degree of postoperative pain and swelling, occurrence of postoperative complications, cosmetic outcome, device function, ease of use, and partner acceptance. Besides shorter length of the penile erection, other reasons given for dissatisfaction include reduced sensitivity, diminished sexual drive, unnatural feeling by the partner, and the partner perception of having a diminished role in initiating erection. Another common patient complaint is the lack of glans engorgement during sexual activity. Typically the patient reports that the corpora cavernosa provide satisfactory rigidity after activating the implant, but notes a soft and mobile glans. One recent study reported on the beneficial effect of sildenafil (Viagra, Pfizer, NY, NY) on glans engorgement in patients having undergone penile implant [64]. By using the International Index of Erectile Function (IIEF), researchers documented that sildenafil caused a statistically significant improvement in implant-assisted intercourse. Similar results were reported with the on demand administration of transurethral alprostadil in patients with self-contained inflatable penile prostheses [65]. Research evaluating the efficacy and satisfaction of prosthesis implantation continues. In a recent study of 146 recipients of two-piece penile prostheses, the authors reported 85% satisfaction among the men and 76% satisfaction among their partners [55]. Even more impressive is the data from a large Italian study, which showed patient satisfaction of 97%, 81%, and 75% with the AMS 700CX, AMS Ambicor, and AMS 600-650; partner satisfaction was 92%, 91% and 75%, respectively [66]. A recent case series from China reported successful coitus in 97.6% (41 of 42) of patients after IPP placement, which was higher than previous reports [67]. Certain patient factors may be predictors of reduced satisfaction. In an Italian multi-institution study surveying patients with penile implants and Peyronie’s disease, 79% of patients and 75% of partners reported satisfaction with the result [61]. It is recognized that patients with Peyronie’s disease, radical prostatectomy, or a BMI >30 kg/m² have a statistically significant reduction in level of satisfaction compared with the general implant population [68]. It is likely that penile length issues play a large role in Peyronie’s disease and radical prostatectomy patients in this regard. It has not been clearly delineated why a BMI >30 kg/m² should be associated with reduced satisfaction, but mechanical issues relating to the pre-pubic fat pad size have been noted in many of these men. Efficacy can also be assessed in a more quantitative fashion with post-operative IIEF scores. One group reported IIEF scores 3, 6, and 12 months after placement of a Mentor/Coloplast Alpha-1 IPP. They found IIEF erectile function domain (EFD) scores to be 13, 21, and 24 and IIEF Satisfaction scores to be 9, 11, and 15 at each respective time interval (baseline in both groups = 7) [69]. A recent study assessing patient overall satisfaction with a specialized questionnaire reported patient satisfaction to be 69%, which is in general agreement with prior reports using other questionnaires [70]. Earlier studies compared inflatable and semi-rigid prostheses and found increased satisfaction in men using inflatable devices over noninflatable penile prostheses. Another study showed a corresponding higher satisfaction among female partners of men using inflatable prostheses in comparison to noninflatable prostheses [71].

</table>

As expected, satisfaction domain scores for patients with corporal fibrosis and shortened penises who had undergone revision prosthesis surgery...
reported lower scores compared to other revision implant groups [72]. In a recent study comparing Mentor/Coloplast Alpha prostheses to the AMS series, no difference in satisfaction rates was found between the two models when employing a specialized follow-up questionnaire [70]. Comparisons between IPP and other forms of ED therapy generally reveal a higher satisfaction rate in men with ED who chose the prosthesis. A 2003 study using IIEF erectile function domain (EFD) and Erectile Dysfunction Inventory for Treatment Satisfaction (EDITS) scoring systems comparing IPP, intracavernous prostaglandin E1 injections (ICI), and sildenafil showed that IPP had significantly higher satisfaction rates compared to the other ED treatment modalities [27].

**Recommendations**

**Indications for penile prosthesis implantation**

- Penile prosthesis implantation is indicated for the treatment of organic erectile dysfunction after failure or rejection of other treatment options.
  - Level of Evidence 3, strength of recommendation C.

- The three-piece inflatable penile prosthesis is recommended for younger patients with normal manual dexterity, patients who wear form fitting clothes, or patients that shower in public.
  - Level of Evidence 3, strength of recommendation C.

- Inflatable penile prostheses are recommended for patients with Peyronie’s disease, as a secondary implantation, or patients with neurological disease.
  - Level of Evidence 3, strength of recommendation C.

- Malleable prostheses are recommended for significantly obese patients, and those with minimal manual dexterity, or when the cost of inflatable penile prostheses is prohibitive.
  - Level of Evidence 3, strength of recommendation C.

**Pre-operative Preparation and Postoperative Care**

- In order to prevent complications, it is important to obtain the patient’s medical and sexual history and perform a physical examination before the prosthesis is implanted. The physician should ensure the patient is aware of all other treatment options and get an accurate idea of what the patient hopes to achieve. This will help in choosing the appropriate prosthesis for the patient.
  - Level of Evidence 3, strength of recommendation C.

- Patients are recommended to follow-up with doctors to learn how to use their devices optimally, ensure their devices are working properly, and confirm there are no postoperative complications such as infection, fluid leaks, or autoinflation.
  - Level of Evidence 3, strength of recommendation C.

**Informed Consent**

The patient should be informed of the following possible complications related to the prosthesis prior to implantation: infection and its consequences, pain, mechanical failure, penile shortening, and autoinflation.

- Level of Evidence 3, strength of recommendation C.

**Anesthesia**

- Inflatable and semi-rigid rods are usually implanted under regional or general anesthesia. Rarely, local anesthesia can be used for malleable types of prostheses.
  - Level of Evidence 3, strength of recommendation C.

**Operative Technique**

- Distal penile, infrapubic, and penoscrotal are the three main approaches for inserting the penile prosthesis. The method chosen is based upon the prosthesis type, patient’s specific anatomy, surgical history, and surgeon preference.
  - Level of Evidence 3, strength of recommendation C.

**Penile Prosthesis Complications**

**a) Infection**

- Periprosthetic infection is an important concern for both doctors and patients, not only because it can cause serious illness, but also requires the complete removal of the devices. Subsequent reimplantation is difficult because of scar formation.
  - Level of Evidence 3, strength of recommendation C.

- A number of measures have been taken to decrease the risk of infection. Still, there is no consensus on a standardized method of minimizing infection rates. AMS and Coloplast, both manufacturers of hydraulic implants, have taken steps to decrease infection rates by applying antibiotic coatings or hydrophilic surfaces to their prosthetic devices. Initial research suggests these newer interventions decreases the rate of prosthetic infection.
  - Level of Evidence 3, strength of recommendation C.

- In addition to using an antibiotic coating on the prosthesis, prophylactic broad spectrum antibiotics...
have also been used with guidelines suggesting application within 60 minutes before surgical incision. Also, antimicrobials should be discontinued without 24 hours after the end of the surgery.

- Level of Evidence 3, strength of recommendation C.

- If the prosthesis becomes infected, it is recommended the entire prosthesis should be removed. In certain situations a salvage procedure may be performed in which the entire area is lavaged with a variety of solutions and a new device is implanted.

- Level of Evidence 3, strength of recommendation C.

b. Other Complications

- Spontaneous inflation is a potential and bothersome problem with the three-piece inflatable penile prosthesis. Additionally, lack of full glans tumescence, shorter erections, unwanted movement of the pump or reservoir, erosion into the urethra, fibrosis, and mechanical failure are other potential complications associated with penile prostheses.

- Level of evidence 3, strength of recommendation C.

Penile Prosthesis Survival

- Many studies have been conducted regarding long-term survival of inflatable penile prostheses, with failure rates of both the 2-piece and 3-piece recorded as fairly low.

- Level of Evidence 3, strength of recommendation C.

- Future studies reporting device survival should express this by using Kaplan-Meier projections which allow meaningful comparisons of various studies and patients with differing follow-ups.

- Level of Evidence 3, strength of recommendation C

Prosthesis Satisfaction

- Numerous studies have shown high satisfaction rates for both patients and partners.

- Level of Evidence 3, strength of recommendation C.

- One study demonstrated a higher satisfaction rate in men with penile prostheses over other treatments for ED such as intracavernous prostaglandin E1 injections, intraurethral alprostadil, vacuum erection devices, and oral PDE5 inhibitors.

- Level of Evidence 3, strength of recommendation C.

- Future satisfaction studies should be prospective, include partners whenever possible, and use standardized forms. A new form for satisfaction in penile prosthesis recipients needs to be developed and validated.

- Level of Evidence 3, strength of recommendation C

II. VACUUM CONSTRUCTION DEVICES

1. History

The first report on the concept of negative pressure being applied to the field of ED was by John King, an American physician who described a method of improving erections by a small vacuum pump [73] (Figure 18). In 1917, a patent was granted to Otto Lederer for his surgical device to produce erections with a combination of a vacuum and a compression ring, now known as the vacuum erection device (VED) [74]. The credit for the popularization of VED is attributed to a Georgian entrepreneur, Geddings D. Osbon who (reluctant to accept his own impotence) developed and constructed his personal VED in 1960. After perfecting the device on himself for over a decade, it became commercially available in 1974, but only in 1982 was he granted permission from the Food and Drug Administration to market the device (known as Erec-Aid), as a prescription product – the first of its kind [75]. Since that time several patents have been granted, although they all share similar device characteristics.

Figure 18. VED with pump, vacuum cylinder, and compression rings.

2. Devices and Mechanisms of Action

There are currently a number of VED commercially available, all using the same principle, but varying slightly in their method of inducing a vacuum, in their pressure-release valves, and in the shape of the rings.

The standard VED consists of suction cylinder and pump to induce an erection by increasing corporal blood flow and then a compression band placed around the base of the penis to maintain the erection-like state by decreasing corporal venous drainage after the suction device is removed (Figure 19).
Figure 19. Pump creating negative pressure in cylinder with resultant penile engorgement and decreased corporal drainage by placing a compression ring at base of penis.

Figure 20. VED with combined pump and cylinder system.

Some models combine the suction cylinder and pump into one piece and most manufacturers offer their device with a battery-driven motor to create the vacuum (Figure 20). The cylinder is usually clear plastic and must be of sufficient length and diameter to fit over the erect penis. The cylinder has a pressure release valve designed to prevent penile injury from excessive negative pressure.

The compression rings vary widely with regard to their thickness and grips, but some manufacturers have introduced shaped rings with a notch to fit over the urethra in an attempt to reduce ejaculatory difficulties and to concentrate pressure onto the corpora.

The base of the penis, the contact area of the VED and the compression rings are lubricated with copious amounts of water-soluble jelly and the rings are fed over a loading cone to the base of the cylinder. The cylinder is then placed over the flaccid penis, pressed firmly against the pubic bone to obtain an airtight seal, and suction is applied for a few minutes to effect penile engorgement [76]. Once an erection-like state has been produced, one or more bands, previously rolled onto the cylinder prior to the vacuum maneuver, are slipped from the cylinder onto the base of the penis preventing venous return and maintaining tumescence [77]. Then the vacuum is released via a valve and the cylinder is removed.

The compression rings are left in place no longer than 30 minutes to avoid ischemic damages to the cavernosal tissue; if intercourse is to be prolonged past this point, the band must be removed and after few minutes the same procedure can be repeated. The time taken to obtain an erection varies but has been reported on an average between 2 and 2.5 minutes [78, 79]. Intermittent pumping can improve penile rigidity, enabling more satisfactory penetration. Patients should be instructed to pump for 1 to 2 minutes, releasing pressure and then pump again for 3 to 4 minutes [80]. Prescription devices are advised and metal or other inelastic rings are contraindicated [76].

3. PHYSIOLOGIC EFFECTS

The erection obtained with VED is not natural and there are distinct differences in the physiology of a spontaneous erection and that of an erection following use of a VED, as outlined by Nadid and associates [81]. Although persistent reduced blood flow during compression has been described by one group using plethysmography, others using duplex Doppler sonography found maintenance of the cavernous arterial inflow [82, 83].

The VED promotes engorgement of the penis through negative pressure effects and blood is trapped in different compartments in the penis, including subcutaneous tissues and the sinusoidal spaces of the cavernous bodies whose diameters double [82]. Cavernosal blood gas analysis has confirmed that engorgement in the penis is composed of predominantly venous blood [84].

Vacuum pressures between 100 and 225 mm Hg are necessary to achieve erection [83]. Excessive negative pressure can cause bruising and hematoma, and to avoid injury to the penis only VED containing a vacuum limiter should be used [85].

It is important that patients and their partners be informed that VED-derived erections are perceived differently when compared to naturally occurring erections. All turgidity is distal to the constriction band and the crura are not involved in the erection, causing some degree of instability, leaving the potential for pivoting at the base and often requiring manual assistance to insert the penis into the vagina.

Owing to extracorporeal congestion, the VED-erect penis appears more cyanotic, is cooler, and girth is usually greater than a normal erection [78, 84].

4. RESULTS OF VED THERAPY

Although VED have proven to be effective in treating ED, even in the era of PDE-5 inhibitors, the literature
consists largely of single center observational series, and a collection of small prospective clinical trials. Efficacy rates of 67 to 90% have been reported in achieving satisfactory erections but patient satisfaction rates with the device are lower, ranging from 34 to 68% [86-90].

There is a great deal of variability in the clinical efficacy and satisfaction of VED therapy. In an evaluation of 216 consecutives patients, Cookson et al. reported regular device use in 69%, with a 90% chance of attaining good-quality erections. Patient and partner satisfaction was 82% and 89% respectively [91]. Vrijhof et al. reported their experience with 67 patients treated with VED, and adequate erections were reported by 72% [90]. In contrast, the experience of other authors with patient satisfaction using the VED has been consistently less.

In a retrospective study, Derouet et al [92] evaluated the medical and psychological outcome of the use of VED in the treatment of ED in 190 patients using a questionnaire and a clinical examination. 110 patients (57.8%) answered the questionnaire. Twenty-two (20%) rejected the device primarily and 34 (30.9%) after a period of up to 16 weeks (primary rejection rate 50.9%). A secondary drop-out rate of 8 patients (7.3%) was observed after an intermediate time of 10.5 months. Forty-two percent of patients were long-term users and were mainly subjects who did not respond to intracavernosal pharmacotherapy.

The general low acceptance of VED therapy in the treatment of mild, moderate, and severe ED was revealed in the series of Dutta et al. [93]. One hundred twenty-nine patients received a follow-up questionnaire regarding satisfaction, months of use, reasons for discontinuing, and further treatment. The overall attrition rate observed was 65% and was lowest among patients with moderate ED (55%). All patients with mild ED discontinued use, and a large number (70%) of patients with complete ED also discontinued use. Of the patients who discontinued, most stopped treatment early (median one month, mean four months) and 63% did not seek further treatment. Thirty-five percent of patients were satisfied with the device and have continued to use it long term (mean 37 months).

Earle et al. conducted a retrospective survey to assess the use, efficacy and acceptance of the VED among 60 impotent men not satisfied with intracavernosal injection therapy and found a high dissatisfaction rate with VED therapy [94]. Eighty-one percent of the men abandoned the device citing lack of efficacy.

Certainly, organic impotence as a whole responds well to VED therapy, with satisfactory erections expected in at least 70% of diabetics subjects, 93% with arteriopathy, 70% with venous leaks, and more than 90% following radical prostatectomy [86, 91, 95-99]. Patient and partner satisfaction appear to be closely correlated and also depends on successful erection [100].

5. SPECIALIZED AND COMBINED USES

In those patients in whom intracavemosal pharmacotherapy has failed, the use of VED in combination with vasoactive injection therapy may lead to an adequate erection. Chen et al. studied the effect of combining intracavernous injection and a VED in 10 men with ED who previously failed attempts at treatment with either method as monotherapy [101]. They conclude that VEDs can augment a partial response to intracavernous injection and the combination may be an alternative treatment before other more invasive treatments such as a penile prosthesis are considered.

Prostaglandin E1 (PGE1) agents delivered by intraurethral administration can significantly increase vacuum-assisted erections. Combination therapy can increase both penile length and diameter [102].

The addition of a phosphodiesterase type-5 inhibitor with VED improved sexual satisfaction and penile rigidity in patients dissatisfied with VED alone after radical prostatectomy. Raina et al. reported the efficacy of combining sildenafil citrate with a VED in men with ED after radical prostatectomy [103]. A total of 31 patients were instructed to take 100 mg of sildenafil 1 to 2 hours before VED use for the purpose of sexual intercourse. Patients used combination therapy for a minimum of 5 attempts. Of the 31 patients, 24 (77%) reported improved penile rigidity and sexual satisfaction. Of the 24 men, 7 (30%) reported a return of natural erections at 18 months using combination therapy, with 5 of 7 reporting erections sufficient for vaginal penetration.

The VED can also be used in men who either have prosthesis in place but find these erections unsatisfactory, those with fibrosis of the erectile tissue secondary to priapism, or after an explanted prosthesis [104, 105].

The VED has been used as a tissue expander following surgical correction of Peyronie’s disease in order to maintain the elasticity of the tissues [106]. More recently, there has been interest in the use of VED in early intervention protocols to augment corporeal rehabilitation of post-radical prostatectomy fibrosis. Raina et al. showed that early use of VED following prostatectomy facilitates early sexual activity and potentially an earlier return of natural erections sufficient for vaginal penetration [107]. Kohler et al. in a pilot study on the early use...
of the VED after radical retropubic prostatectomy showed that this form of treatment improved early sexual function and preserved penile length [108]. For some investigators, VED have become first-line therapy for preservation of erectile function following treatment of prostate cancer [109].

6. SIDE EFFECTS AND CONTRAINDICATIONS

Adverse effects are usually observed early in the treatment and usually decrease with continued use of the VED. Pain on ejaculation is reported in 3 – 16%, with an inability to ejaculate in 12-30% [79, 91, 110]. Pain may occur during the creation of the vacuum in 20 to 40% of users. Petechiae or ecchymosis of the penis are reported in 25-39%, with bruising (especially at the position of the ring) in 6 – 20% [86, 91]. Numbness during erection is reported as the major problem in 5% [91].

Major complications are infrequent. Rare descriptions of isolated, serious adverse effects after VED use have been published including penile skin necrosis, urethral varicosites, capture of scrotal tunica within the penile shaft, Peyronie’s disease, and Fournier’s gangrene [111-114].

There are few contraindications to this form of therapy. Patients on anticoagulant therapy and patients with bleeding disorders must use VED with caution [115]. Similarly, special attention must be given to patients with a tendency for spontaneous priapism or prolonged erections [80].

7. CONCLUSIONS

Use of a VED is a safe and effective form of therapy for men with ED. The British Society for Sexual Medicine Guidelines, an evidence-based guideline for the diagnosis and treatment of ED, concluded that oral pharmacotherapy with PDE5 inhibitors and VED are the first-line therapy for ED [116]. The importance of proper patient selection improves outcome results as confirmed by the experience of a number of authors. VED may be offered preferentially to elderly patients who partake in limited intercourse attempts versus younger patients who document lower preference for VED because of unnatural erections and cumbersome application.

Recommendations

- VEDs are ED treatment devices that employ the use of negative pressure to engorge the penis with blood and constriction rings artificially trap blood in the penis. Studies have reported the time to erection varies, but averages from 2 to 2.5 minutes. Level of Evidence 3, strength of recommendation C.

- A number of studies have reported that erections obtained with VEDs are unnatural and therefore are distinctly different from natural erections. Level of Evidence 3, strength of recommendation C.

Results of VED therapy

- Considerable variability in clinical efficacy and satisfaction has been reported, but, overall, organic impotence responds well to VED therapy, especially in those who do not respond well to intracavernosal pharmacotherapy. Level of Evidence 3, strength of recommendation C.

Specialized and combined uses

- VED use can be combined with vasoactive injection therapy, to give men adequate erections in those whom monotherapy for ED has failed. Level of Evidence 3, strength of recommendation C.

- After radical prostatectomy, VED therapy combined with a PDE5i improved sexual satisfaction in patients dissatisfied with VED alone. Level of Evidence 3, strength of recommendation C.

- VED therapy has also been used as a tissue expander to maintain elasticity following corrective surgery for patients with Peyronie’s disease. Level of Evidence 4, strength of recommendation C.

- Additionally, VED use is indicated for rehabilitation of post-radical prostatectomy patients to facilitate early sexual activity and potentially improve early return of natural erections. Level of Evidence 3, strength of recommendation C.

Side effects and contraindications

- The most common VED side effects are painful ejaculation, inability to ejaculate, generalized pain, petechiae, bruising, and numbness. Level of Evidence 3, strength of recommendation C.

- Serious complications from VED use are rare, but include penile skin necrosis, urethral varicosities, capture of scrotal tissues within the penile shaft, development of Peyronie’s disease, and Fournier’s gangrene. Level of Evidence 3, strength of recommendation C.

VED: Basic Principles

Externally applied device mechanically effects penile blood engorgement

Cylinder/pump placed over penis creates closed chamber; pump creates vacuum, drawing oxygenated blood into corpora

The ring then placed at base of penis to restrict flow of blood

Erections are unnatural

Level of Evidence 3, Recommendation C
VACUUM ERECTION DEVICES (VED)

RESULTS

- Literature:
  - Largely of single observational series
  - Small prospective clinical trials

- Efficacy and Satisfaction Rates:
  - Report by authors – 67 to 90%
  - Report by patients – 34 to 68%
  - Organic ED responds well to VED therapy
  - Patient and partner satisfaction appear to be closely equal

Level of Evidence 3, Recommendation C

Specialized & Combined Uses of VED

- Combined with vasoactive injection therapy *
- Combined with intraurethral alprostadil therapy
- Combined with PDE5 inhibitor therapy
- Rarely in men who have “inadequate” penile implant function

- To prevent penile fibrosis (after priapism or explanted prosthesis)
- After surgical correction of Peyronie’s disease **
- Corporeal rehabilitation after radical prostatectomy ***

* Level of Evidence 3, Recommendation C
** Level of Evidence 4, Recommendation C
*** Level of Evidence 3, Recommendation C

SIDE EFFECTS AND CONTRAINDICATIONS

- Pain during creation of vacuum – 20-40%
- Pain on ejaculation – 3-16 %
- Inability to ejaculate – 12-30 %
- Petechiae or ecchymosis – 12-30 %
- Bruising – 6-20 %
- Numbness during erection – 5%
- Rare side effects:
  - Penile skin necrosis
  - Urethral varicosites
  - Capture of scrotal skin
  - Peyronie’s disease
  - Fournier’s gangrene

* Level of Evidence 3, Recommendation C

III. ARTERIAL REVASCULARIZATION

1. INTRODUCTION

The prevalence of vascular disease increases with age and is a major cause of organic ED in men over the age of 50. A number of medical conditions or risk factors are associated with ED, including hyperlipidemia, atherosclerosis, smoking, diabetes, obesity and peripheral vascular disease. The pathogenesis of ED in these patients appears, in part, to be linked to endothelial dysfunction.

Arterial surgery for ED was popularized in the 1970s and 1980s. It has since become clear that ED is often associated with generalized cardiovascular disease and many of the patients undergoing revascularization surgery have intrinsic smooth muscle dysfunction throughout their body. For this reason, the efficacy of penile revascularization surgery is controversial and considered by many to still be experimental. Follow up studies vary in the procedure used and rarely document adequate long-term objective follow up data.

2. BACKGROUND

Historically, the success of bypass grafting for coronary artery disease suggested bypassing obstructed arteries could restore normal erectile function in men suffering from vasculogenic ED.

3. PATHOGENESIS OF ARTERIOGENIC ERECTILE DYSFUNCTION

It is now evident that ED in patients with cardiovascular disease is multifactorial in origin and cannot be simply attributed to only an impairment of penile blood flow due to occlusion.

A number of in vitro and in vivo studies suggest that both endothelial dysfunction and corporal smooth muscle dysfunction are the main factors leading to ED in these men.

Therefore, even if there is a reduction in blood flow through the penile vessels, there often coexists underlying smooth muscle dysfunction that limits the success of any potential penile bypass procedure. Hence, the only select group where penile revascularization surgery is likely to be successful is in young men with isolated arterial stenosis following perineal or pelvic trauma.

4. PENILE VASCULAR ANATOMY

The main source of blood supply to the penis originates from the internal pudendal artery, although accessory contributions may arise from the external iliac, obturator, vesical, and femoral arteries. The internal pudendal artery becomes the common penile artery after giving off a branch in the perineum.
The three branches from the common penile artery are named the dorsal, bulbourethral, and cavernous arteries. The cavernous artery further delivers multiple helicine arteries, which supply the cavernosal tissues and sinusoids. These helicine arteries are in a contracted state when the penis is flaccid and vasodilate during erection.

The dorsal artery of the penis runs along the dorsal surface of the penis and supplies the glans penis. The bulbourethral artery supplies both the bulb and corpus spongiosum, while distally the three branches anastomose near the glans.

**5. THE HISTORY OF PENILE REVASCULARIZATION SURGERY**

Michal [117] reported the first penile arterial revascularization, in 1973, by anastomosis of the inferior epigastric artery (IEGA) to the corpus cavernosum. This procedure produced only short-term success with ensuing fibrosis of the smooth muscle and thrombosis of the anastomosis. The Michal II procedure was then popularized where the IEGA was anastomosed in an end-to-side fashion to the dorsal penile artery. Hauri [118] proposed direct arterial anastomosis of the IEGA to the dorsal artery, but in addition, incorporating the deep dorsal vein into the anastomosis. In principle arterialization of the dorsal vein would improve arterial flow to the corpora cavernosa in a retrograde manner via the emissary veins.

Virag [119] and colleagues described a procedure in which the IEGA was anastomosed directly to the deep dorsal vein, introducing the concept of venous arterialization. Not only has Virag described modifications of his technique (Virag I-VI), but also a number of other investigators have described other variations on this basic procedure. The principles of surgery remain the same, consisting of distal or proximal ligation of the arterialized vein, windows between the artery and vein, and ligation of the circumflex vessels and destruction of the valves in the dorsal vein. In theory these modifications improve inflow, while reducing venous outflow. In concept these procedures may be attractive not only in men with pure arteriogenic ED, but also those with a venogenic component.

**6. PRINCIPLES OF SURGERY FOR ARTERIAL PATHOLOGY**

The principles of revascularization and arterialization surgery are based upon the following techniques (modified from Sohn [120]):

a. Anastomosis of the IEGA to the dorsal artery (revascularization).

b. Anastomosis of the IEGA to the deep dorsal vein (arterialization)

c. Anastomosis of the IEGA to the deep dorsal vein with venous ligation.

**7. SELECTION AND INVESTIGATION OF THE PATIENT WITH SUSPECTED ARTERIOGENIC ED**

Penile arteriography is the gold standard in assessing patient’s suitability for arterial reconstructive surgery. However, prior to embarking upon this procedure, other organic causes of ED need to be excluded. In those in whom arterial surgery is contemplated, a penile duplex Doppler study confirms vascular insufficiency and documents any venous leak. A peak systolic velocity (PSV) of less than 25cm per second suggests vascular insufficiency.

Cookson [121] analyzed surgical outcomes based on the preoperative etiology of impotence (pure arterial versus arterial combined with corporeal venous leak). There was a significant improvement in surgical outcome in patients with a pure arterial ED compared to those with mixed etiology (67% and 42%, respectively (p < 0.01)). The authors suggest that in patients with arteriogenic ED, concomitant corporeal veno-occlusive dysfunction should be excluded by preoperative dynamic infusion cavernosography and cavernosometry (DICC), as this may further predict postoperative success. A Rigiscan study may be considered in the young patient with suspected arterial injury. Vardi [122] demonstrated that patients under the age of 28 years showed a 73% success rate versus 23% in the older age group. Furthermore, non-smokers had a 57% success compared to 29% in smokers. They also found that the presence of venous leak and type of procedure had no significant impact on success. However, when patients without a venous leak were compared to a group with moderate venous leak, the results showed a 73.3% success versus 26.7%, respectively (P=0.32). The authors argue this conflicting result may have been proven significant with a larger number of patients in the moderate leak group.

** Statistical trend determined by Wald’s test as 0.05<p<0

In a further study [123], success in diabetics and older patients was lower (43% for diabetics, 39% for those older than 50 years at surgery). Based upon their experience, Zumbe [124] recommended the following important factors in case selection for arterial surgery: (i) non-responder to ICI (intracavernous injection); (ii) age less than 55 years; (iii) non-diabetic; (iv) cavernous venous leak excluded; (v) stenosis in the internal pudendal artery.

Therefore, based upon the literature, the following appear to be inclusion criteria in selecting patients for arterial surgery:

- Age less than 55 years
- Non-smoker
- Non-diabetic
- Absence of venous leakage
- Stenosis of the internal pudendal artery

8. COMPLICATIONS FROM PENILE REVASCULARIZATION SURGERY

A number of authors have described complications following penile revascularization procedures [123, 125, 126]. The most frequent complication is glans hyperaemia. In a series reported by Manning [123] glans hyperemia developed in 13% of patients, shunt thrombosis in 8%, and inguinal hernias in 6.5%.

9. OUTCOMES FROM PENILE REVASCULARIZATION SURGERY IN MEN WITH ARTERIOGENIC ED

Surprisingly, there has only been one retrospective case series published in the literature since 2003 [131]. The lack of further studies may reflect consensus opinion, such as guidelines [85] which state that, “Treatment of vasculogenic ED by penile arterial revascularization has been performed using a variety of microvascular procedures for the past 30 years. The efficacy of this surgery is unproven and controversial largely because, in most reported studies, selection and outcome criteria have not been objective and because a variety of surgical techniques have been used.”

The 2005 guidelines are based upon the 1996 guidelines report following a meta-analysis of this literature. The 1996’s, stated arterial surgery was not justified to be performed routinely, although, arterial revascularization procedures appeared to have the highest efficacy in young men with ED secondary to arterial injury from pelvic or perineal trauma. Only four articles with a total of 50 patients met the Panel’s inclusion criteria (Table 8). These studies were retrospective with small numbers of patients (Table 9). Objective outcome was not measured uniformly and follow up interval in most studies was short.

Table 9. Penile arterial surgery: Criteria for article selection by the AUA guidelines committee 1996 (updated 2005)

**Exclusion criteria**
- Diabetes mellitus
- Cigarette smoking

**Length of follow-up**
- 12 month minimum

**Inclusion criteria**
- Normal serum testosterone
- Failed pharmacologic erection test or documentation of organicity by either abnormal nocturnal penile tumescence or abnormal penile blood flows (duplex Doppler ultrasonography (DICC))
- Abnormal penile arteriogram
- Artery to artery or artery to dorsal vein anastomosis employed in surgical technique
- Objective follow-up data reported by either duplex Doppler ultrasonography, penile arteriogram, or validated outcome questionnaire

Table 10. Original studies fulfilling the AUA 1996 guidelines committee inclusion criteria.

One of the largest contemporary retrospective series is that of Kawanishi [125]. Although published in 2004 and using the 1996 guidelines, this study on 51 men with arteriogenic ED stands out from other retrospective series in terms of objective outcome data reported by color Doppler duplex studies and a longer follow-up period. Prior to surgery all patients had a full assessment of their ED, which included intracavernosal pharmacological erection tests, penile duplex Doppler, DICC, and digital subtraction angiography. The etiology of the arterial lesions was blunt perineal trauma in 33 and unknown in 35. Either the Hauri or Furlow-Fischer procedure was used for penile revascularization. The patency of the neoarterial blood flow was assessed objectively by color flow duplex Doppler. The mean (SD) subjectively estimated efficacy rate was 85.9 ± 6.3%, after 3 and 67.5 ± 10.7% after 5 years of follow-up. The objectively estimated efficacy rate was 84.9 ± 7.3% at 3 and 65.5 ± 13.5% after 5 years of follow-up.

In the second Paris consultation in 2003, the literature from 1993 to 2003 was evaluated. Table 6 summarizes these studies and another two studies [135] questioned the role of arterial surgery in men with vascular ED. They compared the sexual satisfaction rate in 130 patients with arterial and/or venous impotence treated with four surgical techniques with long-term follow up. Arterialization of the deep dorsal penile vein was performed in 39 (30%) and 78 (60%) were treated with penile implants. Sexual satisfaction, defined as the possibility of satisfactory sexual intercourse without any additional treatment or pain, was evaluated by patient interview.

Of the evaluable patients, the sexual satisfaction rate was 12% for arterialization compared to 93% for penile prosthesis (Mean follow-up was 46 and 54 months respectively). The success rate for young patients with traumatic arterial lesions was 100%. It is apparent from this 2003 study that patient outcome is poor in men undergoing arterialization compared to other treatment modalities.

Despite the negative opinion by the AUA consensus panel on penile revascularization surgery and the poor outcome from the comparative study by Wespes [135], Kayigil recently published a paper that supported the efficiency of deep dorsal vein arterialization (DDVA) in carefully selected healthy elderly patients [131]. Forty-three patients with a mean age of 59.7±4.6 years underwent corpus cavernosum electromyography, DICC, and penile duplex Doppler ultrasonography. Risk factors including hypertension, diabetes, hyperlipidemia, smoking, psychiatric or neurologic disorders, liver or kidney failure, and a history of major trauma were excluded. All patients underwent DDVA using the Furlow-Fisher technique. Surgical outcome was tested postoperatively using the IIEF-15. A surgical success was achieved if the score in the five-item version of the IIEF (IIEF-5) had increased by at least five points. The mean follow-up interval was 22.1+/-7.1 months. Veno-occlusive dysfunction was found in 21 patients, 13 had arteriogenic disease, and 9 had both caverno-venous and arteriogenic disease. The operation was deemed successful in 26 cases (60.5%) according to IIEF-5 criteria. The authors concluded that DDVA can be performed in carefully selected older patients as long as the major risk factors for ED are excluded. This latest paper adds little to the previous retrospective series, as there is a short follow-up period and no objective data analyzing pre and post-operative erectile function with the exception of the IIEF questionnaire.

10. OUTCOMES FROM PENILE REVASCULARIZATION SURGERY IN MEN FOLLOWING PERINEAL TRAUMA.

Evidence supporting the traditional concept that young men who undergo revascularization appear to have better outcomes compared to other groups is still limited. However, the group of patients who appear to have definite improved outcomes from arterial revascularization remains young men who have sustained blunt perineal or pelvic trauma.

In the study by Vardi [122], 10 patients had documented pelvic trauma with a mean age of 30 years. In this group, all regained satisfactory erectile function at a two year follow-up. The younger traumatic patients had an 80% success rate compared to 20% in the older men (P=0.04). The higher success rates in younger men was also confirmed by Wespes where the success rate for young men with traumatic arterial lesions was 100% [135].

More recently Babaei [136] performed a meta-analysis and systematic review to determine the subjective and objective outcomes of penile revascularization surgery in patients with arteriogenic ED. Published articles were searched up to May 2008 in the Cochrane Central Register of Controlled Trials, MEDLINE, EMBASE, and Biological Abstracts. Data on participants’ characteristics, study quality, population, intervention, cure and adverse events were collected and analyzed. Not surprisingly, the results in men younger than 30 years old were better than older men. The authors conclude that ‘inconsistent measurements of outcomes limited the findings, and none of the studies were randomized controlled trials’.

Recomendations

- There are a large number of retrospective studies reporting outcome data for penile revascularization surgery for arteriogenic ED. Level 3 evidence.
- These studies are limited by variable inclu-
tion and exclusion criteria, short length of follow-up, and lack of objective follow-up data. Level 3 evidence.

- Young men who have sustained traumatic arterial lesions appear to have better outcomes compared to elderly patients. Level 3 evidence.

- There are no comparative prospective randomized studies assessing outcome of penile revascularization surgery for arteriogenic ED. Based upon the evidence within the literature, this surgery may be offered to men less than 55 years of age who are non-smokers, non-diabetic, with absence of venous leakage and demonstrate an isolated stenosis of the internal pudendal artery. Level 3 evidence, recommendation C.

IV. SURGERY FOR CORPORAL VENO-OCCULSIVE DYSFUNCTION (CVOD)

“Venous surgery was performed by stubborn surgeons to a high degree around the end of the nineteenth century, and recommended by similarly stubborn urologists until some years ago.”

Dieter Hauri, 2003 [137]

1. HISTORY

(from ancient times until the Second International Consultation on Sexual Dysfunctions, Paris, 2003)

Although ED was known to Aristotle (364-322 B.C.) and has been described by Sushruta in the eighth century [138], its identification as a vascular event occurred only in the Common Era. Galen (129-200), Avicenna (980-1037), and da Vinci (1452-1519) have all been credited with this [139]. Francesco Parona [140] was the first to suggest a specific role of veins in the causation of ED. In 1873, he conjectured that varicose superficial dorsal veins of the penis could cause ED by excessive blood run-off, and reported good results with saline sclerotherapy. Towards the end of the nineteenth century, superficial, and later, deep dorsal vein ligations were reported by Raymond [141], Duncan [142], Wooten [143], and Lydston [144] (100 cases). In the twentieth century, between 1936 and 1953, Oswald Lowsley [145] introduced the concepts of bulbocavernosum and ischiocavernosus plication and suspensory ligament tightening [146], in addition to reporting an experience with more than 1000 patients, including 273 who were assiduously followed up over 17 years [147]. There was a lull in the development of venous surgery during the middle (1940s to 1960s) of the twentieth century. However, venous shunt surgery for priapism made strides during this time. The 1970s and 80s witnessed a renewal of interest in vascular ED. In 1973, Malvar [148] described the use of a Doppler device to study penile arterial blood flow, and Michal [117] reported direct arterialization surgery of the corpora cavernosa. Around the same time, Fitzpatrick performed spongiosograms, cavernosograms [149], and deep dorsal vein venography [150]. In 1979, Ebbehej and Wagner [151] described the successful correction of a venous fistula causing ED. By this time, microsurgery in urology [152] had also arrived.

In 1980-1, Virag[153, 154]described cavernosometry, arterialization of the deep dorsal vein of the penis (DDV) and also its ligation. In that same year, Shirai and Ishii [155] used cavernosography during visual sexual stimulation (VSS) to study the hemodynamics of erection. In 1982 [156], Virag induced a pharmacologic erection in a clinical setting by injecting papaverine into the corpora cavernosa. Flow [157] and post-papaverine [158] cavernosometry-cavernosography, high-resolution ultrasonography, pulsed Doppler spectrum analysis after papaverine [159], and duplex ultrasound [160] were all performed by Lue in 1984-86. Puech-Leão [161] drew attention to the role of the penile crura in CVOD. The neural control of erection became better understood [162], and the importance of cavernosal smooth muscle pathology in the etiology of CVOD [163] was recognized. The mechanism [164, 165] and pathophysiology [166] of CVOD became more widely understood.

Soon, a classification [167] of CVOD, a diagnostic algorithm [168], the indications for surgery [169, 170], criteria for case selection for surgery [171], lists of post-operative complications [172], and post-operative follow-up guidelines [173, 174] began to appear in the literature. Unfortunately, there was no standard surgical procedure recommended for all patients with CVOD. Hence, different workers in the field employed different operative techniques based on their own convictions and logic. Also, nonsurgical treatments such as oral drugs, vasoactive injections, and VED were employed. Even if not effective by itself, surgery was used as an adjunct to convert penile injection [175] non-responders to responders and later, oral drug non-responders to responders.

A number of different and innovative surgical options were offered to patients with CVOD. These included deep dorsal vein arterialization [130, 176-178], cavernosal vein arterialization [179], deep dorsal vein ligation-excision [180, 181], spongiosotomy [182], pericavernoplasty [183], ligation of multiple venous systems [184], crural vein ligation and/or crural plication [185-188], antegrade and retrograde therapeutic embolization [189-195], and combined

917
ligation-embolization [196] of penile veins using different agents. Over time, many researchers reported their results [173, 197-200] with CVOD surgery and published CVOD reviews [201-203].

However, contrary opinions began to appear, such as Sharlip's 1991 article titled “The Incredible Results of Vascular Surgery,” [204]

'Since the end of the 1970s, many investigators have reported success of 70-80 % or more with various forms of penile vascular surgery. Few investigators have reported surgical success less than this. While the results of penile vascular surgery may actually be this good, there are five reasons I find these reports hard to believe and, therefore, incredible. First, our methods of patient selection for this surgery have been imprecise and unreliable because of unstandardized and inaccurate diagnostic testing for vasculogenic impotence. Second, we have used follow-up methods which are not objective, not controlled and not standardized. Third, some of our surgical techniques are not rational. Fourth, a sham or placebo effect of surgery may account for a large number of successful operations. Fifth, we have not taken care to eliminate author prejudice in the reporting of surgical results.'

In December 1992, the NIH held a Consensus Development Conference [205] on impotence and suggested that arterial revascularization procedures havea very limited role.

Similarly, in 1996, the AUA released its guidelines [76] on the management of ED, wherein it stated that: “Venous surgery and arterial surgery in men with arteriosclerotic disease are considered investigational and should be performed only in a research setting with long-term follow-up available.”

The proceedings of the First Paris International Consultation on Erectile Dysfunction [206] (1999) state, “...the immediate results are satisfactory but relapse can be observed a few months later...these patients must be evaluated by specialized testing and should be treated at centers capable of providing longitudinal follow-up, if possible within research protocols.”

The Second International Consultation on Sexual Dysfunctions [207](2003) was much less optimistic:

“Revascularization and venous ligation procedures have not demonstrated the necessary surgical simplicity and reproducibility of results to make them a widely applicable treatment option for erectile dysfunction...[201, 208]...There is still a need for further study with well defined diagnostic criteria, surgical techniques, and standardized patient and partner outcome assessment.......It is the conclusion of this committee that with the current review of evidence based analysis there are no additional outcomes data of sufficient quality or quantity to supersede this recommendation (viz. that of the NIH, 1993, and the AUA, 1996)."

2. THE PRESENT

(from the Second International Consultation on Sexual Dysfunctions [209], 2003, to the 3rd International Consultation on Sexual Medicine, 2009)

The important guideline publications in this time period have been the AUA Update on the Management of ED, 2005 [85], and the ISSM's Standard Practice in Sexual Medicine [120] textbook:

'Penile Venous Reconstructive Surgery Recommendation: Surgeries performed with the intent to limit the venous outflow of the penis are not recommended. [Based on review of the data and panel consensus.]

Since the publication of the 1992 NIH Consensus Statement and subsequently the 1996 Report, there has been no new substantial evidence to support a routine surgical approach in the management of veno-occlusive ED. While the hemodynamics of veno-occlusive ED are recognized, it is difficult to distinguish functional abnormalities (smooth muscle dysfunction) from anatomical defects (tunical abnormality). It also is difficult to determine what percentage of ED is due to veno-occlusive ED independent of general arterial hypofunction, how to accurately diagnose this condition, how often arterial insufficiency coexists, and whether or not there exists a subset of patients with this disorder who would benefit from surgical intervention. Currently, there is no evidence from randomized controlled trials documenting a standardized approach to diagnosis or the efficacy of treatment for veno-occlusive ED. This lack of new evidence suggests that no changes in the previous guideline statement are warranted.' (Chapter 1-25)

The ISSM's Standard Practice in Sexual Medicine states:

Further research should focus on diagnostic possibilities to differentiate isolated venous leakage from systemic intracavernosal disease. Results of evidence-based medicine meta-analyses in surgery of the venous system should be integrated in our future approaches. Basic research on intracorporal hemodynamics should be pursued. For future clinical studies, validated survey instruments such as the IIEF should be administered both pre- and post-operatively to determine long-term success. However, in spite of all these admonitions, a review of the recent literature on this subject between 2003 and the present time of this writing shows there have been several publications on virtually every aspect of CVOD: basic science and hemodynamics [210-213], pathogenesis [214-218], investigations [213, 219], surgery [131, 220-226], prognosis [227, 228], and post-operative changes [229]. It must be conceded that not all workers in the field continue with the same old techniques of deep
dorsal vein arterialization and penile vein ligation, or minor modifications of the same any longer (the recent description of an otherwise innovative extraperitoneal laparoscopic approach to the ligation of the dorsal penile venous system is an exception). Today, it is agreed by most that venous leakage is an effect rather than a cause, and newer pathogenetic mechanisms that cause CVOD, and therapeutic possibilities that might address these causes, are being examined. The hunt for an effective surgical cure is still on.

3. AND THE FUTURE

It would be utopian to have an oral pill for all CVOD, engineered healthy cavernous smooth muscle, or maybe an injectable endoluminal vein sealant. An aspect of CVOD that needs study is the phenomenon of crural compression. The observation that compression of the crura of an erect penis increases intracavernosal pressures in its distal cylinders and improves erection was first made by Puech-Leão et al in 1987. Since then, although there have been experimental and animal studies [51, 230-233], its therapeutic potential in humans with CVOD has not been exploited [234].

4. APPENDIX

(The bullet points in these lists have been culled from various publications in the literature, collated and merely presented as guidelines to workers in the field of CVOD.)

A) CVOD Surgery – types of interventions

1) Superficial dorsal vein ligation
2) Deep dorsal vein ligation/ excision
3) Crural vein ligation
4) Crural plication/ ligation
5) Deep dorsal vein arterialization
6) Cavernosal vein arterialization
7) Spongiolysis
8) Pericavernoplasty
9) Therapeutic embolization
10) Combinations of the above
11) Extraperitoneal laparoscopic penile vein ligation

B) CVOD Surgery – complications / side effects

1) Glandular hypo/ anesthesia
2) Skin necrosis
3) Wound infections
4) Penile curvature
5) Penile shortening
6) Glans hyperemia
7) Hematomas after DDV arterialization
8) Inguinal hernias
9) Penile edema
10) ‘Vascular’ pain after embolization procedures

C) CVOD – causes

1) Congenital vascular anomalies
2) Trauma
3) Arterial disease, e.g. hypercholesterolemia
4) Arteriosclerosis
5) Alterations in cavernosal smooth muscle, trabeculae, or tunica albuginea
6) ? Psychogenic
7) Post-priapism
8) Unknown

Levels of Evidence and Recommendations

1. At the time of this writing, CVOD surgery in the management of ED remains controversial. Level of Evidence 3, strength of recommendation C.
2. The weight of available evidence is contrary to routine use as a treatment option for ED. Level of Evidence 3 strength of recommendation C.
3. CVOD surgery, as it is practiced today, does not conform to the desiderata of good clinical practice (GCP) or evidence-based medicine (EBM). The normal diagnostic values for available tests, universal diagnostic criteria for case selection for surgery, consensus on choice of operation in a given patient, etc. have not been unequivocally established. There is a need to establish a Standard Operating Procedure (SOP) for CVOD. Level of Evidence 3, strength of recommendation C. While CVOD surgery is still considered investigational, it may be offered in special situations. Level of Evidence 1, strength of recommendation C.

i) With informed consent in writing in a teaching hospital or an investigational or research setting. Level of Evidence 3, strength of recommendation C.

ii) If CVOD is undertaken, it should be required to follow an operated patient longterm (48 months post-operatively). Level of Evidence 3, strength of recommendation C.

iii) Post-operative follow-up should include objective evaluation of the penile vascular and erectile status. Level of Evidence 3, strength of recommendation C.

iv) Penile color duplex Doppler ultrasound after
complete cavernosal smooth muscle relaxation is the gold standard investigation of choice for both pre-op and post-op objective assessment.

v) Young patients with site-specific congenital, post-traumatic or post-inflammatory leaks may also be considered for vein ligation surgery with informed consent. The choice of operation offered should be decided on available wisdom and infrastructure, the experience and preference of the operating surgeon, and the basis of the site, nature, and size of the leak. Level of Evidence 3, strength of recommendation C.

vi) Validated measuring instruments (e.g. IIEF) should be used both pre-and post-operatively. Level of Evidence 1, strength of recommendation C.

INTRODUCTION

For most men with erectile dysfunction, pharmacotherapy provides the initial form of therapy. Historically, locally active agents were used, such as injectable papaverine, phentolamine and prostaglandin. In the late 1990s, the first effective oral agent, namely sildenafil, became available and it was soon followed by other similar drugs such as vardenafil and tadalafil. While all these agents acted peripherally within the penis, drugs that work within the central nervous system to improve erectile function have proven more difficult to develop, with apomorphine currently the only licensed agent.

This chapter seeks to initially place these agents within the physiological and pharmacological context. Brief resumes of the relevant physiology are supplemented by short sections outlining the mechanisms of action and relevant basic science that underpins the most commonly used and investigated agents.

The major portion of this chapter provides an evidence based review of the clinical data that relates to the available orally active agents. The efficacy, tolerability and safety of the drugs are reviewed, with much of the data being presented in tables which summarise the many large controlled trials that have been published. We have not included unpublished data, since it will not have undergone peer review. On the basis of this data we have been able to make a number of recommendations in relation to these agents.

The final portion of the chapter deals with locally active agents, and where possible seeks to present data relating to the efficacy and safety of these agents. The volume of good quality data relating to such agents is small, and our recommendations are accordingly less strong.

Two groups are drugs are also worthy of mention. The first group contains drugs that have been reviewed in previous consultations (notably yohimbine and trazodone). For these drugs, which are not commonly used, and for which there is no new data, we have not included any comments. Interested readers are referred to the publications that have followed previous Consultations. The second group of drugs includes those that are currently under clinical development. Inevitably there is less published data relating to these drugs and we have reviewed that which is available, although much of it is published only in abstract form. This inevitably restricts our ability to make significant recommendations regarding these drugs.

We would regard this chapter as a reference source. It should be the starting point for interested readers and researchers, and hopefully summarises the medical literature in this area at a point in time.

Overall we are able to make the following general recommendations:

1. PDE5 inhibitors are effective, safe and well tolerated therapies for the treatment of men with erectile dysfunction. Almost all currently available evidence relates to sildenafil, tadalafil and vardenafil (Grade A)

2. PDE5 inhibitors are first line therapy for most men with erectile dysfunction who do not have a specific contraindication to their use (Grade C)

3. There is no evidence of significant differences in efficacy, safety and tolerability between the PDE5 inhibitors (Grade A)

4. Apomorphine is an effective and well tolerated treatment for men with erectile dysfunction (Grade A)

5. Sildenafil has superior efficacy to apomorphine in the treatment of men with erectile dys-
function (Grade A). There are no trials comparing the other PDE5 inhibitors and apomorphine.

6. We recommend some standardisation of the assessment of psychosocial outcomes within clinical trials in the field of erectile dysfunction (Grade C)

7. Intracavernosal injection therapy with alprostadil is an effective and well tolerated treatment for men with erectile dysfunction (Grade A)

8. Intracavernosal injection therapy with alprostadil should be offered to patients as second line therapy for erectile dysfunction. (Grade C)

9. Intraurethral alprostadil is an effective and well tolerated treatment for men with erectile dysfunction (Grade A)

10. Intraurethral alprostadil is a less effective treatment than intracavernosal alprostadil for the treatment of men with erectile dysfunction (Grade A)

More detailed recommendations are made throughout the chapter.

A. MECHANISMS OF ACTION

I. CENTRALLY ACTING DRUGS

Although the mechanisms underlying erectile function are not fully understood, some advances have been made regarding the interplay of central and peripheral mechanisms. It is now widely agreed that central disinhibition plays a crucial role in the induction of erectile responses and this has led to the development of a number of centrally acting agents, most notably the dopaminergic substance apomorphine and the melanocortin analogue PT-141.

The current state of knowledge of the central mechanisms involved in the development of and control of penile erection are discussed in Chapter [x]. In short, erections are initiated, in large part, by central stimuli. It is thought that stimuli from higher centers pass via the medial preoptic area (MPOA), and the paraventricular nucleus (PVN), both of which lie within the hypothalamus. The role of the MPOA is to recognise sensory stimuli from the higher brain centres and integrate them with sexual motivation and copulatory motor programmes. The PVN seems to integrate the input from higher centers [1,2] and contains premotor neurones that project directly onto spinal autonomic preganglionic neurones. The PVN plays a key role in the erectile response and stimulation of this nucleus results in seminal discharge in anaesthetised rats [3] and erection and ejaculation in anaesthetised rats [4]. Dopaminergic neurones are the main components of the PVN which is believed to be the nucleus where apomorphine acts as a dopaminergic substance. From the PVN, signals are transmitted to the brainstem nuclei and then to the periphery of the erectile axis [5,6,7].

Dopamine is one among a number of important central neurotransmitters involved in the initiation of erection. It is the main transmitter within the PVN [3,8] and plays an important role in the central control of erection. Dopamine receptors are divided into two main families D1 and D2-like receptors that are in turn further subdivided into D1 to D5 receptor subtypes. Apomorphine has a higher affinity for the D2-like receptors [9] that are thought to be the main site for the induction of erections in the PVN [10]. Apomorphine is therefore postulated to increase erectile responses by acting as a conditioner in the PVN, increasing the response to sexual stimuli resulting in enhanced erections induced in the periphery [11].

Apomorphine is an agonist of the D1-and D2-receptor subtypes that are mainly located in the paraventricular nucleus of the hypothalamus. Oxytocinergic neurones in this nucleus are responsive to the administration of apomorphine via activation of both the D1-and D2-receptor subtypes, which subsequently induces a cascade of events that reach the periphery to elicit penile erection. It has been suggested that nitric oxide acts as a cofactor at the level of the paraventricular nucleus of the hypothalamus with regards to the activation of the oxytocinergic neurones [12]. In this scenario, the presence of nitric oxide is thus mandatory in order to allow for the action of apomorphine. A sublingual formulation of Apomorphine has been approved for the treatment of erectile dysfunction in several parts of the world at the doses of 2 and 3 mg. The erectile effects are usually seen within 20 minutes of its administration.

Melanocortins are implicated in the regulation of sexual behaviour including penile erection, sexual motivation and in the female rat the secretion of sexual attractants from the preputial gland [13, 14]. Through cloning techniques five types of melanocortin receptors (MC1, MC2, MC3, MC4, and MC5) have been characterized [15]. Bremelanotide (PT-141) is a synthetic peptide analogue of α-melanocyte stimulating hormone (α-MSH) activating melanocortin receptors 3 and 4 (MC3R and MC4R). It is an active metabolite of melanotan II. The effects of α-MSH on sexual behaviour, including grooming, stretching, yawning and penile erection, have been demonstrated in laboratory animals, and it is believed to act downstream from dopamine and oxytocin in hypothalamic centres near the third ventricle at the
MC4R [16]. When subcutaneously administered has been reported to initiate penile erection in normal men as well as men with psychogenic and organic erectile dysfunction [17-19]. It is also noted to significantly increase sexual desire. The frequent side effects associated with melanotan II administration are nausea and stretching/yawning. Although clinical trials have been undertaken to assess the potential use of an intranasal formulation of this compound for the treatment of men with erectile dysfunction, it has not yet been licensed, and at the time of writing, development of bremelanotide for men with ED appears to have ceased.

II. PERIPHERALLY ACTING AGENTS

The normal physiology and pharmacology of penile erection is discussed more fully in Chapter [x]. However, a resume of the relevant physiology and pharmacology of the corpus cavernosum is presented here, in order to understand the mechanisms of action of the peripherally acting agents, whether they be orally active, as in the case of the PDE5 inhibitor or whether they be locally active.

1. PDE5 INHIBITORS

In summary, the normal pathway for penile erection is initiated by sexual arousal, which stimulates release of nitric oxide at nerve endings in the penis (Fig. 1). Another source of nitric oxide is vascular endothelial cells. Nitric oxide diffuses into vascular smooth muscle cells in the penile corpus cavernosum to cause stimulation of guanlyl cyclase and elevation of cGMP in these cells. This leads to activation of cGMP-dependent protein kinase (PKG), phosphorylation of several proteins, and lowering of cell calcium or reduction in sensitivity to calcium, which results in smooth muscle relaxation. The increased accumulation of blood in corpus cavernosum caused by this relaxation is the underlying basis for penile erection. Lack of proper cGMP elevation could be due at least in part to insufficient release of nitric oxide from nerve endings or endothelium. PDE5 inhibitors enhance erectile function during sexual stimulation by penetrating into smooth muscle cells and inhibiting PDE5, which is an enzyme.
that degrades cGMP. This results in decreased degradation of cGMP, which maintains higher cellular levels of cGMP in both corpus cavernosum and the vessels supplying it. This increases relaxation of the smooth muscle, which dilates the corporeal sinusoids resulting in increased blood flow, allowing an erection to occur. The pathway shown in (Fig. 1) may not work properly if the cGMP level in corpus cavernosum smooth muscle cells is not elevated sufficiently or if relaxation of smooth muscle in the tissue is deficient/incomplete [1,2].

PDE5 inhibitors do not increase the nitric oxide level, but they potentiate the nitric oxide effect to stimulate erection. Without sexual arousal, which triggers the nerve-nitric oxide pathway, these inhibitors are ineffective. The same type of synergistic effect between PDE5 inhibitors and nitric oxide was found at the time of discovery of the caffeine inhibitory effect on PDEs more than forty years ago [3], whereby caffeine, which is a PDE inhibitor, was shown to be synergistic with epinephrine to elevate cAMP in dog liver. In other words, caffeine alone had little if any effect on metabolism of several isolated tissues, but when added together with a stimulator (such as epinephrine or glucagon) of cAMP production, which also had minimal effect when added alone, caffeine had a pronounced effect to increase cAMP as well as the tissue metabolic response to cAMP. This same principle also applies to the combination of PDE5 inhibitor and nitric oxide (sexual arousal) in the cGMP pathway that causes penile erection. PDE5 was discovered by Corbin and colleagues [4,5]. A cartoon depicting the PDE5 structure is shown in (Fig. 2). The enzyme is a homodimer containing two identical subunits with molecular weight of about 100,000 daltons per subunit. Each of the two subunits has a catalytic domain and a regulatory domain. The catalytic domain, but not the regulatory domain, is the target of PDE5 inhibitors. The catalytic domain contains a single binding site for cGMP. When cGMP occupies this site the catalytic machinery, which is located very near the catalytic cGMP-binding site,
breaks the cyclic phosphate bond of cGMP to form linear 5'-GMP. This dampens or terminates cGMP action. The catalytic machinery has been shown to utilize divalent cations such as Zn$$^{2+}$$ [6]. Because they have similar structures as cGMP, sildenafil or other PDE5 inhibitors can also occupy the catalytic site, thus blocking access to cGMP. In fact, sildenafil occupies the site about 1000 times more avidly than does the natural substrate, cGMP. However, the PDE5 inhibitors are not broken down by the catalytic machinery. Occupation of the catalytic site by these inhibitors competitively inhibits cGMP breakdown since cGMP cannot bind to gain access to the catalytic machinery. Inhibition of cGMP breakdown leads to elevation of cGMP in smooth muscle cells of the penile corpus cavernosum, resulting in relaxation of the muscle and penile erection.

Major research efforts have led to the production and development of compounds that are selective and potent in inhibiting particular PDEs [7]. Sildenafil (Viagra, Pfizer) was the first commercialized compound in the class that inhibits PDE5. This class has been joined by vardenafil (Levitra, Bayer Schering Pharma/Schering Plough) and tadalafil (Cialis, Lilly) in most countries of the world, and by udenafil (Zydena, Dong-A Pharmaceutical) and mirodenafil (SK Chemical Co., Ltd.) in Asia [8]. Other PDE5 inhibitors are in the pipeline. Some of these inhibitors have a similar overall structure as sildenafil and some, such as tadalafil, have significantly different structures (Fig. 3). A part of the structure of each PDE5 inhibitor also resembles the structure of cGMP (see circled component). This is important since these drugs are competitive inhibitors (antagonists) of cGMP for PDE5, and they are believed to form some of the same molecular interactions (hydrogen bonds, hydrophobic stacking interactions, van der Waals contacts, ionic interactions, etc) as cGMP forms with amino acids in PDE5. Based on x-ray crystal structures of PDE5 inhibitors co-crystallized with PDE5 [9,10] and studies using site-directed mutagenesis [11], sildenafil, for example, forms at least seventeen contacts with amino acids in PDE5. Combination of the numerous contacts between inhibitor and PDE5, and the strength of each contact, confer high affinity (low IC$_{50}$) for inhibitor. Three of these amino acids (Tyr-612, Gin-817, and Phe-820 in human PDE5) have been shown to be the most critical contacts for both cGMP and the PDE5 inhibitors that have been studied to date. The fact that PDE5 inhibitors form stronger contacts with PDE5 compared with other PDEs underlies selectivity of PDE5 inhibitors.

Although the catalytic domain of PDE5 is the direct target of PDE5 inhibitors, certain features of the regulatory domain impact PDE5 inhibitor actions on

![Figure 3. Molecular structures of PDE5 inhibitors as compared with that of cGMP. Circled component represents the part of each structure that is believed to mimic the structure of cGMP.](image)
the enzyme [12]. The regulatory domain of PDE5 contains two GAF domains (GAF A and GAF B) and a site for phosphorylation by PKG. The inhibitors do not bind to the regulatory domain. Binding of cGMP to GAF A of the regulatory domain stimulates breakdown of cGMP at the catalytic site, and this process also stimulates phosphorylation of the enzyme. PKG phosphorylates this site (Ser-102 in human PDE5A1) about 10 times faster than cAMP-dependent protein kinase (PKA) does, and PKG is thought to be the main physiological catalyst for this phosphorylation reaction. When cGMP binds to the allosteric site, cGMP is not degraded as it is in the catalytic site, but PDE5 enzyme activity is stimulated by this binding reaction. Phosphorylation also activates PDE5 enzyme functions. The two stimulatory actions together represent a physiological negative feedback process for the cGMP pathway, i.e., when cGMP increases in cells the breakdown of cGMP is stimulated [13]. This negative feedback dampens the cGMP signaling leading to penile erection or other effects of cGMP. Whether or not irregularities in this negative feedback system could partly explain erectile dysfunction, priapism, or other afflictions is unknown. However, in the presence of PDE5 inhibitor the negative feedback is blocked and inhibitor binding to the catalytic site not only elevates cGMP, which stimulates the catalytic site by binding to the regulatory domain, but it also stimulates the catalytic site by inducing phosphorylation of PDE5. Therefore, the PDE5 inhibitor stimulates its own binding to the catalytic site, which turns the negative feedback process of the physiological cGMP pathway into a positive feedback process for the PDE5 inhibitors. This means that when cGMP is elevated in smooth muscle cells after a patient takes a PDE5 inhibitor tablet, this should stimulate the catalytic site to bind more of the inhibitor. That is, the PDE5 inhibitor stimulates its own efficacy. For example, were it not for this built-in enzyme mechanism, a 200-mg dose rather than a 100-mg dose of a particular PDE5 inhibitor might be required to induce penile erection in a particular patient.

An interesting feature of PDE5 is that the catalytic site is an important regulatory site in addition to its catalytic function of breaking down cGMP [13,14]. A result of this regulation is physiological enhancement of both negative feedback of the cGMP pathway and positive feedback of the PDE5 inhibitor effect as follows. When cGMP is elevated and interacts with the catalytic site, both binding of cGMP to the allosteric site and phosphorylation of the enzyme are stimulated. Thus, these two stimulatory effects are reciprocal. Since cGMP binding to the allosteric site stimulates phosphorylation and vice versa, these two stimulatory effects also demonstrate reciprocity. Therefore, all three functional sites (catalytic site, allosteric cGMP-binding site, phosphorylation site) are reciprocally stimulated. The combined result of these interactions represents a powerful negative feedback system for the cGMP pathway, i.e., when cGMP increases, cGMP breakdown is stimulated. Apparently, cells cannot tolerate excess cGMP and have evolved an intricate negative feedback control system to dampen cGMP elevation and facilitate termination of cGMP effects. Again, the PDE5 inhibitors inadvertently exploit the physiological feedback system by substituting for cGMP in binding to the catalytic site to stimulate their own effects in a positive feedback manner.

Assuming all other factors are equal, the higher the affinity (potency) of a PDE5 inhibitor for PDE5, the lower the expected dose of the inhibitor that will be

* DONE HEAD TO HEAD
needed [7]. This concept of potency can be assessed by measuring the concentration of a particular PDE5 inhibitor in vitro that inhibits PDE5 activity by 50%, and is known as the IC50 (Table 1).

Highly potent drugs are expected to have affinities (IC50 values) in the nanomolar (nM) range. Vardenafil, SLX-2101 (Surface Logix, Inc.), and mirodenafil are within a class of biochemically high-affinity PDE5 inhibitors as compared with sildenafil, tadalafil, and udenafil, and avanafil has an intermediate potency. However, as discussed below, factors such as pharmacokinetics have strong impact on the dose required. Higher potency does not mean that a PDE5 inhibitor has a greater clinical effect, but that less of it is needed for the desired effect. For the PDE5 inhibitors, less vardenafil is required than sildenafil or tadalafil to achieve the same degree of in vitro PDE5 inhibition. Vardenafil is therefore more biochemically potent than are sildenafil and tadalafil, although not necessarily more efficacious (as evidenced by head-to-head trials). Based on in vitro potencies, it would be predicted that a lower dosage of vardenafil than sildenafil would be required to cause penile erection in men. This appears to be the case since 5-20 mg doses of vardenafil are recommended compared with 25-100 mg doses of sildenafil. The dose of vardenafil required would be predicted to be even lower were it not for the bioavailability of vardenafil being only 15% vs 40% for sildenafil. The recommended doses of tadalafil are also lower than those of sildenafil, but since these two drugs have similar biochemical potencies, a partial explanation for lower dosage could be higher bioavailability or slower body metabolism of the drug.

Debates over degree of penile rigidity caused by particular PDE5 inhibitors have continued, and head-to-head trials have been inconclusive. Many years of investigations of cAMP and cGMP pathways, which are similar to each other in many respects, may offer insight on this important question. In most body tissues a two- to three-fold elevation in cAMP or cGMP is adequate to produce maximum stimulation of these pathways that lead to numerous physiological responses [22, 23]. This could be due to the likelihood that this rise in cAMP or cGMP causes sufficient stimulation of the next step, e.g., PKA or PKG activation, to maximally stimulate the downstream steps leading to the physiological responses. If this is the case, elevation of cGMP by more than three-fold by increasing the biochemical potency or dose of PDE5 inhibitor would theoretically not be productive to further improve penile rigidity. Therefore, there is a threshold level of cGMP in corpus cavernosum that produces optimum penile rigidity given the conditions of the patient. At sufficient dose, each inhibitor would be predicted to cause enough increase in cGMP to produce equal penile rigidity.

There are methods in addition to classical IC50 to measure potency of a drug. It can be done by assessing the strength of binding of radiolabeled PDE5 inhibitors to PDE5, and the value obtained by this method is termed Kd instead of IC50 [12]. As compared with IC50, measurement of Kd is a more direct method of determining potency. The Kd of a PDE5 inhibitor obtained using this approach should approach the IC50 of the same PDE5 inhibitor. In fact, our results show that the Kd for sildenafil, vardenafil, or tadalafil approximates the IC50 for each compound. The finding that the value of Kd approaches the value of IC50 for each inhibitor suggests that these compounds do not bind to an appreciable extent to sites on PDE5 other than the catalytic domain. The approach of determining Kd not only provides another tool to measure PDE inhibitor potency but has also revealed new properties of PDE5 and PDE5 inhibitors which were not possible to study previously. These include the PDE5 on-rates and off-rates of PDE5 inhibitors, which should help to predict time of onset and duration of inhibitor action in patients. The radiolabeled inhibitors could also be used to search for the presence of non-PDE PDE5 inhibitor-binding proteins of high affinity in body tissues, which might suggest the potential for side effects of a particular PDE5 inhibitor. So far, no such proteins have been found.

Based on comparative IC50 values, the potency of sildenafil is about 1 million times higher than that of the non-selective PDE inhibitor caffeine [24]. Other experimental PDE inhibitors have intermediate potencies. According to literature values, the in vitro biochemical potencies of the commercial PDE5 inhibitors are within the same range of each other—least from a clinically meaningful equipotent range of IC50 values 0.1-10 nM. The in vitro potency of a PDE5 inhibitor is not the same as efficacy. As discussed below, efficacy is based on the actual in vivo (clinical), effects of the inhibitor.

The biochemical selectivity of an inhibitor for PDE5 is a key factor in determining its side-effect profile [7]. Once a large enough separation exists between the affinity (IC50) of the inhibitor for PDE5 and its affinity for non-target PDEs (or other proteins), the less likely it is that it can achieve sufficient plasma concentrations to activate the non-target site at therapeutic doses. For PDE5 inhibitors, selectivity is usually expressed in terms of potency (IC50) to inhibit PDE5 as opposed to inhibiting any others in the PDE family. Selectivity is computed by dividing the IC50s of the two compounds that are compared. PDEs are comprised of 11 families of enzymes that catalyze the termination of second messenger activity in cells by breaking the phosphodiester bond of either cAMP, cGMP, or both. These families (PDE1 to PDE11) are known or implicated in a broad range of cellular functions. Within some families, more than a single gene exists, for a total of at least 21 PDE genes, and some of these genes have multiple prod-
ucts brought about by alternative mRNA splicing, resulting in a grand total of at least 100 PDE forms [25]. PDE5, which is cGMP-specific, exhibits only one gene, although its mRNA can be spliced to yield at least three isoforms. However, it should be noted that these isoforms may not differ significantly in their catalytic domains, which is the site of action of PDE5 inhibitors. PDE5 is present in high concentrations in the smooth muscle of corpora cavernosa of the penis. Sildenafil and vardenafil cross-react slightly with PDE6, i.e., their IC₅₀ₐₕ values for PDE6 are only 4-10 fold lower than those for PDE6. This may explain the complaint of some patients that sildenafil or vardenafil causes visual disturbances since PDE6 predominates in the retina. Tadalafil cross-reacts with PDE11 to some extent, but the consequences of this effect are unknown. PDE11 is found in the heart (cardiac myocytes), testes (germinal cells and Leydig cells), and anterior pituitary. Neither of the PDE5 inhibitors cross-reacts to a large extent with any of the other PDEs except for PDE6 and PDE11, i.e., the IC₅₀ₐₕ values of these compounds for PDE5 are more than 1000 times lower than those for most of the other PDEs. Except for visual disturbances, the other reported side effects of PDE5 inhibitors (headaches, flushing, slight lowering of blood pressure, etc) are likely caused by PDE5 inhibition in smooth muscle and other tissues outside the penile corpus cavernosum.

In addition to biochemical properties discussed above, pharmacokinetic properties of PDE5 inhibitors (ingestion/food interaction, movement in the circulation, tissue uptake, elimination) have great impact on efficacy [7]. There are several common pharmacokinetic parameters that can be measured and quantified that describe distribution of a PDE5 inhibitor. The bioavailability, maximum plasma concentration (Cₘₐₓ), time (tₘₐₓ) required for attaining Cₘₐₓ, and time (t₁/₂) required for elimination of one-half of the inhibitor from plasma are all important factors (Table 2). Bioavailability is the ultimate percentage of an orally administered drug that is found in the circulation compared to an injected dose. It is a reflection of intestinal absorption and the effects of first-pass hepatic metabolism.

Sildenafil, vardenafil, udenafil, and avanafil have broadly similar tₘₐₓ, which predicts a similar time of onset of action. The t₁/₂ values of tadalafil and udenafil are longer than those of the other two PDE5 inhibitors, which could be due to slower intestinal absorption and/or slower degradation of this drug by the liver, or it could be due to other factors. The extended t₁/₂ of tadalafil provides a longer therapeutic effect [32], and this may also be the case for udenafil [26,27] and SLx-2101 [28]. This may be preferred by patients who prefer spontaneous sexual activity. The Cₘₐₓ of udenafil is significantly lower than that for sildenafil and tadalafil, which might be expected based on its lower bioavailability.

PDE5 inhibitors are believed to be degraded in the liver. Therefore, since they are not degraded by PDE5 or any other enzyme in smooth muscle cells of corpus cavernosum, they must dissociate from PDE5, exit the smooth muscle cells and then be transported to the liver via the bloodstream before they can be degraded (Fig. 1). The rate of exit of a PDE5 inhibitor from smooth muscle cells should be considered when comparing PDE5 inhibitors since this could affect its duration of action. Disappearance

of the inhibitor from plasma may imply, but does not prove, its disappearance, or clearance, from the cells in which it produces its effects. Since the inhibitor binds tightly to PDE5 in these cells, as portrayed in cartoon form in Fig. 1 this could significantly retard its exit from these cells and prolong effects of PDE5 inhibitors in patients. It is conceivable that PDE5 inhibitors with higher affinities for PDE5 would dissociate from the enzyme more slowly, resulting in a more retarded clearance from corpus cavernous cells. Studies of clearance of PDE5 inhibitors from plasma are documented, but studies of clearance of these inhibitors from smooth muscle cells are rare.

CONCLUSIONS

The first potent and selective PDE5 inhibitor, sildenafil citrate, has had a revolutionary effect on the management of male erectile dysfunction. Newer inhibitors, including some still in the development pipeline, have different profiles of dosage, side effects, onset of action, duration of action, and other features. This translates into greater physician and patient flexibility.

REFERENCES

antagonist with similar affinity for alpha 1- and alpha 2-adrenoceptors. Both types of receptors are present in corpus cavernosum and penile vascular smooth muscle [1-4]. Pre-junctional alpha 2 adrenoceptors in the corpus cavernosum modulate stimulus-evoked release of noradrenaline from sympathetic nerves in the erectile tissue [1], whereas those in the horse penile resistance arteries regulate the release of nitrergic transmitter [4].

Phentolamine mesylate induced relaxation of corpus cavernosum erectile tissue is thought to occur by direct antagonism of alpha 1- and alpha 2-adrenoceptors, as well as by indirect functional antagonism via a non-adrenergic, endothelium-mediated mechanism suggesting nitric oxide synthase activation [5, 6]. The clinical utility of phentolamine is presumably a reflection of the contribution of adrenergic neurotransmission to the maintained rugosity of the penis, and thus, inhibition of α-adrenoceptor activity alone may be sufficient for erection to commence [7].

Oral/intracavernosal phentolamine therefore may facilitate penile erection by inhibiting the functional predominance of alpha 1- alpha adrenoceptor activity that maintains erectile tissues in a non-erect state. Attenuation of the opposing adrenergic contractile response enhances NO-mediated corpus cavernosum relaxation. Furthermore, phentolamine may delay detumescence, which is mediated by noradrenaline, contributing to the maintenance of penile erection.

b) Vasoactive intestinal polypeptide

Vasoactive intestinal peptide (VIP) is a naturally occurring neurotransmitter. VIPergic nerves are most densely concentrated in the penis around the pudendal arteries and in the erectile tissue of the corpus cavernosum. VIP is known to exert regulatory actions on blood-flow, secretion, and muscle tone. Its presence in considerable amounts in the male genital tract suggests that this peptide neurotransmitter may be important in the nervous control of male external genitalia [8]. VIP co-localizes with NOS within the perivascular and trabecular nerve fibres innervating the penis [9]. Most of these NO- and VIP-containing nerves appear to be cholinergic, since they also contain vesicular acetylcholine transporter, a specific marker for cholinergic neurons [10]. The effects of VIP are mediated by a specific membrane-bound receptor linked to adenylyl cyclase via a stimulatory G-protein. VIP has been shown to elevate cAMP concentrations in cavernosal tissues without affecting cGMP levels [11,12]. Though VIP is a potent relaxant of both the corpus cavernosum and penile vascular smooth muscle in vitro, in vivo evidence suggest that it is not likely to be the primary neurotransmitter mediating penile erection in man [13, 14].

c) Prostaglandin E1

PGE1 produced relaxation of human corpus cavernosum smooth muscle and this relaxant activity was first described by [15] Karim and Adaikan (1975). PGE1 mediates relaxation of corpus cavernosum smooth muscle via activation of EP prostaglandin receptors (EP2/4) which results in an increase in the intracellular concentration of cAMP in corpus cavernosum smooth muscle [16-19]. PGE1 may also act by inhibiting the release of noradrenaline from sympathetic nerves [20] and suppressing angiotensin II secretion in the cavernosal tissues [21].

PGE1 is metabolised by the 15-hydroxydehydrogenase present in the corpus cavernosum [22]. The ability of human corpus cavernosum to degrade PGE1 probably aids in regulating the activity of PGE1 and reducing the risk of undesirable side effects such as prolonged erection and priapism. PGE1 suppressed the induction of collagen synthesis by TGF-beta-1 in cultured human corpus cavernosum suggesting that PGE1 and TGF-beta-1 may play a key role in modulation of collagen synthesis and in the regulation of fibrosis of the corpus cavernosum [23]. This suppressant effect seems to correlate with the low incidence of local fibrotic lesions reported in PGE1 treated ED patients [24].

d) Papaverine

Intracavernosal papaverine injection was the first clinically effective pharmacological therapy for ED. It is a smooth muscle relaxant. In vitro, papaverine evokes relaxation of isolated corpus cavernosum smooth strips, penile arteries, cavernous sinusoids and the
penile veins and attenuated contractions induced by stimulation of adrenergic nerves and exogenous noradrenaline [25, 26]. It acts as a nonspecific phosphodiesterase inhibitor that initiates an increase in intracellular CAMP and cGMP leading to corporal smooth muscle relaxation and penile erection. Papaverine may also regulate cavernosal smooth muscle tone via inhibition of voltage-dependent L-type Ca²⁺ channels independent of cAMP as demonstrated in tracheal smooth muscle and suppression of angiotensin II secretion in cavernosal tissue [21,27].

e) Combinations

Phentolamine, papaverine, PGE1 and VIP are the vasoactive agents most commonly used in combination therapy to treat erectile dysfunction. Combination therapy is not only predictably more efficacious as a result of well-planned strategies based on sound pharmacological principles but it is also associated with a reduction in incidence of side effects and cost per dose.

In vitro studies on human and rabbit cavernosal strips demonstrated that phentolamine significantly potentiated relaxation induced by sildenafil, VIP and PGE₁. These vasodilators also significantly enhanced relaxation induced by phentolamine in the cavernosal tissue strips. The enhancement by phentolamine of VIP and PGE₁-induced relaxation (cAMP-mediated) suggests a synergistic interaction while the interaction between phentolamine and sildenafil (cGMP-mediated) appears to be additive [28]. The same investigators also show that sildenafil and PGE₁ has additive and synergistic effect respectively with phentolamine-induced relaxation.

Hence, in combination therapy employing phentolamine as an adjunct, reducing the predominance of adrenergic tone through the blockade of oc-adrenoceptors, increases the efficacy of vasodilators that initiate erection via other independent relaxatory pathways.

B. ORAL THERAPIES FOR ERECTILE DYSFUNCTION

I. PHOSPHODIESTERASE INHIBITORS

In most countries, the phosphodiesterase inhibitors are the initial form of pharmacotherapy for men with erectile dysfunction. Three such drugs, sildenafil, tadalafl and vardenafil, are licensed for use around the world. A number of phosphodiesterase inhibitors are available in a few countries (udenafil, mirodenafil) and others (avanafil, lodenafil, SLX-2101) are currently under development.

1. SILDENAFIL

A comprehensive review of the literature has identified a number of publications which attest to the efficacy, tolerability and safety of sildenafil in men with erectile dysfunction. The salient features of the level 1 publications have been tabulated in Tables 3a-3e, which outline the trial design, the patients randomized, the efficacy outcome and the side effect profiles of the studies.

For assessment of efficacy we have not included pooled studies or analyses of pooled studies, and we have attempted to ensure that no dataset is reported more than once. For assessment of safety and tolerability, we have included pooled analyses in an attempt to identify relatively infrequent tolerability or safety issues.

a) EFFICACY IN THE BROAD POPULATION OF MEN WITH ERECTILE DYSFUNCTION

Overall we can recommend that there is clear evidence that sildenafil is efficacious in the treatment of erectile dysfunction in the broad population when taken on demand at doses of 25mg, 50mg and 100mg. There are multiple level 1 studies with consistent outcomes [1-24]. The overall grade of recommendation is grade A.

b) EFFICACY IN SPECIAL POPULATIONS OF MEN WITH ERECTILE DYSFUNCTION

Overall we can recommend that there is clear evidence that sildenafil is efficacious in the treatment of erectile dysfunction in a number of special populations of men with erectile dysfunction. These populations include:

- Men with diabetes and ED [25-28] (Consistent level 1 studies with an overall grade of recommendation = A)
- Men with depression and ED [29-32] (Consistent level 1 studies with an overall grade of recommendation = A)
- Men with spinal cord injury and ED [33,34] (Single level 1 publication with an overall grade of recommendation = A)
- Men with multiple sclerosis and ED [35,36] (Consistent level 1 studies with an overall grade of recommendation = A)
- Men with cardiovascular disease and ED [37, 38, 40, 41] (Consistent level 1 studies with an overall grade of recommendation = A)
- Men with hypertension and ED [39] (Single level 1 studies with an overall grade of recommendation = A)
- Men with lower urinary tract symptoms and ED [42] (Single level 1 study with an overall grade of recommendation = A)

c) TOLERABILITY AND SAFETY

Overall, we can recommend that although side effects do occur with sildenafil (most notably headache, flushing, indigestion, nasal congestion and occasional visual changes), providing that the drug is used in line with the labeling recommendations, there is no convincing evidence in the literature of any significant safety issue, including cardiovascular, visual and aural safety [1-111] (Consistent level 1 studies, Overall grade of recommendation is grade A).

2.TADALAFIL

A comprehensive review of the literature has identified a number of publications which attest to the efficacy, tolerability and safety of tadalafil in men with erectile dysfunction. The salient features of the level 1 publications have been tabulated in Tables 4a-4e, which outline the trial design, the patients randomized, the efficacy outcome and the side effect profiles of the studies.

For assessment of efficacy we have not included pooled studies or analyses of pooled studies, and we have attempted to ensure that no dataset is reported more than once. For assessment of safety and tolerability, we have included pooled analyses in an attempt to identify relatively infrequent tolerability or safety issues.

a) Efficacy in the Broad Population of Men with Erectile Dysfunction

Overall we can recommend that there is clear evidence that tadalafil is efficacious in the treatment of erectile dysfunction in the broad population when taken on demand at a dose of 10mg and 20mg. There are multiple level 1 studies with consistent outcomes [1-10, 12-15]. The overall grade of recommendation is grade A.

In addition there are two level 1 studies that confirm that tadalafil is also efficacious when taken daily [11,16]. Although several doses have been tested, the doses that have been licensed are 2.5mg and 5mg. The overall grade of recommendation is grade A.

b) Efficacy in Special Populations of Men with Erectile Dysfunction

Overall we can recommend that there is clear evidence that tadalafil is efficacious in the treatment of erectile dysfunction in a number of special populations of men with erectile dysfunction. These populations include:

• Men with diabetes and ED (A single level 1 study using on demand dosing [17] and a single study using regular dosing [18]. The overall grade of recommendation = A)

• Men with ED who have undergone bilateral nerve sparing radical prostatectomy (A single level 1 study using on demand dosing [19]. The overall grade of recommendation = A)

• Men with ED who have undergone external beam radiotherapy for prostate cancer (A single level
1 study using on demand dosing [20]. The overall grade of recommendation = A)

- Men with ED secondary to spinal cord injury (A single level 1 study using on demand dosing [21]. The overall grade of recommendation = A)
- Men with lower urinary tract symptoms and ED (Two level 1 studies using regular dosing [22,23] with an overall grade of recommendation = A)

c) Tolerability and Safety

Overall, we can recommend that although side effects do occur with tadalafil (most notably headache, flushing, indigestion, nasal congestion and back or girdle pain), providing that the drug is used in line with the labeling recommendations, there is no convincing evidence in the literature of any significant safety issue, including cardiovascular, visual and aural safety (Consistent level 1 studies [1-47], Overall grade of recommendation is grade A).

Safety and tolerability of tadalafil

3. VARDENAFIL

A comprehensive review of the literature has identified a number of publications which attest to the efficacy, tolerability and safety of vardenafil in...
men with erectile dysfunction. The salient features of the level 1 publications have been tabulated in Tables 5a-5e, which outline the trial design, the patients randomized, the efficacy outcomes and the side effect profiles of vardenafil in those studies.

For assessment of efficacy we have not included pooled studies or analyses of pooled studies, and we have attempted to ensure that no dataset is reported more than once.

For assessment of safety and tolerability, we have included pooled analyses in an attempt to identify relatively infrequent tolerability or safety issues.

b) Efficacy in the Broad Population of Men with Erectile Dysfunction

Overall we can recommend that there is clear evidence that vardenafil is efficacious in the treatment of erectile dysfunction in the broad population at doses of 10mg and 20mg taken in an on demand fashion. There are multiple level 1 studies with consistent outcomes [1-12]. The overall grade of recommendation is grade A.

II. NEWER PDE5 INHIBITORS

1. UDENAFIL

Udenafil is a new PDE5 inhibitor currently available in
Korea, Russia and Saudi Arabia. The time to reach maximum concentration (Tmax) is 0.76 – 1.25
hours while the plasma elimination half-life (T1/2) is
9.88 – 12.13 hours (100 and 200 mg, single dose
study) [1]. During multiple dosing, a steady state was
reached at 5 days and little accumulation occurred after repeated dosing for 7 days. Preclinical studies
revealed that udenafil’s PDE5 selectivity is similar to
sildenafil [2].

A phase III study evaluated the efficacy and safety of oral udenafil in ED patients in Korea (level of
evidence: 1) [3]. This was a randomized, double-
blind, parallel-group, placebo-controlled, fixed-dose,
multicentre trial. 167 men with ED of broad aetiology
and severity received udenafil 100 mg (mean age:
53.6 years), 200 mg (mean age: 54.6 years), or
placebo (mean age: 55.7 years), for 12 weeks. More
than 70% of patients had previous PDE5 inhibitor
experience before entering the study. Results are
shown in Table 6: The safety analysis of udenafil
included 164 patients. The most common adverse
events were facial flushing (10.5-23.2%), nasal
congestion (3.5-7.1%), ocular hyperemia (3.5-7.1%) and
headache (1.8-8.9%). Most adverse events were
mild or moderate in severity and no serious adverse
events were reported. Only 2 patients (both in the
udenafil 200 mg group), withdrew from the study due
to adverse events (one for flushing and headache
and one for chest pain).

At the time of writing, much of the data relating to
udenafil is available in abstract form only. One study
investigating the duration of action of udenafil dem-
onstrated efficacy up to 12 hours post dosing [4]
while another Phase 3 study investigated the efficacy in men with diabetes [5]. The change from baseline to endpoint in IIEF-EF domain scores was 7 for udenafil 100 mg and 8.21 for udenafil 200 mg compared with 1.2 for placebo (p < 0.0001). The mean SEP3 rates were 53.13% (100 mg), 63% (200 mg) and 22.6% (placebo, p < 0.0001). Overall, improved erections (GAQ) were reported by 65.5% (100 mg), 83.9% (200 mg) and 30.9% (placebo, p < 0.0001).

The most frequently reported adverse events were flushing and headache, and all were mild. Finally, a third study assessed the efficacy and safety of udenafil 50 mg taken once daily [6]. After 12 weeks of treatment, the IIEF-EF domain score increased significantly (p<0.001) in the udenafil group compared to placebo (12.93 vs 1.57).

### 2. MIRODENAFIL

Mirodenafil is a new PDE5 inhibitor already available in Korea (approved in November 2007). The time to reach maximum concentration (Tmax) is 1.25 hours while the plasma elimination half-life (T1/2) is 2.5 hours. Preclinical studies suggest that mirodenafil’s selectivity toward PDE5 is 10-fold higher than that of sildenafil, whereas its inhibitory effects on other PDEs are much lower than those of sildenafil [7-9].

Preliminary results from a phase II clinical study provided evidence for the efficacy and safety of mirodenafil (level of evidence: 1) [10]. The optimal doses in terms of efficacy and safety were determined from this study to be 50 mg and 100 mg. A 12 week phase III, randomized, double-blind, parallel-group, placebo-controlled, fixed-dose, multicentre clinical trial was conducted at fifteen sites in Korea to evaluate the efficacy and safety of the drug (level of evidence: 1) [11]. 223 men were randomized. About half of these patients were not treatment naive to PDE5 inhibitors. Results are shown in Table 7.

The safety analysis of mirodenafil included all 223 patients. The most common adverse events were facial flushing (9.46-16.22%), headache (8.1-10.81%), nausea (2.7-4.05%) and eye redness (2.7-4.05%). Most adverse events were mild, resolving spontaneously by the end of treatment. Only 4 patients (all from mirodenafil 50 mg group), withdrew from the study because of mild to moderate

</table>
No alterations of color vision and no clinically significant changes in laboratory values, electrocardiographic findings, or vital signs were reported.

Recently, the results in men with ED secondary to diabetes were reported in abstract form. This was a double-blind, fixed dose, controlled trial [12]. The IIEF-EF domain score changes from baseline were significantly higher for mirodenail compared to placebo (9.31 vs 1.37, p<0.0001). SEP3 success rates increased significantly after mirodenail treatment compared to placebo (68.99% vs 22.25%). A positive response to the General Assessment Question (GAQ) reported by 76.92% of patients in the mirodenail group. Most treatment-emergent adverse events were of mild intensity, recovering spontaneously.

3. LODENAFIL CARBONATE

Lodenail carbonate is another new PDE5 inhibitor under development in Brazil. It is a dimer formed by two lodenail molecules linked by a carbonate bridge. After ingestion, the bridge is broken delivering the active compound lodenail. Lodenail carbonate has been shown to be more potent as an inhibitor of cGMP hydrolysis in PDE extracts than lodenail and sildenafil [13]. The time to reach maximum concentration (Tmax) was 1.2 hours while the plasma elimination half-life (T1/2) was 2.4 hours.

Recently, a phase II clinical trial has been completed in Brasil (level of evidence: 2) [14]. This was a randomized, double-blind, placebo-controlled, parallel group, multicentre trial. 72 men with ED of various aetiologies and an IIEF –EF domain score between 7 and 24 were randomized to receive placebo, 20, 40 or 80mg of lodenail for 4 weeks. Results are shown in Table 8. for the EF domain score and SEP3 only lodenail 80mg was superior to placebo (p=0.007) but the treatment groups were not homogeneous regarding basal IIEF-EF scores.

Lodenail was well tolerated. Adverse reactions were mild and self-limited and included headache (15-22.2%), dyspepsia (5-22.2%), rhinitis (5-11.1%), flushing (5-5.9%) and color visual disorders (0-5.9%). The drop-out rate was about 5%. However, no details are provided on adverse events that resulted in discontinuation in the different treatment groups. These preliminary findings suggest that lodenail is an efficacious and well tolerated treatment but remains to be confirmed from a phase III clinical trial.

4. AVANAFIL

Avanail is a pyrimidine derivative synthesized as a PDE5 inhibitor [15]. It is rapidly absorbed (Tmax approximately 35 minutes) and has a short plasma elimination half-life (T1/2) of < 1.5 hours without any significant accumulation of the drug with either once or twice daily administration [16]. It is a strong (50% inhibitory concentration [IC50] = 5.2 nmol/L) and highly selective inhibitor of PDE5. Avanail showed higher selectivity (120-fold) against PDE6 than sildenafil (16-fold) and vardenail (21-fold).

Data relating to avanail is currently only available in abstract form. A 12 week phase II, randomized, double-blind, placebo-controlled, parallel group, multicentre, study explored the efficacy and tolerability of avanail at doses of 50, 100, 200 or 300 mg, taken 30 minutes before initiation of sexual activity [17]. 284 men aged 32–70 years were enrolled. The majority (87%) of the subjects had used PDE5 inhibitors experience before entering the study. After 12 weeks, the IIEF-EF domain scores were 16, 19.9, 21.3, 22 and 22.7 for the placebo, avanail 50 mg, 100 mg, 200 mg and 300 mg group, respectively (p<0.001 vs placebo for all avanail groups). SEP3 success rates were 28%, 53.9%, 58.6%, 62.1% and 64.3% for the placebo, avanail 50 mg, 100 mg, 200 mg and 300 mg group, respectively (p<0.001 vs placebo for all avanail groups). The most common adverse event was headache.

Further studies, again only available in abstract form, have explored the efficacy and safety of avanail compared to both placebo and sildenafil 50 mg using a rigiscan methodology [18] and the haemodynamic effects of co-administration of avanail and glyceryl trinitrate (NTG) [19]. Currently, phase III clinical trials are running to assess efficacy and safety of avanail in general ED population and diabetic men with ED. The results are expected in early 2010.

5. SLX-2101

SLX-2101 is a new PDE5 inhibitor that it is converted to an M1 metabolite, SLX-2081, which continues to be active. In preclinical studies, SLX-2101 demonstrated excellent potency at the molecular, cellular, ex vivo and in vivo levels, and pharmacokinetic studies revealed the drug to be long lasting, maintaining therapeutic levels for >24 hours in rats [20]. Again, only abstract data is currently available. A randomized, double-blind, single-dose study in healthy male volunteers was conducted to assess preliminary safety, tolerability, pharmacokinetics and endothelial function [21, 22]. Five different doses (5, 10, 20, 40 and 80 mg) were used, with six subjects receiving active doses and two receiving placebo at each dose level (mean: 35±6.4 years). The Tmax was 1 hour (SLX-2101) and 2.8 hours (SLX-2081); T1/2 was 6–13 hours (SLX-2101) and 9–14 hours (SLX-2081). This pharmacokinetic profile predicts inhibition of PDE5 for at least 36–48 h at all doses tested. RigiScan® data showed positive effects at 24–24.5 hours post-administration with VSS for 20, 40 and 80 mg doses. No clinically significant effects on blood pressure, heart rate or ECG were noted. SLX-2101 was well tolerated in single doses up to 40 mg with headache being the most common adverse event while visual effects were noted at 80 mg. At this time, four Phase 2a clinical studies have been completed in hypertension, Reynaud’s disease and erectile dysfunction but no new clinical trials are registered for SLX-2101.

REFERENCES FOR NEW PDE5 INHIBITORS

III. CENTRALLY ACTING AGENTS

1. APOMORPHINE

A review of the literature identified a number of publications which attest to the efficacy, tolerability and safety of apomorphine in men with erectile dysfunction. For assessment of efficacy we have not included pooled studies or analyses of pooled studies, and we have attempted to ensure that no dataset is reported more than once. For assessment of safety and tolerability, we have included pooled analyses in an attempt to identify relatively infrequent tolerability or safety issues.

a) Efficacy in the broad population of men with erectile dysfunction

Overall there is evidence that apomorphine is efficacious in the treatment of erectile dysfunction in the broad population at doses of 2mg and 3mg taken sublingually in an on demand fashion. There are two level 1 studies [1,2] and two level 2 studies [3,4] with consistent outcomes. The overall grade of recommendation is grade A.

b) Efficacy in special populations of men with erectile dysfunction

There is a single level 2 study suggesting efficacy in the treatment of erectile dysfunction in men with erectile dysfunction secondary to diabetes [5].

c) Tolerability and Safety

There are several publications attesting to the tolerability of apomorphine at a dose of 2mg and 3mg [1-9]. The most common side effects are nausea, headache and dizziness, with small numbers of patients developing syncope. This latter side effect was particularly noted at doses higher than those licensed for use in Europe. Overall providing the drug is used in line with labeling we could find no evidence of significant tolerability of safety issues. (Consistent level 1 studies. The overall grade of recommendation is grade A.)

APOMORPHINE REFERENCES

2. BREMELANOTIDE

Double-blind, placebo-controlled phase I and phase II studies evaluated intranasal bremelanotide in healthy males and patients with mild-to-moderate ED who had been treated successfully with sildenafil for at least the last 6 months using a Rigiscan methodology [1]. Median time to (C max) was 0.5 hours and mean half-life (t½) ranged from 1.85 to 2.09 hours. In both studies, an erectile response induced by bremelanotide administration was statistically significant at doses >7 mg compared with placebo. The onset of the first erection occurred in approximately 30 minutes. Bremelanotide was safely administered and well tolerated in both studies. Flushing and nausea were the most common adverse events reported in both studies (up to 33.3% using the 20 mg dose).

Similar double-blind, placebo-controlled phase I and phase II studies were designed to evaluate the safety, pharmacokinetic properties and pharmacodynamic effects of subcutaneous bremelanotide in healthy males and in patients with ED who had an inadequate response to sildenafil [2]. An inadequate response was defined by a patient report indicating that achievement of an erection suitable for vaginal penetration occurred ≤50% of the time while taking sildenafil 100 mg. Median t max ranged from 0.5 to 1 hour and mean t½ ranged from 1.9 to 2.7 hours. A >2-fold increase in the duration of base rigidity ≥60% compared with the response of individual patients to placebo was observed in 82% and 84% of ED patients who received 4 mg or 6 mg of bremelanotide, respectively. In the phase II study, nausea (36.4%), headache (27.3%), flushing (9.1%), diaphoresis (9.1%), lower back pain (9.1%) and vomiting (9.1%) were the most common adverse events at the 6-mg dose. Subsequent studies have only been published in abstract form. In phase Iib studies bremelanotide was delivered intranasally in non-diabetic patients (726 men) who were randomized to receive placebo or one of five doses (5, 7.5, 10, 12.5 or 15 mg). The mean change in IIEF-EF domain score was 1.8 for placebo, 4.2 for 5 mg, 5.7 for 7.5 mg, 6.4 for 10 mg, 6.1 for 12.5 mg and 8.4 for 15 mg (statistically significant from placebo for all doses except 5 mg). Similarly, mean intercourse completion rates (question 3 of SEP [SEP3]) improved and were statistically significant from placebo for all doses except 5 mg. Major adverse events included nausea, emesis and blood pressure increases, and the discontinuation rates were dose-related and ranged from 4% in the placebo group to 49% in the 15-mg group [3]. In a second study in diabetic men the mean change in IIEF-EF domain score was 2.3 or placebo, 3.7 for 10 mg, 5.9 for 12.5 mg and 7.1 for 15 mg (statistically significant from placebo for all doses except 10 mg. SEP2 and SEP3 rates were improved, but none reached statistical significance. Major adverse events included nausea, emesis and blood pressure increases, and the discontinuation rates were dose-related and ranged from 4% in the placebo group to 49% in the 15-mg group [4]. A third study explored the efficacy of bremelanotide in combination with sildenafil using a rigiscan methodology. Nineteen patients with ED who were responders to either sildenafil or vardenafily by self-report were given sildenafil 25 mg plus intranasal bremelanotide 7.5 mg, sildenafil 25 mg plus an intranasal placebo spray, or a placebo tablet plus an intranasal placebo spray in a randomized, crossover design. A statistically significant difference was demonstrated between combination therapy and sildenafil (p<0.05), combination therapy and placebo (p<0.001) and sildenafil monotherapy and placebo (p<0.05). The combination treatment did not result in new adverse events or in an increase in the frequency or severity of adverse events compared with sildenafil or historical data of intranasal bremelanotide alone. Four patients (21%) experienced flushing, and one of these patients also reported nausea after combination therapy [5].

IV. COMPARATOR STUDIES

A number of studies have compared the efficacy and safety of the oral medications used in the treatment of men with erectile dysfunction. A careful review of the published trials was undertaken and the salient features of the studies are shown in tables 9 a-e. The trial designs used was variable with many studies demonstrating inadequate design resulting in clear bias. Almost all the studies were pharmaceutically sponsored.

1. COMPARISONS OF PDE5 INHIBITORS

The authors consider that one trial comparing sildenafil and tadalafil could be considered a Level 1 study [1,7,8] with the other published studies suffering from biases such as inadequate duration, inadequate washout, and biased dosing [2-6]. The single level 1 study was an open label study, but in other respects was well conducted and of adequate size. Overall, there was no evidence of superiority for any one of the PDE5 inhibitors over the others in terms of efficacy or safety (Grade A recommendation).

2. COMPARISONS OF SILDENAFIL AND APOMORPHINE

The authors consider that several trials comparing the efficacy and tolerability of apomorphine and sildenafil could be considered level 1 trials [9-12] with other published studies suffering from design limitations [13-15]. All Level 1 studies were all open label studies, but all were otherwise well designed trials, with adequate numbers of patients randomized. Overall there was clear evidence that sildenafil has greater efficacy in the treatment of men with ED than apomorphine (Grade A recommendation).

[8] Eardley I, Montorsi F, Jackson G et al. Factors associated with preference for sildenafil citrate and tadalafil for treating erectile dysfunction in men naïve to phosphodiesterase 5 inhibitor therapy: post hoc analysis of data from a multicentre, randomized, open-label, crossover study. BJU Int 2007; 100: 122–9

C.LOCAL THERAPIES

The dawn of the age of pharmacologic treatment began 25 years ago with the recognition that vasoactive drugs when injected into the penile erectile tissue were capable of initiating and maintaining erection [1,2]. Currently there are three main agents for intracavernosal injection (ICI) therapy (one of which is approved by prominent national drug approval agencies (i.e. FDA, European Agencies) for the treatment of erectile dysfunction (ED)). Additionally one agent for intravesical therapy of ED has also received approval.

These were relegated to second line therapy after the appearance of effective oral phosphodiesterase-5 inhibitors (PDE5Is). However, the local delivery of medications remain useful for the treatment of men with ED since PDE5Is are ineffective in about 25-32% of men [3], secondly a significant proportion will ultimately fail to respond to oral therapy secondary to progression of their disease and thirdly are a small number of men have contraindications to PDE5Is. The result is a large number of men who are unable to utilize oral treatments for ED.
I. INTRACAVERNOSAL

1. INTRACAVERNOSAL PROSTAGLANDIN E1 (ALPROSTADIL)

Intracavernosal prostaglandin E1 is licensed for the treatment of men with erectile dysfunction. Linet and Ogrinc reported three multi-centered, randomized prospective clinical trials and a six month open label extension examining the efficacy of intracavernosal alprostadil [4]. The initial trial was a dose-response study of 296 men randomized between increasing doses of alprostadil (2.5 micrograms to 20 micrograms) and placebo. All doses of alprostadil were better than placebo in producing an erectile response and there was a significant dose-response relation, resulting in higher response rates with increasing doses PGE1. In the second study of 201 men with erectile dysfunction of neurogenic, vasculogenic, psychogenic, or mixed causes, alprostadil also demonstrated significant efficacy. In a six-month open label flexible dose self-injection study in 683 men, 94 percent of patients had better erections after the injections. Sexual activity was rated as satisfactory by 87% of the males and 86 percent of their partners. Penile pain was the most commonly reported adverse event, occurring in 50 percent of the men at some time but was usually mild. Prolonged erections occurred in 5 percent of the men.

In an open-label, multi-center study, 67 ED patients who had failed previous PDE5 inhibitor therapy, Shabsigh et al reported successful rescue with prostaglandin E1 [5]. After an in-office titration phase to determine the optimal dose, these patients used alprostadil (up to 40 µg) at home for up to 6 weeks. Erections adequate for sexual intercourse during the 6-week at-home trial were reported by approximately 88% (57) of patients. Headache was the most commonly reported side effect with sildenafil use, and penile pain was the most frequent complaint with alprostadil alfadex. A recent meta-analysis reported intracavernosal injections of alprostadil has an efficacy >70% [6].

We are able to conclude, on the basis of this evidence that intracavernosal prostaglandin E1 is an effective treatment for men with erectile dysfunction (Grade of Recommendation = A).

2. VASOACTIVE INTESTINAL POLYPEPTIDE AND PHENTOLAMINE

The first instance of the use of VIP as intracavernosal injection monotherapy for ED was disappointing; Wagner and Gerstenberg reported that VIP did not induce erection when injected [7]. VIP has shown more promise when used for combination therapy with phentolamine. Several observational reports and two randomized clinical trials are available for review.

Dinsmore and Alderdice studied vasoactive intestinal polypeptide (VIP) combined with phentolamine mesylate (PM) in 70 men who had failed previous intracavernosal therapy [8]. Patients were titrated with 25 micrograms of VIP/1 mg PM (VIP1) and if unsuccessful, 25 micrograms VIP/2 mg PM (VIP2). Forty-seven (67%) of patients achieved erections sufficient for sexual intercourse (33 on VIP1 and 14 on VIP2). In a second observational series, 52 men received 30 micrograms vasoactive intestinal polypeptide and 0.5 to 2.0 mg. phentolamine [9]. In this report all patients obtained erection sufficient for penetration with a median duration of treatment was 6 months (range 1 to 22).

Two multi-centered prospective clinical trials using combination VIP/PH therapy have been used to successfully register VIP as an approved pharmacologic agent for the treatment of men with ED in the United Kingdom, Denmark and New Zealand [10,11]. In the first 236 men with primarily non psychogenic were treated with 25 micrograms VIP combined with PM 1.0 mg (VIP/P-1) or 2.0 mg (VIP/P-2) in the office [10]. This was followed with a placebo-controlled phase, during which 171 patients were subsequently treated and self-administered up to 12 injections over a 6-month interval. Erections were graded on a 4 point scale (0-III). The results are shown in Table 10. The second study involved 195 men with organic ED who received 25 micrograms vasoactive intestinal polypeptide (VIP) combined with phentolamine mesylate 1.0 mg (VIP/P-1) or 2.0 mg (VIP/P-2) versus placebo [11].

The combination of vasoactive intestinal polypeptide and phentolamine appears to be safe and well tolerated. Most commonly observed adverse effects were facial flushing and headache, characteristic events noted with vasoactive therapy.

999
We are able to conclude, on the basis of this evidence that an intracavernosal injection of the combination of vasoactive intestinal polypeptide and phentolamine is an effective treatment for men with erectile dysfunction (Grade of Recommendation = A).

3. PAPAVERINE

Papaverine was the first agent discovered to be effective as intracavernosal pharmacotherapy for erectile dysfunction [2]. It is highly effective but has fallen out of favor as monotherapy because of its high rates of fibrosis. In one series 163,042 papaverine injections were administered to 1,748 patients. The main side effects noted were priapism and fibrosis. Priapism occurred in 106 (6%) of patients after 235 (0.14%) of the injections. Fibrosis or nodule formation occurred in 187 (11%) of patients [12]. In a further study priapism was noted in 92 (7%) of 1300 patients while fibrosis, induration and nodules occurred in 5.7% (60 of 1,056 patients). Other important side effects were injection site pain, which occurred in 4% (18/452 patients), and hematoma, which occurred in 11% (98/858 patients) [13]. Papaverine is currently not licensed for use.

4. TRIMIX (PAPAVERINE, ALPROSTADIL, PHENTOLAMINE)

Combination therapies for intracavernosal injections were conceived both to improve efficacy as a result of the synergistic effects of the drugs, and later, to reduce side effects as a result of using lower dosages of each agent. One difficulty encountered with the use of combination agents is the need for the pharmacy to compound these agents since there are no combination intracavernosal injection drugs currently approved by the FDA. Concentrations of each component vary widely in the literature, but ratios of 12-30mg papaverine: 10-20μg alprostadil:1mg phentolamine appear standard.

Bechara et al reported a crossover study of alprostadil versus trimix in a group of 32 men who had failed high dose bimix therapy [14]. In this study, 50% responded to trimix compared to only 22% responding to alprostadil.

Rates of pain for alprostadil was significantly higher than for trimix (41% vs. 12.5%). Seyam et al. studied multiple combinations of trimix ingredients versus alprostadil in a 180 men with erectile dysfunction [15]. They found that all tested mixtures were highly effective and produce erections that are of equal frequency and quality to those produced by alprostadil. Sixty-eight percent of men using alprostadil and 67% of men using trimix achieved a rigid erection. However, duration of erections was longer than alprostadil and a larger number of episodes of priapism (5% vs. 0.6%) were produced. Interestingly, rates of pain were similar between the combined trimix group and the alprostadil group (14.5% vs. 17.9%, respectively).

5. TOLERABILITY AND SAFETY OF INTRACAVERNOSAL AGENTS

Patients must be made aware of the risk of priapism that occurs with ICI use and educated about the proper course of action to take should they experience a prolonged erection. Some evidence exists to support the use of sympathomimetic drugs, such as pseudoephedrine and terbutaline [16]. Both terbutaline and pseudoephedrine performed better than placebo, with detumescence resulting in 36%, 28% and 12% respectively. The other patients required irrigation and/or phenylephrine injections. None required surgical intervention. A study by Priyadarshi (1994) showing detumescence in 42% of patients with ICI induced priapism compared with 15% detumescence with placebo in 68 men supported the claimed efficacy of terbutaline [17].

Cavernosal fibrosis is another serious side effect of intracavernosal injections. It occurs most commonly with injectables containing papaverine. Rates are less than one percent with alprostadil, approximately 6% with papaverine and around 12% with bimix. Rates with trimix were 4% in a small study. These are likely dependant on dose and frequency of use. There is no treatment to reverse penile fibrosis, though it sometimes regresses on its own. Tsao and Nehra recommend temporary discontinuation of ICI for 3-4 months to allow [18] (Grade of Recommendation = D). Persistence of fibrosis should prompt a change to more invasive methods of improving erectile function, i.e. placing a penile prosthesis.

Reported rates of pain with injection are 7% for alprostadil, 4% with papaverine, 12% with bimix [13] and 12-15% with trimix [14, 15]. Significantly it has been observed that pain decreases substantially during the course of treatment so it is likely that the psychological component plays a large role.

6. CONTRAINDICATIONS TO INTRACAVERNOSAL THERAPY

Intracavernosal injections should not be used in men with conditions which predispose them to priapism. These notably include men with sickle cell disease, multiple myeloma and leukemia. Anticoagulation however is not a contraindication to ICI. In a series of 605 injections in 33 men using warfarin for anticoagulation, Limoge et al recorded only three ecchymoses [19]. This rate of 9% of patients is comparable to the 14% (434/3143) of patients on PGE1, papaverine, or bimix who developed hematoma in Porst’s 1996 literature review [13]. Despite this, it is advisable that the physician stress the need, in anticoagulated patients, to place pressure on the injection site for five full, uninterrupted minutes of pressure to prevent hematoma.
II. INTRAURETHRAL

MUSE (Medicated Urethral System for Erection) is a licensed alternative way to deliver alprostadil to the corporal bodies. MUSE involves the insertion of the delivery catheter into the meatus and depositing an alprostadil pellet in the urethra and the method is based on the absorption of drug through the urethral mucosa and into the corpora cavernosum.

One of the largest studies to describe the efficacy of MUSE was published by Padma-Nathan et al [20]. Notable in this study, 995/1511 patients had in-office responses to MUSE. Of those patients with in-clinic response to MUSE, only 299 of the 461 patients assigned to the MUSE arm of the trial achieved intercourse at home. Thus, the true success rate of MUSE in this large study was only 42.44%. Furthermore, of the patients who did achieve intercourse at home, only 73% of doses (2634/3593) were successful in achieving intercourse, orgasm or a 10 minute erection sufficient for intercourse. MUSE has been used successfully in men who have undergone radical prostatectomy. Costabile et al. reported a 40% rate of home success for MUSE in a group of 384 men greater than three months post-prostatectomy [21].

A systematic review of MUSE therapy (3 RCTs, 1828 men) reported that compared to placebo, alprostadil increased the proportion of men achieving ≥1 successful intercourse (average response: 65.3% with alprostadil vs. 17.6% with placebo; OR 7.22, 95% CI 5.68 – 9.18; p< 0.00001) [6]. In sildenafil failures, this treatment is shown to be effective in up to 43% of men with ED [22]. Direct comparison trials between MUSE alprostadil and ICI alprostadil are summarized in Table 11.

MUSE alprostadil had similar rates of pain to ICI alprostadil, but priapism and fibrosis were rare. Side effect rates are noted in Table 12. Other side effects unique to MUSE compared to ICI were dizziness, hypotension, and sweating. These occurred at a frequency of 1-6%. Syncope occurred at a rate of <1% and urethral bleeding also occurred at a rate of 1-5%.

Overall, we are able to conclude that there is evidence of efficacy and good tolerability for the use of intraurethral alprostadil as a treatment for men with erectile dysfunction (Grade A recommendation). The evidence also suggests that intracavernosal injection therapy is a more effective treatment than intraurethral alprostadil (Grade A).

III. TOPICAL AGENTS

There have been several advances in the understanding of the pharmacokinetics of topical therapy. The transdermal route has a well established technology to provide durable and constant plasma levels of drugs such as hormonal replacements, narcotics and vasodilators. When it comes to local penile therapy using direct smooth muscle relaxants, the durability and onset of action of such methods may not be useful attributes. In this regard there are several issues worth mentioning: 1) High systemic levels are undesirable as they may result in an unacceptable level of adverse events., 2) Agents may be largely metabolized in the first pass through the lungs or liver., and 3). The vasoactive agent(s) need to reach the corpora cavernosa in a timely fashion with the effective (highest) concentration.

Topical penile therapy has a unique set of anatomic and physiologic issues that are important to consider. There are several anatomic/fascial layers between the penile skin and the corpus cavernosa. The tunica albuginea is presumed to be difficult to penetrate due to its thick layers of collagen. Therefore, topical treatment trials have emphasized exposure to the glans penis as it has direct venous communication to the corpora cavernosa [27,28]. The skin itself is a relatively impermeable tissue due to the stratum corneum. The horny cells at the stratum corneum are bonded with a very tight intercellular lipid matrix bilayer that makes the passage of drugs challenging [29]. To overcome this barrier investigators have used penetration enhancers which permeate this layer and reach the subdermis. Fortunately, the penis and scrotum are unique in that their stratum corneum is the most permeable of all anatomic locations tested.

With the assortment of confounding factors as mentioned above one wonders exactly how gel applied to the penis could ever induce an erection. One attractive possibility is gel applied to the glans is rapidly absorbed through the porous skin of the glans into the venous vasculature of the corpora spongiosum. From that location it could travel into the corpora cavernosa akin to the intrarethral delivery of drug [30].

Several transdermal enhancers incorporated as one of the excipients in topical formulations have been reported [27,28,31,32]. The task of these enhancers is to: 1) Disrupt the stratum corneum lipid bilayer, 2) Interact with the membrane keratin, 3) Produce a weak interaction with the drug molecule, and 4) Reverse all actions in a short time. The available evidence indicates that this agent enhances skin penetration by altering the fluidity of lipids in the stratum corneum, without any interaction with the chemical whose skin permeability is enhanced.

1. TOPICAL ALPROSTADIL

Evidence providing comparative efficacy remains lacking thus this therapy remains investigational. To date no sufficiently effective product exists.. In trials of alprostadil with SEPA, doses of 2500 μg alprostadil were used with a resulting 39% of patients achieving erection sufficient for penetration versus 7% of the placebo group [33]. Unfortunately, baseline characteristics were not provided in this study. Ultimately, alprostadil/SEPA trials were discontinued because of their apparent lack of efficacy at safe doses.

A large trial of topical alprostadil without a skin penetration enhancer was also published by Padma-Nathan et al. which showed a statistically significant but very slight improvement in sexual function with topical alprostadil [34]. This study used 100, 200 and 300μg doses of alprostadil and achieved successful penetration rates of 57.5%, up from a baseline of 50% at the highest dose. A criticism of this study is that its high initial function rates do not adequately represent population seeking treatment for erectile dysfunction.

2. TOPICAL PAPAVERINE

Since the introduction by Virag in the early 1980s of injection of papaverine into the corporal bodies for the treatment of sexual dysfunction has become a widespread and well accepted method. It use as a topical therapy has a much shorter experience and one that has not moved beyond preliminary clinical trials. Serum papaverine levels after topical administration have been measured in a single study with a high performance liquid chromatography assay [35]. At 60 minutes mean serum levels increased 50% suggesting that absorption did occur, but not significantly over baseline values. The papaverine levels in this study indicated that topical absorption is less than 1% of a comparable intravenous dose indicating minimal systemic uptake after topical administration to the genitalia.

3. TOPICAL NITROGLYCERIN

The use of topical nitroglycerin is a standard treatment for unstable angina pectoris because predictable blood levels can be achieved. The use of nitroglycerin ointments, pastes, plasters or patches for the treatment of erectile dysfunction has been tried in several studies. Relaxation of vascular smooth muscle is the principle pharmacologic action of nitroglycerin. Nitroglycerin produces, in a dose dependent manner, dilation of both arterial and venous beds, dilatation of the post-capillary vessels including large veins and decreases in venous return. Contraindications to the use of topical nitroglycerin include those who have allergic reactions to organic nitrates. These are extremely rare, but they do occur. Allergies to the adhesives used within the nitroglycerin patches have also been reported.

Erectile Function Rehabilitation In The Radical Prostatectomy Patient

JOHN P. MULHALL, ANTHONY J. BELLA, ALBERTO BRIGANTI, ANDREW MCCULLOUGH, GERARD BROCK.

I. INTRODUCTION

Prostate cancer represents the second most common solid malignancy diagnosed in adult men in many Western societies. The American Cancer Society estimates that 9% of all cancer deaths in the US in 2009 will be a direct result of prostate cancer[1]. In spite of advances in diagnosis and early case finding through the widespread adoption of prostate specific antigen (PSA), coupled with advances in surgical technique, significant morbidity is still reported in most contemporary surgical series[2-5]. Our understanding of the pathophysiological basis of post-prostatectomy erectile dysfunction (ED) has evolved over the past decade, with recognition of the anatomical location of the cavernous nerves, their essential role in erection and the impact nerve injury has on cavernous smooth muscle content and function as well as potentially the tunica albuginea[6-8]. Enhanced knowledge of the consequences of cavernous nerve percussion, traction, cautery and transection, accessory pudendal arteries and ultimately their impact downstream on cavernous smooth muscle, has sparked important basic and clinical research evaluating various strategies aimed at minimizing the likelihood of post-prostatectomy ED [9-17].

The concept of penile rehabilitation, the use of any intervention or combination of interventions (medications, devices or actions) whose goal is broadly thought of as being aimed at restoring erectile function to pre-treatment levels, is believed to be based on three inter-related concepts: (i) improving cavernosal oxygenation, (ii) promoting endothelial protection and (iii) preventing cavernosal nerve injury-induced structural changes of the penis [18].

In this chapter, we have undertaken a comprehensive review of the peer-reviewed scientific literature, with the goal of providing an unbiased integrated analysis of the existing knowledge related to preservation of erectile function following radical prostate surgery. As with all areas of sexual medicine, the literature has areas of great strength and significant weaknesses, where further work is needed. In our report, areas of clear consensus are highlighted, controversial questions are discussed and clinical problems in need of further research are identified, with the goal of providing clinically relevant information on erectile function rehabilitative approaches following radical prostatectomy (RP).

1. NON-ED SEXUAL DYSFUNCTIONS

While, the focus of this treatise is erectile function recovery and its optimization, it is becoming increasingly recognized that a number of sexual dysfunctions may occur after RP. These dysfunctions include reduction in libido, anejaculation, alterations in orgasm, penile size alterations and possibly Peyronie’s disease

a) Anejaculation

RP involving the surgical removal of the prostate, seminal vesicles and transection of the vasa, essentially disrupts the ejaculatory mechanism. Data regarding the impact of ejaculation loss following prostate cancer treatments are scarce. Anejaculation has several implications: firstly, it may interfere with subject’s self perception of his manhood and body image. Then as ejaculation and orgasmic sensations are closely related at least in some men, anejaculation may be associated with reduced orgasmic quality, and finally, it renders men infertile. Prostate cancer is perceived as a disease of old men, to whom infertility is no longer an issue. However, in the era of early prostate cancer detection, men are diagnosed at a younger age and generally have excellent long term recurrence-free survival rates[19]. At the same
time, the age of paternity in the general population is increasing and it has been suggested that a cancer diagnosis may actually increase the motivation for parenting[20]. Though advanced sperm extraction and fertilization techniques are available, the issue of anejaculation and its implication on future fertility should be discussed and the clinician should not assume this to be non-relevant and semen should be cryopreserved for men who may potentially bmay desire future fatherhood[21]. The advent of intracytoplasmic sperm injection (ICSI) has allowed the application of assisted reproductive technologies to couples whose male partner cannot deliver sperm in an antegrade fashion. This has particular relevance to the patient who has undergone RP.

b) Orgasm Alterations

Despite major advances in our understanding of the erectile mechanism in the last decade, the process of orgasm remains poorly understood. Both physiological and psychogenic elements contribute to the genesis of orgasm. Ejaculatory events that include smooth muscle contraction of the accessory sex organs, buildup and release of pressure in the posterior urethra, sensation of the ejaculatory inevitability, rhythmic contractions of the pelvic floor muscles and semen emission contribute to the sensation of orgasm. Sensory cortical neurons perceive these events as pleasurable[22]. Normally, orgasm is closely coupled with ejaculation, however, after RP orgasm occurs without semen ejection perse, yet ejaculatory muscular activity does persist.

Though orgasmic changes have received much less attention than ED, such alterations are not uncommon and can be categorized into three areas (i) changes in orgasm presence and quality (ii) orgasmic pain (dysorgasmia) and (iii) orgasm associated incontinence. Schover et al, in a study of 1236 men treated for localized prostate cancer (52% RP, 48% radiation therapy), found that 65% of the sample reported a problem with their orgasms including 31% who no longer tried to reach orgasm, 17% who tried but were unable to reach orgasm and 28% with orgasms that were disappointingly weak[23]. To define the type of orgasmic dysfunction in men after RP, Barnas et al used a validated questionnaire, including questions addressing the presence or absence of orgasm, orgasm quality before and after surgery, the presence of orgasmic pain, the location of orgasmic pain and consistency and duration of orgasmic pain. Of the subjects, 22% of patients reported no change in orgasm intensity but 37% reported a complete absence of orgasm, 37% had decreased orgasm intensity and 4% reported a more intense orgasm after RP than before. Pain during orgasm occurred in 14% of the patients, located in the penis (63%), abdomen (9%), rectum (24%) and other areas (4%). In those respondents who had dysorgasmia, pain was reported to occur always (with every orgasm) in 33%, frequently in 13%, occasionally in 35%, and rarely in 19%. Most patients (55%) had orgasm-associated pain for less than a minute, a third reported pain for 1–5 minutes and pain lasting more than 5 minutes was reported by 12%; only 2.5% of patients complained of pain lasting more than an hour[24]. No consensus exists as to the etiology of orgasmic pain, however it is postulated that bladder neck/pelvic floor spasm plays some role, akin to the condition of chronic pelvic pain disorder. Based on this assumption, a prospective, non-placebo controlled study was conducted to assess the use of tamsulosin, an alpha-adrenergic blocking agent in patients with orgasmic pain. In this study, 77% patients reported significant improvement in pain and 12% noted complete resolution of their pain with significant increase in IIEF libido score, supporting the hypothesis that orgasmic pain is related to bladder neck and/or pelvic floor muscle spasm [25]. Alternatively use of an analgesic taken prior to sexual activity has been described may be a pragmatic approach.

Urinary incontinence during orgasm (climacturia) is another phenomenon that may adversely affect the satisfaction with sexual activity for men following RP and their partner. Choi et al reported that climacturia occurred in 20% of patients following RP (only 4% with radical cystectomy), which they showed was unrelated to the type of prostatectomy performed (open vs laparoscopic). These authors reported that climacturia is more likely to be reported within year 1 following surgery and in men who complain of orgasmic pain and/or penile shortening[26]. Lee et al reported a prevalence of climacturia after RP of 45%. In 68% of the cases reported, it happened rarely or only occasionally, while in 21% it occurred most of the time or always. Urine leakage quantity was only a few drops in 58% of the subjects but 16% reported a loss of more than 1 ounce. Bother was none or minimal in 52% and significant in 48%. Treatment was bladder emptying in 84% and condoms use in 11% [27].

The take-home message for the clinician is that alterations in orgasmic function following RP is common and frequently impactful to the patient and partner. At present, there is no effective treatment to restore the nature of preoperative orgasm. Interestingly, some men report an enhanced orgasmic experience following RP, but this represents a less common scenario. Dysorgasmia can be managed symptomatically using alpha-blockers and climacturia may be managed behaviorally (fluid intake restriction and bladder emptying prior to sexual activity) or mechanically (using a rubber constriction ring or condoms, if the leakage amount is small). The mainstay of treatment is patient and partner education before surgery and supportive care afterwards.
c) Peyronie's Disease (PD)

The prevalence of PD following RP has been addressed by a single paper in the literature and in this analysis of 110 men who presented with ED after RP, 45 (41%) had penile fibrotic changes, representing 11% of all men who had RP in their institute at the specified period. This incidence of PD is higher than that of the general population. The clinical presentation was penile curvature in 93% and 'waistband' deformity in 24%; palpable plaques were present in 31 (69%)[28]. The actual prevalence of PD after RP may be even higher, as this condition, manifested as penile curvature during erection, is evident only in men who achieve some degree of penile rigidity. Originally ascribed to undiagnosed preoperative PD or spongiosis due to urethral catheterization, we routinely see men who had normal genital exams preoperatively who develop PD after surgery. Furthermore, most of these patients have PD plaques dorsally nowhere near their corpus spongiosum. Thus, catheter-related spongiosis is not likely to be a significant factor.

Another explanation that patients are given is that the intracavernosal injections they are using after surgery has caused the tunical fibrosis, despite the fact that there is no data to support this whatsoever[29]. Indeed, it is not uncommon for us to see men three months after RP who are present in clinic for their first penile injection training session, who had no documented PD prior to RP and who on their first injection demonstrate penile curvature never having received an injection prior to that. A review of a prospectively built sexual medicine database at Memorial Sloan Kettering Cancer Center including 1161 RP patients from 2002-2008, the PD incidence was 16.7% at a mean ± SD follow-up of 24±25 months. At multivariate analysis, older age (OR=1.25, for 5 year increase in age) and white race (OR=3.6, vs non-white) were independent significant predictors of post-RP plaque development.

While the precise process of plaque formation leading to eventual clinically evident PD following RP is still ill-defined, it is not unlikely that it may be related to other post RP penile fibrotic changes, secondary to denervation and/or local ischemia [10]. Thus, patients after RP should be routinely evaluated for the existence of penile plaques, as a part of their post-operative follow-up. This condition may also be considered part of the informed consent of the surgical procedure but certainly as a component of the erectile function recovery discussion for men interested in treatment.

d) Penile Volume Alterations

Penile length changes after RP have been described. Penile shortening, even if sexual intercourse is still feasible, once it is identified by the patient or his partner may adversely affect body image, self-esteem, sense of manhood and self confidence. In 1999 Fraiman et al found significant decrease in all penile dimensions after RP: decreased penile length of 9% and decreased volume of 22% in the erect state. The most substantial change occurred between the first 4 and 8 months postoperatively [30]. Munding et al found a measured decrement in penile length in 71% of men after RP, which was greater than 1 cm in 48% of the cases, 3 months postoperatively [31]. Similar findings were obtained in a study by Savoie et al with a decrease in the stretched penile length in 68% of the cases and greater than 15% length loss in 19% [32]. Gontero et al have suggested that penile shortening has been shown to be independently associated with nerve preservation status and postoperative erectile function outcome [33].

The reasons for penile volume changes can be explained by struratical and functional alterations in the penis. Fibrotic changes have been demonstrated in penile biopsies taken in early and late stages after RP (2 and 12 month postoperatively), showing significantly decreased elastic fiber and smooth muscle content as well as increased collagen content [10]. It is postulated that the chronic absence of erectile activity leads to absence of cavernosal oxygenation (see later) [34].

In addition to anatomical changes, there are also functional alterations. It is well recognized that even in the hands of an experienced surgeon using nerve-sparing techniques, some degree of nerve injury, commonly neuropraxia, is likely to occur. Penile smooth muscle and vascular relaxation is accomplished through the release of nitric oxide (NO) from cavernosal nerve endings and the generation of the second-messenger cyclic nucleotides, cGMP and cAMP and is likely to be compromised after surgery. Contractility of the smooth muscle is generally tonic and under the control of erectolytic neurotransmitters such as adrenaline. Sympathetic hyper-innervation (also termed competitive sprouting) refers to the concept that when autonomic nerves are injured, sympathetic fibres are biologically primed to recuperate from injury and regenerate more quickly, resulting in unantagonized sympathetic tone in the end organ [35]. After cavernosal nerve injury, this phenomenon results in a penile hypertonic state. Any factors that result in reduced NO production or increased sympathetic tone, such as nerve injury after RP, may lead to decreased relaxation or diastemibility of corporal smooth muscle and may lead to loss of length. Regardless of the exact mechanism of penile length alteration, most concerning are structural changes that probably result from a combination of neural injury-mediated denervation apoptosis and collagenization of smooth muscle.

It is the recommendation of the ICSM that clinicians discuss with the patient that radical

prostatectomy is associated with a number of sexual dysfunctions, some of which may be permanent. The sexual dysfunctions that should be discussed include, erectile dysfunction, libido reduction, changes in orgasm, anejaculation, penile size changes and possibly Peyronie's disease. Discussion should be held prior to surgery and at regular intervals after surgery. Furthermore, clinicians following patients after RP should examine patients' penis serially to determine if Peyronie's disease has occurred. This was a unanimous committee recommendation.

**RECOMMENDATION 1**

Grade A

The clinician should discuss with the patient that radical prostatectomy is associated with a number of sexual dysfunctions, some of which may be permanent.

**II. PREVALENCE OF ED FOLLOWING RADICAL PROSTATECTOMY**

This field of research began in earnest in the early 1980’s, with the landmark report from Walsh and Donker describing the potential and demonstrating the importance of nerve sparing in radical prostate cancer surgery [36]. The challenges faced by the clinician researcher in achieving the goal of preserving erectile function are significant. The proximity of the cavernous nerves to the prostatic capsule, anatomically arranged as a diffuse poorly visualized nerve plexus adherent to the lateral aspect of the prostate, represents a considerable surgical obstacle. Additionally, the cavernous nerves’ small size, delicate nature and dependent location deep within the male pelvis make visualization and therefore preservation difficult, even in the current era with improved lighting, optics, laparoscopic and robotic instrumentation even among men with low volume disease [8, 37].

Even to the casual observer, it is apparent that success in achieving the goal of preserving and restoring erectile function in all men following RP has not yet been achieved [4]. Prevalence can be defined as the number of all new and old cases of a disease or occurrences of an event in a particular period of time. Prevalence is typically expressed as a ratio in which the number of events is the numerator and the population at risk is the denominator [38]. This contrasts with incidence that defines the rate of increase or decrease of a condition over a specific interval of time.

For the purpose of this section of the chapter, defining the actual prevalence of ED among men following RP is essential in deciding whether there is a clinical need and therefore merit, in pursuing a rehabilitative strategy. The determination of true prevalence of any condition is dependent on knowing both the true number of cases and the number of men at risk. In the case of ED following RP, we generally lack accurate numbers defining the total number of men with ED, but have reliable statistics on the total number of cancers diagnosed (192,000 in the US in 2009) and numbers of procedures [1]. The confounding issues related to the number of men with ED are numerous and include all of the following: inadequate assessments of pre-operative erectile function, poor data collection related to post-operative recovery of erectile function, lack of consensus related to optimal timing for reporting recovery of function, non-uniform agreement of what constitutes ED post RP [4, 5]. The exact scale of the problem is thus inadequately defined owing to significant limitations of data accrual, reporting and perhaps most importantly a lack of consensus of defining what constitutes success from an erectile function recovery standpoint.

Given these limitations, a review of the existing medical literature demonstrates a large variance in reported rates of ED following RP (20-90%) [4, 39-43]. There are many reasons why these differences in reported outcomes exist, and as depicted in Table 1, can best be thought of as: intrinsic patient factors, surgical factors, and reporting biases. In contrast to many of the other post-operative complications such as incontinence, erectile function is more difficult to define and represents a moving target, as recovery from surgery generally shows improving function but with advancing age, a decrease in function would normally be expected. ED is known to increase with advancing age among all men, including those who have undergone definitive management of their prostate cancer. As such measuring erectile function prospectively has a moving baseline [44, 45]. There is an important psychologic component for these men, as well as a subjective degree of assessment and it is further complicated by the necessary partner involvement [46].

At present, no precise and generally agreed upon time-points post-treatment have been defined as the optimal interval post treatment to determine erectile function outcomes. Basic animal and human volunteer data suggest that following an initial period of 3 months may peak and a nadir level of response can be experienced by many men who early in the post-operative course experienced some degree of responsiveness [47, 48]. As one follows men out beyond 2 years, some modest degree of ongoing improvement in erectile function has been reported. It remains unclear whether this represents progressive neural and vascular recovery, an adaptive response of the host and partner to their erectile deficiency and accommodation to use of phosphodiesterase type 5
inhibitors (PDE5i) or other erectogenic agents or the process of confidence restoration, whereby there is significant recovery of the "erectile machinery" by 2 years after RP, but confidence has been eroded and with time (2-4 years), confidence is restored and reported erectile function improves [49]. Additionally, no clear consensus exists defining what an acceptable level of erectile function is, for men and their partners post RP. While some investigators use the IIEF erectile function domain score of 26 points or greater (or 21 on the Sexual Health Inventory for Men also known as the SHIM), others utilize IIEF EF domain scores of 21 or even 17 on a scale of 30. Furthermore, some reports define erectile function with or without the use of PDE5i and only rarely are the response rates segregated based on the use of erectogenic agents [4].

In the current era of early prostate cancer detection, many young and sexually active men are undergoing radical surgery and express concern about preservation of erectile function following the procedure, a fact that is true for older men as well. Since Walsh and Donker published their landmark article describing the etiology and prevention of impotence following retropubic RP in 1982, the nerve sparing technique they described is widely employed and believed to improve postoperative erectile function [50]. Furthermore, there continue to be modifications to the nerve sparing technique in an attempt to minimize nerve compromise and improve post operative erectile function as reported by Chuang et al. and Masterson et al [8, 37]. However, optimal sexual functioning often requires 18-36 months to return, even among men in whom bilateral nerve sparing was performed with reported recovery rates varying from 16% to 86% [51]. Sexual dysfunction has been reported to be an independent determinant of a poorer general health-related quality of life at 2 years after primary treatment for prostate cancer [52].

Recent advances in the understanding of the pathophysiology of post-prostatectomy erectile dysfunction have resulted in great attention being directed towards the concept of penile rehabilitation, in which prophylactic measures are instituted to promote early recovery of sexual and erectile function as well as to modify post-prostatectomy pathophysiologic changes [18].

In this portion of our report, we have reviewed the current English language medical literature in an attempt to provide accurate estimates of the prevalence of ED following RP using contemporary surgical approaches. Ideal prevalence data should be obtained through large, multicenter, multinational prospective studies among large cohorts of men with variable but clearly established erectile function pre-operatively. The ability to define the effect of various surgical approaches, such as laparoscopic/robotic and open RP on recovery of erectile function would be useful (Table 2). Additionally, the ability to determine the optimal time for measurement of erectile function, and the most clinically relevant minimum erectile function score, which would result in sexual satisfaction of the patient and partner would be ideal. Finally, such a study may allow for the identification of an optimally effective post-operative protocol consisting of oral, injectable, intraurethral, externally applied devices or other modalities facilitating recovery of EF. The ability to identify intra-operative techniques to localize the cavernous nerves or in some other manner minimize the negative impact of prostatectomy on erectile function would also be ideal (Table 3) [13].

Table 1: Predictive Factors For Erectile Function Recovery Following Radical Prostatectomy
Sadly, the reality of the current literature is a dire lack of well-powered, well-designed prospective clinical studies defining the true prevalence of ED, following contemporary RP. While there exists a plethora of small, poorly powered studies, they all suffer from one or many deficiencies, which limit their validity and make the task of providing accurate information to the individual patient a clinical challenge. The ability to create a nomogram predicting erectile function preservation for an individual patient would, in our opinion, have great utility. The components of such a prediction model would certainly include the key variables previously defined in the literature, predictive of success. These include surgical experience, surgeon volume, extent of nerve sparing, age of the patient, co-morbid conditions, pre-operative erectile function, requirement for adjuvant therapy post-surgery. To the best of our knowledge there are at least two groups (Memorial Sloan Kettering Cancer Center, New York and Vita Salute San Raffaele, Milan) that have nomograms in development. Other factors which should be investigated are: the impact of the partner, the extent of continence, occupation, cultural background, surgical approach (laparoscopic, robotic, open), surgical technique (use of cautery; veil of Aphrodite

Table 3: Components of Ideal Study to Define True Prevalence of ED after RP

1. Establish true baseline erectile status prior to diagnosis of prostate cancer.
2. Seek partner confirmation in initial EF assessments.
3. Define comorbidity status of patients.
4. Full intra-operative description of extent of dissection, tumor location, amount of bleeding, duration of surgery, approach (open/laparoscopic/robotic, open) and confidence in nerve preservation (preferably graded).
5. Description of post-operative rehabilitation strategy and level of compliance by patient.
6. Assessment of EF post-op using validated questionnaires at frequent time points (Q 3-6 months) from surgery to at least 36 months.
7. Quality of life assessments for patient and partner at time points listed above.
It is the recommendation of the ICSM that clinicians should discuss ED prevalence rates and the limitations and implications of the currently available literature. Furthermore, patients should be given individualized outcomes based on patient and surgeon factors. On discussion, it was accepted that many urologists do not have accurate data on erectile function recovery from their own patient population. This recommendation was to circumvent the frequent occurrence of surgeons citing the best erectile function recovery figures in the literature, thus giving patients unrealistic expectations. In the absence of an available nomogram, surgeons should make an attempt to categorize the patients’ risk for postoperative erectile function recovery into good, fair or poor. This was a unanimous committee recommendation.

However, even among the very best reports the reliability of their estimated prevalence rates are suspect owing to extensive methodological shortcomings in reporting, patient bias, limited numbers and incomplete data collection related to sexual functioning. In some reports, recovery was defined as an IIEF EF domain score of 17 or greater [54] whereas most men who score in that range would certainly be unhappy with their sexual experience and would likely deem themselves as having ED. While achieving a IIEF EF domain score of 26 points or greater is generally accepted as normal erectile function, only 3 studies using this criterion, involving a total of roughly 300 men, exist in the current medical literature [55-57].

While the IIEF EF domain score of 26 is unequivocally normal, and perhaps should be the gold standard recovery definition, in a study by Teloken et al, approximately 70% of men with EF domain scores of 22-25 agreed completely or somewhat with the statement that “they could have sexual intercourse whenever they wished”[58]. It is likely that somewhere between 22 and 26 on the EF domain score represents functional erectile ability. However, even in reports where an appropriate threshold has been reported, other limitations were significant, including use of non-validated endpoints, with only two reports involving just over 100 men where information on the use of erectogenic agents was provided. In fact, we believe that men who score 26 points or greater on the IIEF EF domain while using a PDE5i or other erectogenic agent are not truly normal.

It is the recommendation of the ICSM that clinicians should use a validated instrument with recognized cut-offs for normalcy and severity in their preoperative and postoperative evaluation of their patients. It is recommended to use either the IIEF erectile function domain or SHIM with score cut-offs of 26 and 21 respectively to define normal erectile function. This was a majority recommendation of the committee. It is appreciated that many men with IIEF EFD scores of <26 and SHIM scores <21 are satisfied with their erectile function and there was significant discussion as to whether an EFD score of 21-24 was adequate. In the final analysis, the committee believed that there were published validated cut-offs for the scores recommended and that the concept of adequate erectile function should be a decision left to the patient/couple. The concept of post-surgical patients regaining erectile function ‘back to baseline’ was also discussed by the committee. We suggest that future research focus on capturing these data so that large data sets can be used to aid patients in defining the probability of returning to their baseline level of erectile function. The committee also appreciates that baseline erectile function assessment is problematic and that the ideal timing of this assessment is poorly defined. The committee understands that many men have a significant negative effect on their erectile function after the diagnosis of prostate cancer and that assessment of EF immediately prior to RP may not be fully representative of the patient’s true EF, however, asking about function prior to diagnosis of cancer is fraught with problems also not the least of which is recall bias.

Furthermore the ICSM recommends that clinicians should discuss the recognized predictors of erectile function recovery. These factors include patient age, baseline erectile function, and nerve sparing status. It should be pointed out to patients also that other factors such as comorbidity status and surgeon experience have been shown to be significant contributors to recovery. This was a unanimous recommendation of the committee. The committee also suggests that surgeons should discuss with patients the definition of nerve sparing and its implications. It is the clinical experience of the expert panel that patients do not have an adequate understanding of the concept of nerve sparing, thinking that nerve
sparing always means complete preservation and that complete preservation means there will be absence of any transient postoperative ED.

The ICSM also recommends that clinicians should provide patients with a realistic time frame for EF recovery. Patients should be informed that the period of potential recovery is 6-36 months, but that the majority of patients have functional recovery within 12-24 months after RP. It is the clinical experience of the expert panel that many patients are given recovery timeframes that are too short and generally unrealistic. This is furthermore reflected in the timing of data reporting in the published prevalence series.

Finally, the committee recommends efforts should be made by interested medical organizations including ISSM to standardize erectile function end-points.

Thus, the prevalence of ED following contemporary RP is poorly defined by the current peer reviewed literature. The existing patient database is limited by numerous methodological flaws, such as: small population reports, incomplete data acquisition, absence of consensus on a definition of success or failure to recover erections, limited data concerning quality of life and satisfaction with sexual life, of the patient and partner, variable questionnaires or in-person interviews and inadequate patient follow up.

The true impact of rehabilitative strategies on rates of erectile recovery in this population is not yet fully defined[59]. Perhaps the most prudent and reasonable conclusion one could arrive at following a careful review of the current literature related to prevalence of ED following RP is that it is common, independent of surgical approach or other patient baseline characteristics. At a minimum half of the men, independent of age, co-morbid status or exposure to adjuvant therapy instituted to improve recovery, will experience significant degrees of erectile function loss. As outlined in this section, large prospective multi-center trials evaluating the many innovative pharmacological and external devices targeting penile rehabilitation strategies are needed, to provide our patients with the essential information optimizing their erectile recovery post-RP.

RECOMMENDATION 2

Grade B
Clinicians should discuss ED prevalence rates and the limitations and implications of the currently available literature. Patients should be given individualized outcomes based on patient and surgeon factors.

III. PATHOPHYSIOLOGY

The pathophysiology of ED after radical prostatectomy involves the interplay of three factors (Figure 1): namely, neural injury, vascular injury, and corporal smooth muscle damage. Additionally, the extent and reversibility of these injuries ultimately will define the degree of recoverable erectile function.

1. NEURAL TRAUMA

It is well appreciated that transection of, or extensive thermal injury to the cavernous nerves will result in permanent loss of erectile function after surgery. However, traction and/or percussive injury to the nerves may be just as deleterious. In a recent study, Masterson et al. demonstrated that alteration in technique whereby the urethral catheter is no longer used as a traction tool to apply tension to the lateral pedicles, resulted in a significant improvement in EF recovery post-prostatectomy [37]. Three hundred seventy-two patients were evaluated: 275 patients (74%) underwent a standard technique while 97 (26%) underwent the no-traction technique. Sixty-five of the 97 patients (67%) who were exposed to the no-traction technique had recovery of functional erections at 6 months. The expected probability of 6-month EF recovery in these patients, had they been exposed to the standard technique, was 45%. Thus, the absolute improvement in EF recovery apparently attributable to the new technique was 22% (95% CI 5-40%; p = 0.013), suggesting that a no-traction approach may maximize EF recovery.
Since the initial description of the anatomic radical retropubic prostatectomy and the elucidation of the course of the cavernous nerves, many urologists have been trained to perform nerve-sparing surgery [60]. The variability in the anatomic location and distribution of these nerves, combined with variations in nerve-sparing technique and nerve handling, has resulted in variable erectile function outcomes after this refined approach. It is irrefutable that the nerve-sparing status of a RP is predictive of recovery of erectile function. Bilateral nerve sparing is associated with superior spontaneous and oral therapy–assisted recovery of erectile function compared to unilateral nerve sparing, which in turn is more likely to lead to functional erections than non-nerve sparing surgery [61-63]. However, the definition of nerve sparing is somewhat arbitrary. The term generally refers to the macroscopic preservation of the cavernous nerves, as defined by the surgeon at the time of the procedure. While rarely reported in a quantitative fashion, the degree to which nerves are spared depends on the amount of nerve handling and stretching as well as the use of electrocautery during RP as outlined above.

It is also becoming increasingly appreciated that postoperative factors, such as edema and inflammation around the bladder neck and the cavernous nerves, may in fact have a significant impact upon erectile function. Clinical experience has shown us that some men respond to PDE5 inhibitors within 4 weeks after surgery but by 12 weeks no longer respond, possibly due to ongoing postoperative Wallerian degeneration, in part perhaps, due to perineural inflammation. Data has shown that 25% of men who were functional with or without PDE5 inhibitors within the first 3 months were non-functional by the sixth month (Katz et al: manuscript under review). Recovery of functional erections was defined as a score of either 4 or 5 on question 3 of the IIEF, “Over the course of the past 4 weeks, how often were able to penetrate your partner?” Of note, in this analysis, only 14% of men were PDE5 inhibitor responders within 3 months of surgery.

Several animal models have recently focused on the pathophysiology of erectile dysfunction (ED) after radical prostatectomy (RP) [11, 64-67]. The elucidation of the key mechanisms involved in the development of ED after cavernous injury has paved the way for the potential application of penile rehabilitation protocols, aimed at reversing the complex cavernosal consequences of nerve injury during RP. Histologically, neuroapraxia/neurotomy leads to cavernosal biochemical, morphological, and functional changes at the level of both smooth muscle and endothelial cells. The first consequence of the transient or prolonged neural injury is the absence of erection and cavernosal oxygenation [11]. When penile smooth muscle cells are exposed to a prolonged hypoxic environment, there is a significant over-expression of hypoxia-related profibrotic substances, like transforming growth factor-$\beta$1 (TGF-$\beta$1) and TGF-$\beta$1 dependent endothelin-1 (ET-1), which promote the deposition of collagen I and III within the corpus cavernosum [11, 68, 69]. The increased level of TGF-$\beta$1 demonstrated in cavernosal tissue exposed to low oxygen tension seems to be mediated by the inhibition of prostaglandin-E1 (PGE1).

2. CORPORA SMOOTH MUSCLE ALTERATIONS

In normal conditions, PGE1 indeed inhibits collagen formation by inhibiting TGF-$\beta$1 that induces collagen synthesis. With the inhibition of PGE1, TGF-$\beta$1 is allowed to induce connective tissue synthesis [70]. The trabecular smooth muscle is then replaced with

---

**Figure 1:** Schematic representing the pathophysiology of ED after radical prostatectomy.
collagen, which alters the mechanical properties as well as the integrity of the corpora cavernosa [11, 66]. Several studies have shown a significant increase in collagen content and a decrease in the smooth muscle-collagen ratio in the penile tissue of denervated animals compared to controls [11, 66, 71-75]. However, one of the key processes associated with neural injury and exacerbated by absence of cavernosal oxygenation is represented by apoptosis [66, 72, 75]. Apoptosis, or programmed cell death, is essential for the normal development of multi-cellular organisms as well as for physiological cell turnover. In the penis, denervation has been shown to stimulate apoptosis: it is likely that cellular apoptosis leads to increased deposition of connective tissue that may finally lead to a decrease in penile distensibility, and in turn, veno-occlusive dysfunction [66, 71, 72]. The role of apoptosis in the pathophysiology of post-RP ED has been elucidated in animal models. Klein et al [64] developed the first animal model of cavernous nerve damage aimed at addressing the extent of apoptosis in rat models after specific time intervals following nerve damage. DNA fragmentation and condensed cell nuclei characteristic of apoptotic cells were seen in the glans penis and the corporal bodies of denervated rats. Conversely, this was not seen in the sham-operated controls. Interestingly, the rise in TRPM-2, a gene product that has been postulated to play a role in programmed cell death, had a peak at day 2 after cavernous neurectomy, suggesting an early occurrence of apoptosis after nerve damage. However, the authors were unable to identify the specific cell subtypes undergoing apoptosis.

This issue was later addressed by User et al [66], who randomized post-pubertal rats to bilateral or unilateral cavernous nerve transection or a sham operation. At different time intervals following the procedure, penile wet weight, DNA content and protein content were measured. Wet weight of the denervated penes was significantly decreased after bilateral cavernous neurotomy while unilateral cavernous neurotomy allowed much greater preservation of penile weight. DNA content was also significantly reduced in bilaterally denervated penes. Confirming the findings of Klein et al, bilateral cavernous neurotomy induced significant apoptosis, which peaked on postoperative day 2. In addition, the authors found that the most apoptotic cells were located just beneath the tunica albuginea of the corpus cavernosum, in the area where the subtunical venular plexus is located. Interestingly, these investigators suggested that the apoptotic process involves smooth muscle cells but not endothelial cells. The subsequent hypothesis suggested by the authors was that the bilateral injury to the cavernous nerves may induce significant increased apoptosis of smooth muscle cells, particularly in the sub-tunical area, thus causing an abnormality of the veno-occlusive mechanism of the corpus cavernosum [66].

However, other investigators have found that the apoptotic process involves not only smooth muscle cells but also endothelial cells [76, 77]. Mulhall et have shown in a cavernous nerve crush injury model that neural injury can cause apoptosis in both smooth muscle and endothelium in a more delayed fashion compared to the neurectomy model[65]. Moreover, the exact sequence of the molecular and cellular changes involved in the development of tissue atrophy subsequent to cavernous nerve damage remains to be elucidated. The most plausible theory in explaining why the corporal smooth muscle deteriorates together with an increase in collagen content following RP is that neural injury itself might induce pro-apoptotic (loss of smooth muscle) and pro-fibrotic (increase in collagen) factors within the corpora cavernosa. The ablation by neuropraxia of certain growth factors produced by the cavernosal nerves may be responsible for inducing smooth muscle fibrosis and atrophy observed in corporal tissue [78]. However, the production of cytokines and noxious agents by the damaged nerve axons may also be the causal factor of the increased early smooth muscle apoptosis [71, 74], which in turn, may trigger collagen deposition to replace the lost cells.

3. ARTERIAL INJURY

Vascular injury involves damage to accessory pudendal arteries (APA). These arteries are variable in their incidence in the literature depending on what kind of series is assessed (Table 4): operative series, angiographic series, or cadaveric series [79-87]. APA are supra-diaphragmatic arteries (lying above the levator ani) and are predisposed to injury at the time of RP. Their origin is variable coming from femoral, obturator, vesicle or iliac arteries. These arteries can be visualized on endorectal MRI or CT scan. Cadaveric studies have the highest incidence of APA. Probably the most important study is that of Breza et al[80]. In this study, 10 cadavers underwent extensive pelvic dissection and the arterial anatomy was defined in detail. In this analysis, seven of the 10 cadavers had APA found. In seven cadavers the APA were the major source of arterial inflow into the penis and one cadaver had APA as the sole source of inflow into the corpora cavernosa. Droupy et al have shown in a small study using transrectal and transperineal ultrasound that these arteries are functional [81]. Nine of 12 patients studied had peri-prostatic arteries coursing forward towards the penis. Upon intracavernosal injection, the hemodynamic changes that were seen in the cavernosal arteries were mirrored in the peri-prostatic arteries suggesting that the APA were functional. Rogers et al have shown that APA preservation at the time of open RP translates into an improvement in erectile function recovery and possibly even shortening of the time to recovery of erections [83].
4. CAVERNOUS OXYGENATION

The concept that neuropraxia results in smooth muscle alterations has already been discussed. It is possible that this is amplified by the absence of erections. One of the purported mechanisms by which this happens is the absence of cavernosal oxygenation. This is the concept that the penis is a large vein in the flaccid state and a large artery in the erect state (Figure 2). In the flaccid state, the $pO_2$ is approximately 35-40 mm Hg. It has been postulated that this results in up-regulation of profibrotic cytokines including TGF-beta. TGF-beta up-regulates collagen production, which may eventually lead to smooth muscle fibrosis and venous leak. During erection, the penis is oxygenated with $pO_2$ rising to 75-100 mm of mercury. In vitro evidence demonstrates that oxygenation up-regulates production of endogenous prostanoids as well cAMP [88].

Moreland et al have shown in a series of in vitro experiments that exposure of cultured corporal cavernosal smooth muscle cells to a low oxygen environment suppresses PGE1 and cAMP production. Upon restoring the environment to normoxia, levels of both PGE1 and cAMP are normalized. In a further series of experiments the same authors showed that in the in vitro setting, prostanoids inhibit TGF-beta activity and thus reduce collagen production[89]. Therefore, in a healthy male there is a balance between the flaccid and erect states and as long as men obtain erections with some degree of regularity, erectile tissue health is preserved. However, after RP in a state of unantagonized flaccidity, the normal balance of factors is shifted in favor of fibrogenic cytokine production leading to structural changes and venous leak development. It is important to appreciate that as biologically plausible this mechanism is, the data are purely in vitro in nature.

Figure 2: Schematic representing the concept of cavernosal oxygenation.
In a recent study Mueller et al demonstrated the potential benefit of hyperbaric oxygen therapy (HBOT) in the cavernous nerve injury model [90]. Animals with bilateral nerve crush injury were divided into treatment with room air within a hyperbaric chamber versus hyperbaric O2 (3atm) for 90 minutes. Animals were treated for a period of 10 days consecutively and at 28 days after bilateral nerve crush, animals underwent functional assessment. Using intracavernosal pressure/mean arterial pressure (ICP/MAP) ratios the animals treated with room air had an ICP/MAP ratio of 31%. This compared with ICP/MAP ratio of 55% in animals exposed to 10 days of HBOT (p <0.005).

These data support the concept that cavernosal oxygenation is important to recovery of erectile function. In data, unpublished other than in abstract form, emanating from Pfizer Central labs in the UK, a canine model was used to explore the impact of hypoxic conditions on erectile function (Wayman et al, unpublished data). In the anesthetized, ventilated dog with the cavernous nerve exposed, cavernous nerve stimulation resulted in progressively poorer ICP/MAP ratios as the FiO2 was dropped from 21% to 18%. In a second series of experiments, the pre-treatment of the animals with sildenafil citrate resulted in preservation of erectile response following cavernous nerve stimulation even under profoundly hypoxic conditions. This suggests that sildenafil at least and perhaps PDE5 inhibitors in general are capable of preserving erectile tissue relaxation profiles even under hypoxic conditions.

One of the issues that remains unresolved is what level of erectile rigidity is optimal for cavernosal oxygenation. Based on data from Kim et al and Tal et al [91, 92] it appears that minimal rigidity is required to achieve complete oxygenation of the corpora cavernosa. In 1983, Lue et al published their pioneering study describing penile hemodynamics and oxygenation during erection in a monkey model (3 monkeys) [93]. They induced erections by cavernous nerve electro-stimulation and measured arterial blood flow, corporal pressure and pO2, in the proximal and distal corpora, before and 1, 5, 20 and 30 minutes after the monkeys achieved a sustained erection. They showed that during erection, corporal blood had a higher pO2 than in the flaccid state and it remained oxygenated for the whole erection duration, even after 30 minutes of full erection. These findings were later corroborated in human subjects.

During a fully rigid erection, cavernosal pO2 is close to arterial partial oxygen pressure. Knispel et al reported that after penile injection of an erectogenic agent (papaverine/phentolamine), cavernosal pO2 rose continuously and gradually, starting after 30-60 seconds and continued up to 8.5 minutes after injecting[94]. This is in contradistinction to the steep increase in cavernosal pO2, immediately after injections, followed by a plateau, reported by Kim et al [91]. While Knispel et al did not measure ICP simultaneously with cavernosal pO2, Kim et al showed that an increase in oxygenation occurs before ICP elevation and development of rigidity. Knispel et al assessed duplex Doppler ultrasound peak arterial flow with maximal cavernosal pO2 and found good correlation in 71% of the cases. They hypothesized that in the remaining cases, lack of correlation was due to isolated cavernous perfusion defects, a hypothesis that has never been confirmed or refuted.

While oxygenation is maximal just prior to the development of a full erection, where maximum arterial inflow exists at low corporal pressure, it remains of interest if partial erections are sufficient for adequate oxygenation. In clinical practice, the association of erection rigidity and cavernosal oxygenation state is important in men who wish to regain or preserve erectile function. Commonly, an inability to fully oxygenate their corporal tissue is experienced in the early post-operative period after radical pelvic surgery when many men struggle to achieve spontaneous or medication-induced fully rigid erections. Tal et al studied 13 patients and analyzed 21 corporal blood samples aspirated at the time of cavernosometry [92]. Blood specimens were collected at an ICP range of 6-90mmHg. Mean±SD pO2 was 39±6mmHg at ICP<10mmHg, 87±2 at ICP 11-20mmHg, 89±3 at ICP 21-40mmHg, 93±5 at ICP 41-60mmHg and 103±11 at ICP>60 mmHg (Figure 3), suggesting that low cavernosal arterial inflow and pressure development permits complete oxygenation of the corpora.

![Figure 3: Correlation between intracavernosal pressure and intracavernosal pO2](image-url)
In the urogenital tract, the effect of hypoxia on smooth cell proliferation was studied in an obstructed urinary bladder model. In the initial stages, the compensatory response to bladder outflow obstruction is smooth muscle hyperplasia and hypertrophy. With increased bladder wall thickness and mural pressure, bladder wall perfusion decreases with resultant hypoxia and eventual decompensation. Galvin et al showed in a cell culture study that hypoxia did not induce apoptosis, however it significantly reduced smooth muscle cells proliferation [95]. Unfortunately, for clinical use, frequent cavernosal blood analyses or Doppler ultrasound flow measurements are not practical in monitoring such patients and a more applicable tool is needed to assure adequate cavernosal oxygenation. Thus, cavernosal blood oxygenation occurs at low ICPs, during the initial stages of erection. Additional increases in ICP and consequently, in rigidity, leads only to minimal further increases in cavernosal blood partial oxygen pressure.

5. VENOUS LEAK

Positioned between the tunica albuginea externally and the corporal smooth muscle internally are a series of sub-tunical venules. As the smooth muscle expands in a three-dimensional fashion under nitric oxide control, the sub-tunical venules are compressed against the tunica. This is the veno-occlusive mechanism. In conditions where the muscle fails to expand adequately some or all of the sub-tunical venules are left in a non-compressed state and this results in the concept we know as venous leak (synonyms: corporovenocclusive dysfunction, venogenic ED). The two things that lead to failure of the corporal smooth muscle to expand are adrenaline, the world’s most potent anti-erection chemical, and structural changes such as fibrosis.

Nehra et al. have shown in human corporeal tissue biopsy taken at the time of cavernosometry, once smooth muscle content in the penis drops below 40% venous leak occurs[96] (Figure 4). Indeed, the further this figure dropped below 40%, the greater is the magnitude of leak. Iacono et al have shown that as early as two months after radical prostatectomy in an untreated man there is a marked increase in collagen deposition and a marked decrease in elastic fiber content in erectile tissue[10]. This is in keeping with the animal data outlined above that suggest even in the earliest stages after cavernous nerve injury, structural changes occur.

Mulhall et al have shown in a series of 16 patients who had preoperative and postoperative hemodynamic assessment that more than half of the men had venous leak after surgery[97]. In a more recent analysis by Mulhall et al[98], in men who had partner-corroborated excellent erectile function prior to surgery, who underwent duplex Doppler penile ultrasound after surgery, there was an increase in the incidence of venous leak (based on elevated end diastolic velocities) as time progressed after surgery (Figure 5). The incidence of venous leak less than four months after surgery was approximately 10% and rose to 35% between 8-12 months after surgery and 50% after 12 months. The importance of this information is that in the same series, men with normal erectile hemodynamics were more likely to have recovery of natural erectile function. However, only 8% of men who had venous leak had recovery of natural functional erections after surgery. We also know from other data that men with venous leak are far less likely to respond to PDE5 inhibitors than men with arterial insufficiency [99].

It is the recommendation of the ICSM that in an effort to facilitate the discussion on erectile function rehabilitation, clinicians should discuss the pathophysiology of erectile dysfunction after radical prostatectomy. Factors that clinicians should discuss include including the concepts of accessory pudendal artery injury, cavernosal oxygenation, erectile tissue structural alterations and venous leak. While the committee does not expect all clinicians to be experts in the pathophysiology of post-RP ED, it is suggested that all develop a simple script for patients to communicate not just what the rehabilitation strategy involves but also the rationale behind it, which is based on the pathophysiology of post-RP ED.

*Figure 4: Correlation between cavernosal smooth muscle content and flow-to-maintain values (venous leak) during cavernosometry.*
RECOMMENDATION 6

Grade C

To facilitate the discussion on erectile function rehabilitation, clinicians should discuss the essential elements of the pathophysiology of erectile dysfunction after radical prostatectomy.

IV. BASIC SCIENCE EVIDENCE REGARDING REHABILITATION

1. NEUROMODULATORY AGENTS

As is clearly evident by the limited approaches available for optimization of erectile function post-radical prostatectomy[12], significant therapeutic and knowledge gaps remain between the primary pathophysiologic mechanism responsible (nerve injury) and treatment. Contemporary options available to the clinician are ‘reactive’ responses to the damage initiated at surgery and subsequent downstream changes that result from compromise of cavernous nerve (CN) signaling due to intraoperative injury (for nerve-sparing procedures) or non-reversible nerve damage/nerve excision. Despite a rapid growth in basic science understanding of tissue and cell-level response to injury, the treatment goals of neuromodulation of the cavernous nerve response to injury at surgery (with potential of pre and post-operative optimization) to promote nerve regeneration and neuroprotection remains elusive. Neither PDE-5 inhibitors nor vasoactive injection therapy has been definitively shown to directly influence CN pathobiology. It is likely that future penile rehabilitation treatments will require combination strategies to counter primary and secondary injury, including nerve-centered foci enhancing axonal regrowth, inhibiting apoptosis, and promotion of synaptic plasticity via neurotrophic factors, stem cell therapies, or neural and smooth muscle protectants [100]. For non-nerve sparing procedures, neuromodulatory interventions are more limited, but may include seeded nerve “bridges” or “scaffolds” to counter the significant physical gaps following cavernous nerve excision at radical prostatectomy; penile rehabilitation in these groups will remain a challenge, and likely focus on end-organ preservation (endothelium and smooth muscle) while the nerve signaling continuum is re-established.

At the core, the concept of neuromodulatory therapy post-RP encompasses the basic science of neurotrophic growth factors, neuroprotection, nerve regeneration and establishment of signaling continuity, neuronal stem cells, and the prevention of neuronal cell death as it applies to the nerve supply of the penis [100]. For example, approaches conceivably range from the exogenous supply or endogenous optimization of nerve growth factors that improve axonal regeneration or accelerate target re-innervation, to introduction of progenitor cells allowing for replacement of non-viable tissue. The translational potential of neuromodulatory therapy is based upon the fact that although the peripheral nervous system demonstrates an intrinsic ability to recover after injury, this endogenous response is somewhat limited and does not usually allow for a full recovery of function as axonal degeneration and loss of neurogenic function occur [101-103].

Various types of CN injury have been studied in an attempt to model RP-associated CN injury using primarily rodent models, including crush, freezing, transection, and excision of the CN either unilaterally or bilaterally depending on the underlying aims each particular experiment[104]. Detailed anatomic studies in animal models have demonstrated that CN crush does not disrupt the nerve sheath and may provide a nerve conduit or ‘guide’ for regenerating axons[105]; although it is a less severe injury model (attempting to approximate nerve-sparing procedures), cavernous nerve electro-stimulation proximal to the injury consistently results in decreased intracavernous pressure readings compared to intact animals and allows for testing of hypotheses for new treatment approaches via measurement of physiologic function [13, 65, 106, 107]. More severe types of injury include transection (where the outer neurolemma sheath is disrupted) and excision, the latter excluding the possibility of erectile tissue responsiveness [9, 66]. Burnett and colleagues demonstrated that nitric oxide (NO) is a neuronal transmitter-like messenger and physiologic mediator of erection via CN neuronal fibers innervating the corpora cavernosa [108]. One week after performing...
bilateral CN transection, NOS immunoreactivity was absent in penile neurons, compared to sham. Downstream changes secondary to nerve injury include smooth muscle and endothelial apoptosis, reduced nitric oxide synthase (NOS) nerve density, upregulation of fibrogenic cytokines, pathological signaling responses, and corporal veno-occlusive dysfunction [72, 101, 104].

a) Neurotrophic Factors

Evidence suggests that a return to functional erection status following injury to the CNs is dependent in part, upon axonal regeneration in the remaining neural tissues and upon successful functional re-innervation of the end-organ (intact synapses and neuronal NO reactivation) [109]. Endogenous neurotrophins (NTs) play key roles in the survival, development, and differentiation of neurons in the peripheral nervous system. There is great interest in the potential therapeutic stimulation of endogenous NT response or exogenous application of this family of molecules which include the classical NTs: brain-derived nerve growth factor (BDNF), nerve growth factor (NGF), and NTs 3-5, (binding to two distinct classes of glycosylated receptor: the p75 NT receptor and tyrosine kinase receptors) as well as atypical agents such as erythropoietin (EPO), morphogenetic factor Sonic hedgehog (SHH) protein, glial cell line derived NTs such as neuritun, and bone-morphogenetic proteins (BMP) [100, 101, 109].

The Lue group at the University of California San Francisco, has demonstrated BDNF enhanced recovery of erectile function and regenerated NOS-containing nerve fibers using established in vivo rat models of neurogenic impotence, as well as subsequently showing that CN axotomy upregulates in vivo expression of penile BDNF and leads to endogenous activation of the JAK/STAT pathway in the MPG [110-112]. BDNF has also been shown to exert its effects on several classes of neurons, acting in an autocrine or paracrine fashion early after nerve injury and distally to the site of trauma (end-organ response) [100]. Vascular endothelial growth factor (VEGF) treatment in a rat model of traumatic arteriogenic erectile dysfunction is also associated with intrapenile nerve fiber growth, demonstrating a secondary neuromodulatory role in addition its better known angiogenic effects [112, 113]. Application of IGF-1 and IGF binding protein-3 complex also leads to the regeneration of penile nerve fibers and enhanced erectile function recovery in a rat model of cavernous nerve ablation [114]. Post-bilateral crush injury recovery of erectile function in the rat model has also shown improvement with treatment using growth-differentiation factor-5 (a BMP), whose effector pathways include intermediary serine/threonine kinase receptors [115] and neuritun (a target-derived survival and/or neuritogenic factor for penile erection-inducing postganglionic neurons) [116, 117]; a key point is that the external location of the penis allows for intracavernous introduction and retrograde transport of potential therapeutic agents to the site of injury [116]. However, there have been no translational trials to date for the classical neurotrophins, as potential limitations include whether the administration of neurotrophic compounds to the site of injury or penis itself (which may be feasibly performed before, at, or after surgery) could exert adverse mitogenic effects upon remaining loco-regional cancer cells, and difficulties for in vivo human dosing as positive treatment effects tend to occur within defined neurotrophin concentrations.

The Burnett group at Johns Hopkins has recently explored the use the atypical neurotrophic cytokine/hormone erythropoietin (EPO) as a neutrotrophic factor in the cavernous nerve injury model [118]. Initially, male rats underwent unilateral CN transection and excision of a 5 mm segment of the contralateral CN, with daily rhEPO effectively recovered erections after CN injury compared with saline treatment. Maximal intracavernous pressure area under the curve normalized to mean arterial pressure was significantly greater in EPO treated versus saline treated animals (p <0.05) [119]. EPO receptor expression was localized to neuronal cell bodies of the major pelvic ganglion, penile nerves and endothelial cells in the penis, and electron microscopy revealed significant improvement in axonal regeneration [119].

Podlasek and colleagues have identified substantial potential for sonic hedgehog protein (SHH) for penile delivery in prostatectomy patients at the time of surgery in order to prevent apoptosis induction and long-term ED development [109]. Although SHH is a secreted protein regulating cellular proliferation, apoptosis, differentiation, and cell survival, and is expressed at sites of mesenchymal–epithelial interaction, recent studies have identified the presence of SHH in Schwann cells, suggesting a role for the SHH pathway in maintaining CN integrity [120]. Previously, SHH inhibition in the pelvic ganglia resulted in increased apoptosis in the penis, in addition to SHH’s role in smooth muscle preservation [121]. Cumulatively, these results suggest that SHH may be a Schwann cell factor and that SHH is an important neuromodulatory target for neural regeneration after CN injury.

b) Immunophilin Ligands

Immunophilins are a large group of cellular proteins that were initially identified as targets for drugs like FK506 (FK), cyclosporine, and rapamycin (Rapa) and have undergone extensive preclinical CN injury studies demonstrating CN neuroprotective effects [103, 107, 122-125]. The term immunophilin refers
to two families of soluble, intracellular proteins that act as receptors for the aforementioned immunosuppressant agents. The group identified as FK binding proteins (FKBPs) binds to tacrolimus and rapamycin while cyclophilin binds with cyclosporine A [126]. It is known that the tacrolimus/FKBP-12 complex acts as an immunosuppressant by inhibiting activation of calcineurin, an enzyme required for cytokine transcription and ultimately activation of antigen-reactive T cells. The discovery of increased concentrations of immunophilins in the central nervous system and specifically FKBP-12 in the peripheral nerves has lead to further investigation of a potential therapeutic role for immunophilins [127]. Tacrolimus, a macroline immunosuppressant which is FDA-approved for the prevention of allograft rejection in liver and kidney transplantation. Tacrolimus is an immunosuppressant with proven anti-inflammatory, neuroprotective, and neurotrophic effects. It is currently under development in the United States for asthma, acute stroke, psoriasis, and rheumatoid arthritis. The neuroprotective properties of tacrolimus have been demonstrated using various animal models of focal cerebral ischemia that mimic human ischemic brain damage caused by stroke. Sharkey and Butcher compared tacrolimus to saline in rats that were subjected to middle cerebral artery occlusion [128]. Tacrolimus was found to be neuroprotective at doses of 0.1–1.0 mg/kg body weight; cortical damage was reduced in tacrolimus-treated animals by 58%–65%. This study also examined the timing of drug administration to determine if there was an optimal therapeutic window. Animals that received tacrolimus 60 minutes post-occlusion had significantly less reduction in cortical damage than those who received the drug after 1 minute (p<0.05). Tacrolimus was the only immunophilin ligand that was found to be effective in these experiments.

The process by which tacrolimus exerts its neuroprotective effects is unknown. It is thought that the inhibition of calcineurin may play an important role in the neuroprotective process either by regulating calcium channel activity or by reducing free radicals through the inhibition of the calcineurin-mediated dephosphorylation of an enzyme required for nitric oxide production [128]. Gold et al. first reported on the axonal regenerative properties of tacrolimus following a study of sciatic nerve crush in rats [129]. The animals that received tacrolimus had function return in their hind feet more quickly following injury. In additional studies by the same investigators, animals received two 30-second crushes to the sciatic nerve and were administered daily subcutaneous injections of either tacrolimus or saline. Electron microscopy was used to evaluate axon regeneration after 18 days of treatment. Rats that received tacrolimus demonstrated larger, more myelinated axons distal to the crush site than those treated with saline [129, 130].

Previous studies utilized tacrolimus doses that were considered therapeutic for immunosuppressive properties. An efficacy study was completed using low-dose tacrolimus to potentially reduce associated side effects of the drug [131]. Animals were randomized to receive either no treatment or a 0.5 mg/kg dose for 2 or 3 months after a sciatic nerve transaction and suture. This dose was chosen by the investigator as it had been determined to be sub-therapeutic in previous allograft transplantation studies. Both groups of tacrolimus-treated animals had a faster functional recovery and demonstrated no drug-related side effects. At the 3-month postsurgical assessment, both the tacrolimus-treated groups had significantly greater muscle mass ratios than the untreated group (p<0.05). Both treatment groups had greater fiber density and more neural tissue at the 2 and 3 month assessments despite discontinuing study drug at 2 months in half the animals. There was a significant increase in muscle weight in the treated animals between the 2 and 3 month assessments compared to the untreated animals (36% vs. 7%, p<0.05). This study demonstrated that an immunosuppressive dose of tacrolimus was not required to obtain significant neuroregenerative effects. Several possible pathways have been postulated to explain the regenerative effect of tacrolimus, including increasing growth proteins and stimulating nerve growth factor [131].

Animal studies also provide support for a potential role for tacrolimus as neuroprotective for penile innervation. Sezen, Burnett, and colleagues performed partial penile nerve crush injuries using multiple 15- or 60-second forceps applications to rats in an attempt to mimic the nerve injury associated with nerve-sparing RP [122, 123]. These rats were treated simultaneously with daily injections of tacrolimus (1 mg/kg) or saline solution. Erectile response was measured by changes in the intracavernosal pressure induced by electrical stimulation. Rats that received tacrolimus had a 90% intracavernous pressure response following stimulation of the cavernous nerve compared to the sham operated side. Saline-treated animals response was 50% of the sham-operated side. Tacrolimus-treated animals had a significantly greater erectile response on the uncrushed side, 54% compared to controls, 24% (p<0.05).

Surviving unmyelinated axons in the cavernous nerve distal to the crush site were quantified using electron microscopy for each rat. Saline-treated rats had 30%–40% axonal survival compared to 65%–80% in drug-treated animals. In those that received saline, the degenerated axons manifested swelling of the axon profile and clearing of the axoplasm. These results were found at 1, 3, and 7 days after injury [123].
Burnett et al. demonstrated long-term recovery of erectile function with tacrolimus treatment. A limited pelvic dissection and focal transection of the right cavernous nerve was performed on a rat model. Postoperatively the animals received either tacrolimus or saline solution subcutaneously for a period of 5 days. After 4 weeks, rats treated with tacrolimus showed improved penile erection following neurostimulation of both the non-transected left and transected right cavernous nerves, as measured by intracavernosal pressure (ICP). The percent recovery of ICP in the right cavernous nerve was found to be 77% in the animals treated with study drug versus 43% in the saline-treated animals (p=0.019) [122].

Although the neuroprotective and neuroregenerative mechanism of action of the immunophilin ligands has not been fully elucidated, it may be through calcineurin inhibition that the FKBP12-tacrolimus complex exerts its effect. In a recent study in rats, tacrolimus was associated with better erectile response after cavernous nerve injury than a non-immunosuppressant immunophilin ligand (GP1-1460), as measured by stimulated intracavernous pressure [132].

The immunophilin ligand tacrolimus has been shown to be both neuroprotective and neurotrophic in numerous animal studies using a variety of models. This effect has significantly improved the erectile function in animals receiving injuries similar to those from nerve-sparing retropubic RP. Most recently, Mulhall et al. demonstrated in the rat model of cavernous nerve crush injury that short-term tacrolimus results in significant preservation of cavernous nerve architecture, confirming the findings of Burnett et al. in a slightly different model with a different dosing strategy [103].

The major concern about agents like tacrolimus is their immunosuppressant properties (although no signs of such were seen at the doses used in the aforementioned clinical trial). Thus, great interest in the development of non-immunosuppressant, immunophilin ligands was generated, and Guildford Pharmaceuticals (now defunct) developed a series of compounds. GPI-1046 was shown in vitro to stimulate neurite growth in co-culture models [133]. A recent study examined the effect of FK506 and GPI-1046 on rats who had undergone cavernous nerve injury [132]. This study found that animals treated with either FK506 or GPI-1046 had significantly greater recovery of erectile function compared to animals treated with saline. Electrically stimulated maximal intra-cavernous pressure and rate of tumescence were better in the treated animals compared to controls. Based on these preliminary animal data, a multi-center, randomized, placebo-controlled trial was conducted assessing two doses of GPI-1485 against placebo in patients treated with RP. Six-month data presented at the 2007 annual meeting of the AUA failed to demonstrate any significant differences in IIEF scores between placebo and treatment groups. As the company has since dissolved, it is unclear whether any later data will ever be seen. Most recently, laboratory data has been presented on FK1706 a non-immunosuppressant derivative of FK506 [134].

c) Erythropoetin

Erythropoietin stimulates erythropoiesis under hypoxic conditions. Recently, it has been shown that erythropoietin protein and its receptor are expressed within the central and peripheral nervous systems [135]. Administration of erythropoietin in animal models of neurodegenerative diseases and toxic insults of the brain, spinal cord, and sciatic nerve results in reduced neuronal damage and improved nerve recovery [136]. A recent clinical trial confirmed the therapeutic efficacy and safety of recombinant human erythropoietin administration to recover function in patients suffering from acute ischemic stroke [137].

The recently established role of erythropoietin as a neurotrophic agent has stimulated interest in its use in men after RP. In a rat model of cavernous nerve injury, Burnett and colleagues at Johns Hopkins have shown that erythropoietin promotes the recovery of erectile function [138]. They also confirmed localization of the erythropoietin receptor to the major pelvic ganglia and cavernous nerves [139].

d) PDE5 Inhibitors

Recent evidence has shown a potential neuroprotective effect of chronic PDE5i treatment. In a cavernous nerve injury model, chronic sildenafil treatment (20 mg/kg) was associated with an improvement in neural organization and greater density of myelin sheaths compared with the control group [75]. These descriptive findings of the improved cavernous nerve preservation with daily sildenafil administration were consistent with the functional data reporting increased maximal intracavernosal pressure (ICP)/mean arterial pressure (MAP) ratio during electrical cavernous nerve stimulation [75]. These results are also supported by emerging evidence of enhanced angiogenesis, axonal remodelling and synaptogenesis as well as neurological recovery in a rat model of stroke treated with sildenafil or tadalafil [140, 141].

e) Stem Cells

The neuromodulatory action of stem (progenitor) cells as part of penile rehabilitation may eventually involve their application and subsequent differentiation into elements that function as cellular substrates for axonal growth, release neurotrophic growth factors and cytokines, inhibit demyelination or replace non-viable or non-functional neuronal elements[100]. Embryonic and autologous adult adipose-derived
stem cells have shown improved preservation of cavernous nerve fibers and improved erectile function in rats exposed to CN crush injury [142-144]. Early results for these, and other erectile dysfunction stem cell therapies are promising; however stem cell neuromodulation is in its early phase and clinical application in the post-RP setting is likely years away [145, 146].

2. ERECTILE TISSUE PRESERVATION
   a) PDE5 inhibitors

Recently, emerging experimental data have demonstrated a benefit to penile rehabilitation after cavernous nerve injury in animal models. Recent studies focusing on the molecular mechanisms of apoptosis and fibrosis have elucidated the potential mechanisms involved in the beneficial effect of chronic use of pro-erectile drugs such as PDE5i in this animal model. Emerging scientific evidence suggests that persistently elevated levels of nitric oxide (NO) and cGMP may have an anti-fibrotic effect on a variety of tissues, including tunica albuginea and corporal tissue [147, 148]. Since PDE5i work by inhibiting the enzyme that degrades cGMP, this may be a key means of anti-fibrotic action of PDE5i. In this context, several studies have demonstrated a reduced amount of collagen deposition and fibrosis in penile tissues of animals chronically treated with PDE5i [71-75, 149].

Ferrini et al [71] found that chronic vardenafil was effective in preventing both the fibrosis and loss of smooth muscle seen following bilateral cavernous nerve resection. Compared with the sham group, rats exposed to nerve injury demonstrated a three-fold increase in corporal smooth muscle apoptosis, a 60% reduction in the smooth muscle:collagen ratio, a two-fold increase in inducible NO synthase (iNOS) expression and development of venocclusive dysfunction (CVOD). When vardenafil was given daily for 45 days to the animals that underwent bilateral nerve resection, the corporal smooth muscle:collagen ratio was normalized and the subsequent CVOD was prevented. The authors suggested that the effect of vardenafil in preventing corporal fibrosis might be mediated by an increased iNOS expression and activity. Prolonged endogenous induction of iNOS seems to produce sufficient NO to reduce collagen synthesis, inhibit TGF-β1 expression and myofibroblast differentiation, and activate metalloproteinases that break down collagen [150].

Similar results have been reported in other animal models of post-RP ED using continuous long-term administration of sildenafil as well as tadalafil [14-16,24-26]. Mulhall et al[75] demonstrated that chronic administration of sildenafil given subcutaneously daily for three different durations (3, 10, 28 days) resulted in preservation of the smooth muscle-collagen ratio. In this series of experiments, the investigators also showed increased expression of the endothelial factor CD31 and increased phosphorylation of Akt and eNOS, which may account for the endothelial protection mediated by these agents. Similarly, Vignozzi et al[149] found that chronic tadalafil administration (120 days) to rats reversed the decline in the cavernosal smooth muscle:collagen ratio that occurred after bilateral cavernous neurotomy.

Interestingly, the efficacy of Sildenafil after neural injury seems to be directly related to the timing of its administration. Indeed, the effect of this drug on all post-neural injury alterations (such as penile hypoxia and over-expression of the pro-fibrotic ET-1 type B receptor) was more evident the earlier it was administered [151]. Therefore, at least at the animal level, the effect of sildenafil in reversing the alterations induced by penile denervation and hypoxia was higher in the early stage of the disease. Furthermore, the effect of chronic sildenafil in improving erectile function after cavernous nerve injury has been shown to be time and dose-dependent[75]. The highest rate of erectile function recovery indeed occurred with higher doses and longer time of sildenafil administration. Preliminary work presented by the Mulhall group at Memorial Sloan Kettering Cancer Center, but yet published, suggested that administration of sildenafil 3 days prior to cavernous nerve crush injury resulted in even further improvements in erectile function and tissue preservation.

However, chronic treatment with PDE5i might exert at least some of its beneficial effects through much more complex mechanisms than a simple sustained increase in intra-cellular cGMP. We have previously briefly reviewed the potential for neuromodulatory effects of PDE5i. The effect of chronic administration of PDE5i might also be associated with structural and functional changes, which may involve not only smooth muscle cells but also endothelial function. The first proof of such association was given by Behr Russel et al [152] who showed that a daily, eight-week treatment with sildenafil (60 mg/kg) administered subcutaneously to neurally intact rats was associated with enhanced endothelium-dependent relaxations of cavernosal strips to acetylcholine after chronic treatment with sildenafil. Conversely, relaxations in response to sodium nitroprusside were unchanged after sildenafil treatment. Moreover, the erectile responses to acute sildenafil were greater in chronically sildenafil treated rats. The findings suggested that the endothelium-dependent response is promoted by long-term PDE5i treatment and that the therapy does not confer an adverse effect on cavernosal tissue responsiveness involved in physiological erection. The investigators concluded that long-term sildenafil treatment may have long-lasting, physiologically significant erectile tissue benefits. The effect of chronic treatment with PDE5i seems to be mediated by increased Akt-dependent endothelial NOS (eNOS) activation[153]. This is key,
since the predominant proportion of data suggest that endothelial eNOS plays a major role as homeostatic regulator of penile vascular function and health[154]. Similar results reporting improved eNOS activity and endothelial relaxations after chronic treatment with sildenafil have also been obtained in animal models of diabetes as well as of age-associated ED[152, 155, 156].

The effect of chronic PDE5i on endothelial function might not be only mediated through increased eNOS activation. Indeed, recent studies have suggested a restoration of endothelial progenitor cells (EPCs) to normal levels in patients with ED treated chronically with PDE5-I (either sildenafil, tadalafl or vardenafl) [157-160]. The role of NO in EPC mobilization as well as activation has been recently demonstrated. Moreover, it has been demonstrated that a lack of eNOS induces defective haematopoietic recovery and PC mobilization[161]. The effect of chronic PDE5i in increasing the number of circulating EPCs might be the effect of the inhibition of PDE5 in the bone marrow. Of note, reverse transcriptase-polymerase chain reaction analysis showed that human bone marrow expresses PDE5 messenger RNA [162].

Finally, chronic administration of PDE5i has also been shown to reduce the cavernosal apoptotic process after cavernous nerve injury[75, 76]. The effect of PDE5i in decreasing the number of penile apoptotic cells in cavernous injured models appears to be mediated by the phosphorylation of the survival associated kinases Akt and extracellular signal-regulated kinase (ERK) 1/2 [76]. The effect of chronic PDE5i in reducing apoptosis has also been studied in clinical scenarios other than post-RP models. Salloum et al. demonstrated that both sildenafil and vardenafil reduced the area of cardiac necrosis in a rabbit model of cardiac ischaemia-reperfusion[163, 164]. Das et al. using mouse cardiac myocyte cells exposed to hypoxia and reoxygenation showed that sildenafil-treated cells demonstrated less necrosis and apoptosis than control cells[165, 166]. Interestingly, sildenafil-treated myocytes demonstrated an early increase in the ratio of the antiapoptotic protein Bcl-2 compared with the pro-apoptotic protein Bax, which may have been responsible for the anti-apoptotic effect of sildenafil. The increase of Bcl-2/Bax ratio, as well as the anti-apoptotic effects of sildenafil, were inhibited by treatment with the NOS inhibitor l-nitro-amo-methyl-ester, suggesting the role of NO signalling in the protective effect of the drug against apoptosis[165].

V. CLINICAL EVIDENCE REGARDING REHABILITATION

Regardless of the technique, the removal of the prostate appears to result in an obligate period of neuropraxia with secondary end-organ damage and resulting ED of varying degrees [10]. In a longitudinal penile biopsy study after RP, profound histologic changes were observed in human erectile tissue microstructure in men not enrolled in any penile rehabilitation program [10]. These changes were observed as early as two months after surgery. The erectile tissue became progressively disorganized with a decrease in the number of elastic and smooth muscle fibers, and an increased accumulation of collagen. This was accompanied by a complete lack of response to three challenges of 100 mgs of sildenafil at 2 months. Disappointment with surgical results has led to attempts at improving outcomes. While the aforementioned animal experiments have demonstrated clear benefit to pharmacologic manipulation, few good human rehabilitation trials exist. Rehabilitation strategies have grown over the past decade and include (i) neurmodulatory agents (ii) intracavernosal injections (iii) PDE5i (iv) intraurethral alprostadil and (v) vacuum therapy.

Most studies assessing penile rehabilitation are small, single center, non-randomized and suffer major methodological flaws [4]. Differing outcome measures and non-uniformity of data presentation and inclusion criteria, have made comparison between trials difficult. Despite a lack of robust human data, in a survey conducted by Teloken et al, among 301 physicians from 41 countries, almost 84 % performed some form of sexual or penile rehabilitation, including post operative PDE5i (95%), ICI (75%), vacuum erection device (30%), and intraurethral alprostadil (10)(Teloken, 2009 #4336). Slightly less than half of the respondents (48%) started penile rehabilitation at the time of catheter removal and 37% initiate their rehabilitative strategy within the first 4 months. Though rehabilitation is widely practiced, there exists no consensus on what represents the optimal program.

1. NEURMODULATORY AGENTS

Despite robust data on a variety of neurmodulatory agents in animal models, no such data exists in the RP population. Although a recent clinical trial (phase II, multicenter, randomized, double-blind, placebo-controlled, three-arm, 12-month study) conducted in men undergoing nerve-sparing RP and treated with GPI-1485 did not reveal significant agent efficacy, it is possible that drug formulation or scheduling was suboptimal and further investigation in this area remains warranted (Burnett, A.L. personal communication). Based on the aforementioned animal data, a multi-center, randomized, placebo-controlled trial has recently been conducted assessing the impact of tacrolimus in men undergoing RP. Patients were randomized to placebo versus tacrolimus (2–3 mg) beginning 7 days before RP and continuing for 6 months after surgery. Data should be available in the first half of 2010.
The Johns Hopkins group has recently presented data on the potential clinical use of erythropoietin as a neuromodulatory agent to preserve erectile function in men undergoing RP [167]. In this clinical study, those patients opting for erythropoietin treatment (in a non-randomized fashion) received a single dose (40,000 IU administered subcutaneously) of recombinant human erythropoietin in the form of Epoetin-alpha on the day before surgery. This dosing was consistent with dosing used in the clinical trial for acute stroke. The final analysis consisted of 15 erythropoietin-treated patients (treatment group) and 21 patients who did not receive erythropoietin treatment (control group). The mean preoperative IIEF-5 score for both the treatment and control groups was 24. At 12 months, 87% of the erythropoietin-treated and 68% of the untreated patients reported performing sexual activity, although these rates were not significantly different (p=0.213). However, a significantly greater proportion of erythropoietin-treated patients reported erections that could be maintained to complete sexual intercourse (47%) compared with that of untreated patients (16%; p<0.05). A larger randomized, placebo controlled trial is planned.

It is likely that future patients undergoing radical pelvic surgery will receive multimodal therapy to promote erectile function recovery including agents that are neuromodulatory (Table 5). Future neuromodulatory directions may include (i) oral systemic agents that have proven efficacy in humans, (ii) the perineural application of neuromodulatory molecules to the cavernous nerves at the time of radical prostatectomy, (iii) the use of implantable neurostimulators proximal to the site cavernous dissection in an effort to promote neuroregeneration[168], and (iv) novel means of cavernous nerve visualization. A number of laboratories are exploring proprietary agents that can be applied to the cavernous nerve intraoperatively, but no data has yet been presented or published. Burnett et al have reported on a feasibility study assessing an implantable electrode around the cavernous nerve[168]. Prior work has demonstrated that cavernous nerve stimulation can lead to an intraoperative erection in animal and human models. Electrical stimulation of the cavernous nerve has resulted in increased arterial flow, relaxation of cavernous muscles, and venous outflow restriction in monkeys [169], dogs [169] and rats [170]. Intraoperative stimulation of the cavernous nerves to induce penile erection in humans has previously been performed [171].

2. INTRACavernosal INjections

The first prospective randomized post-RP rehabilitation study involved penile injection therapy. In the late 90’s most urologists believed that long term ED after NSRRP was due to poor surgical technique and men were generally counseled to wait one year before addressing their post operative ED. Montorsi demonstrated a benefit to using intracavernosal injections using alprostadil (PGE1) monotherapy on the return of “spontaneous erections satisfactory for sexual intercourse” [172]. All men “reported normal preoperative erections allowing for satisfactory sexual intercourse at all times”. This study predated validated erectile function questionnaires hence no baseline or postoperative questionnaires were used. One month after surgery, subjects were randomized to intracavernosal injections of alprostadil three times per week versus no therapy. It was not declared whether patients were enrolled into the trial after or before surgery or what the randomization process involved.

This study was conducted in the pre-sildenafil era, so that PDE5i use was not an issue. Injections were started one month after surgery and continued for

3 months, after which the patients were evaluated. The outcomes were patient reported successful intercourse, nocturnal penile tumescence (NPT), and penile duplex Doppler studies. No preoperative NPT studies or Doppler studies were performed. 8/12 (67%) completers in the treatment group recovered erections vs. 3/15 (20%) in the observation group. The group that recovered erectile function used ICI before sexual activity no more than 1/3 times. For such a short term follow up of 4 months, these results are unparalleled in contemporary studies. Interpretation of the objective results is difficult as authors only provided summary data and did not indicate what NPT or Doppler parameters they considered “normal”. (Figure 6). This study provided the first signal that intervening pharmacologically in the early post operative period might beneficially impact recovery of erectile function after nerve sparing surgery but the study suffered from low numbers and has never been duplicated or carried out on a larger scale. The authors hypothesized that the absence of cavernosal oxygenation occurring during the early postoperative period reduced “the percentage of functional smooth muscle cells with a concomitant increase of cavernous fibrosis and deterioration of erectile function”.

In 2005, Mulhall et al in a non-randomized study of 132 patients compared patients who opted for penile rehabilitation versus those who did not pursue rehabilitation [57]. All patients had partner-corroborated functional erections preoperatively. Patients studied were seen by a sexual medicine physician only after surgery but within the first 6 months. At that time, they opted for either the rehabilitation program or no intervention. The protocol consisted of an initial challenge with sildenafil (on four occasions at 100 mg). If an erection of “≥60% rigidity” (penetration hardness) was obtained, patients were encouraged to use this medication to obtain three erections per week. If sildenafil failed to induce such an erection, patients were encouraged to consider penile injection therapy, depending on tolerability. Three injection-induced erections per week were encouraged. All patients were followed every 4 months until they were 18 months postoperatively. Sildenafil failures were instructed to re-challenge themselves every 4 months after surgery to determine if they had become responders. Once this occurred, they were permitted to cease injections if they wished and to use sildenafil three times a week to achieve erections. All patients were followed every 4 months until they were 18 months postoperatively.

The average time from surgery was over 4 months, missing the benefit of early intervention. The rehabilitation group agreed to participate in the program and comply with the protocol for at least 12 months (58 men). “Patients who decided not to pursue the program of treatment but who presented for follow-up for periodic evaluation of their erectile function constituted the no rehabilitation group” (74 men). Overall, 67% of the group had bilateral nerve

*Figure 6: End-points in the Montorsi rehabilitation study using intracavernosal injections as a strategy.*
sparing surgery, 11% unilateral nerve sparing, and 22% non-nerve sparing. No attempt was made to stratify results by nerve sparing as the nerve sparing status was roughly equal between groups.

Those in the rehabilitation group averaged 1.9 erections/week. The patients opting for rehabilitation had significant improvement in natural response (52% vs 19%), sildenafil response (64% vs 24%) and intracavernosal injection response (95% vs 76%). Though the results are supportive of penile rehabilitation the strength of the conclusions are severely weakened by its non-randomized nature, introducing significant potential for investigator bias and patient motivation issues.

3. PDE5 INHIBITORS

There exist two large prospective, randomized, multi-centered controlled studies after BNSRP; one assessing sildenafil and the other vardenafil. The sildenafil trial was designed shortly after the drug’s approval[14]. It was designed when the existing radical prostatectomy literature quoted “potency preservation” rates of greater than 80% after BNSRP at centers of excellence and rehabilitation was not the standard of care. The study designers set out to “evaluate the efficacy of prophylactic, nightly use of sildenafil in preventing long-term ED”. The second objective was to investigate the effects of sildenafil on nocturnal penile erections after BNSRP. It was not designed to evaluate the efficacy of sildenafil after BNSRP. Montorsi et al had previously shown that the use of sildenafil at night enhanced nocturnal penile tumescence [173]. Improving nocturnal erections was thought to improve penile oxygenation and minimize the theoretical hypoxic damage to the cavernous tissue during the period of neuropraxia after RP.

The a priori determined primary outcome in this trial was preservation of natural erectile function, defined as a combined score of at least 8/10 on questions 3 and 4 of the International Index of Erectile Function (Q3 "Over the past 4 weeks when you attempted intercourse, how often were you able to had penetrate your partner?"; Q4 Over the past 4 weeks, during sexual intercourse, how often were you able to maintain your erection after you had penetrated your partner?) and a “yes” answer to the question, “Over the past 4 weeks, have your erections been good enough for sexual activity?”. The secondary endpoints were mean IIEF-EF scores and NPT. A subset of men underwent longitudinal NPT testing to assess objective changes in NPT on and off treatment.

The trial design was a three arm parallel design (placebo, sildenafil 50mg, sildenafil 100mg) with treatment starting one month after surgery and lasting for 9 months. The commencement of treatment at one month was an arbitrary choice based on the unknown safety profile of starting men on nightly sildenafil immediately after radical pelvic surgery. Though starting sildenafil immediately after surgery was contemplated, there was concern about postoperative sildenafil induced erections with an indwelling catheter. In retrospect, in light of data demonstrating histologic damage as early as two months, the one-month delay may have resulted in a compromise of therapeutic efficacy. After 9 months, treatment (at 40 weeks after RP) was withheld for 2 months. At 48 weeks after surgery men were then queried with the IIEF and the efficacy question. Though a longer period of observation to allow more complete return of function would have been preferable, it was felt that a longer placebo period might be detrimental to eventual return of function. A mid-study blinded review of data was planned. Active recruitment ceased after 125 men, when a blinded review revealed a 25% response rate, far lower than that reported in contemporary surgical series from centers of excellence.

The two US centers carrying out NPT testing remained open, from which a sub-analysis was possible. At 48 weeks, 27% (14/51) of men on sildenafil vs 4% (1/25) in the placebo arm were considered responders (p<0.01). Mean IIEF-EF domain scores in responders vs non-responders off sildenafil were 26.8 vs 11.5 (sildenafil 100mg), 26.3 vs. 8 (sildenafil 50mg), 23 vs. 7.6 (placebo) (Figure 7). Overall IIEF by treatment was 13.7 (sildenafil 100mg), 12.4 (sildenafil 50mg) and 8.8 (placebo).

The results of the sub-analysis mirrored the larger study[174]. In 54 men, NPT testing was done preoperatively and at 5 postoperative time points (4, 12, 24, 36, 48 weeks). In order to enter the study, men had to demonstrate basal penile rigidity of greater than 55% rigidity for 10 minutes on at least 1 of two nights and have normal preoperative function. The primary penile NPT outcome was the duration at which penile rigidity (base and tip) was ≥55% of maximum rigidity (R ≥ 55%). The clinical outcome measures were the same as those stated for the larger study. Forty-eight weeks after surgery, 6/18 (33%) men who received sildenafil 100mg, 4/17 (24%) men who received sildenafil 50mg, and 1/19 (5%) men who received placebo were categorized as study responders. These response rates in the NPTR subset are similar to those in the overall study (29%, 26%, and 4% respectively). Because only one man in the placebo group was a responder, comparisons between the placebo responder and non-responder groups should be undertaken with caution.

Across the three groups at baseline (preoperative), the mean R ≥55% ranged from 64-81 minutes at the base and from 48-56 minutes at the tip (Figure 8). R ≥55% was decreased profoundly at 4 weeks after surgery. No treatment group returned to baseline values during the trial, but R ≥55% in the
Figure 7: End-points in the Pfizer sponsored nightly sildenafil post-RP study.

Figure 8: Results of serial nocturnal penile tumescence and rigidity analysis in the Pfizer sponsored nightly sildenafil post-RP study.
sildenafil groups increased several-fold from the nadir compared with little change in the placebo group. The sildenafil 100mg group had the greatest improvement from the nadir in R ≥55%, achieving 36% (base) and 65% (tip) of baseline values by the end of the trial. This is the only rehabilitation study clearly documenting longitudinal objective and clinical data showing benefit to pharmacologic intervention in the postoperative period. It underscored the early and profound loss of nocturnal erections after surgery.

Though this abbreviated study met its endpoints and had highly statistically significant p values, it suffered from low numbers, thus weakening the strength of the conclusions. Its strength lies in the congruence between the NPT data and the clinical outcome and provides clinical data to support animal data. Mechanistically, it was suggested originally that men were obtaining nocturnal erections and oxygenating their corporal bodies. However, the NPT data demonstrate what little nocturnal erectile activity was occurring early after RP.

Another less rigorous and smaller observational sildenafil rehabilitation study was conducted by Bannowsky et al.[175] From an unknown denominator of patients, 43 men after nerve sparing surgery by a single surgeon (11 UNS,22 BNS) had NPT testing. The NPT testing was not done preoperatively and only once postoperatively, the night after catheter removal. NPT testing immediately the night after catheter removal is particularly problematic, as many of the men are incontinent during that first week and the penes contract making the ring application for the apparatus a challenge. Patients were distributed roughly 1:3:1 to sildenafil 25 mgs nightly vs. no treatment. Sildenafil was started the day after NPT testing and continued for an unspecified period of time, presumably the entire 52 week observation period. Patients were “randomized” roughly equally between treatment group based on preoperative SHIM, NPT findings and nerve sparing status. The study was observational and not powered for a particular endpoint.

Bannowsky had shown in a previous NPT study, that nocturnal tumescence was preserved at one week in 95% of men after NSRP[176]. As in the current study, only one NPT observation was made, on the day of catheter removal. The results are in stark contrast to the observation of the profound loss of NPT at one month in the longitudinal study in men after strict bilateral nerve sparing surgery by McCullough et al [174]. Men were seen at weeks 6,12,24,36 and 52. The outcomes reported were SHIM score and "the ability to achieve and maintain an erection satisfactory for intercourse", on and off sildenafil. At 36 and 52 weeks a statistically significant difference in SHIM score was seen between the two groups and at 52 weeks a qualitative difference between intercourse success rates was observed. Though the IIEF scores seemed to trend with intercourse success, neither a definition of intercourse success nor any details of a sildenafil challenge at 52 weeks were given. While statistically significant, the 3.2 and 4.8 point difference in SHIM scores between treatment and control patients at 36 and 52 weeks is likely minimally clinically significant. However, this study lends support to the larger prospective study and also demonstrates the profound early loss of clinical erectile function after NSRP. Combining the NPT data from the McCullough with the Bannowsky study, one sees how quickly penile innervation deteriorates, as well as the sensitivity of NPT testing for nerve integrity and recovery.

These analyses have forced us to analyze how a PDE5i may facilitate erectile function preservation. Given what we now know from animal studies, attention has been focused on endothelial protection, smooth muscle protection and neromodulation. All three PDE5 inhibitors in phase II-IV trials have demonstrated a lower incidence of myocardial infarction compared to those patients in the placebo groups of the trials (data on file). We know that PDE5 inhibitors are potent endothelial protectants in the diabetic patient population as well as in patients with increased cardiovascular risk[177, 178]. All three PDE5 inhibitors have been shown to improve flow-mediated dilation at low doses and for a significant period of time after the cessation of the medication. Thus, it would appear that PDE5 Inhibitors result in cellular events that protect endothelium beyond the presence of drug within the blood. Furthermore, as previously mentioned, there is elegant evidence in humans and animals that PDE5 inhibitors generate the production of endothelial progenitor cells from the bone marrow [157-159]. Circulating EPCs originate from hematopoietic stem cells in bone marrow, migrate into the peripheral circulation, and differentiate into mature endothelial cells. In this way, EPCs are able to provide a circulating pool of cells that may contribute not only to endothelial repair, but also to neovascularization[179, 180].

Schwartz et al. conducted a randomized, (non-placebo) controlled trial evaluating the impact of sildenafil on corporal smooth muscle integrity in men after radical prostatectomy [181]. Twenty-one patients used sildenafil every other day at 50mg or 100mg. They had corporal biopsy performed prior to radical prostatectomy and six months postoperatively. Histopathological analysis showed significant preservation of smooth muscle content with sildenafil use at both the 50 and 100 mg level. In this study, each patient served as his own control as they all had preoperative corporal biopsies. Though supportive of the concept of penile rehabilitation the interpretation of the biopsy material is extremely subjective and subject to observer bias and sampling error. No attempt was made to “blind” the person evaluating the tissue. Nevertheless, the rapidity of
the acute histologic findings correlate with a study demonstrating a virtual complete loss of nocturnal penile tumescence activity within one month of nerve sparing prostatectomy.

The third mechanism that has been explored, albeit to a lesser extent, is the concept of PDE5 inhibitors may in fact be neuromodulatory. Zhang et al. have shown with both sildenafil and tadalafil in a rat middle cerebral artery occlusion model of stroke that dosing with medication compared to saline results in significant functional recovery [141, 182]. No human studies have been conducted to date, to demonstrate improved cavernous nerve function in response to PDE5i.

More recently, the vardenafil (REINVENT) trial was published [12]. This study was designed to investigate the effect of early postoperative dosing with vardenafil in three different fashions: nightly (N), vardenafil on-demand (OD), or placebo (P) on the recovery of erectile function in men with ED following BNSRP. As in the sildenafil study its planning and design predated much of the strong supportive animal data for penile rehabilitation after cavernous nerve injury. The design of the study was complex (Figure 9). Each arm had a different titration schedule. The P arm consisted of placebo nightly with placebo on demand with no dose titration. The N arm consisted of 10 mgs of vardenafil nightly with the ability to titrate the nightly dose downward but not upward and then this group used placebo for on-demand sexual relations. The on-demand placebo was not titrated. The OD arm received nightly placebo with no titration, and for on-demand sexual relations, a titratable vardenafil dose (5, 10 or 20mgs). Without considering variability in on-demand dosing in the OD arm there were 6 different possible permutations of drug administration. Thus, the different dosing permutations with 87 sites raises concerns regarding dose accountability. Protocol violations were almost three times more common in this study than the Brock et al. study after BNSRP, Brock et al had reported that in 302 men, 1.7 years after surgery, the per patient success rates using sexual encounter profile questions 2 and 3 (SEP 2 and 3) were 22% and 12% with placebo compared to 52% and 40% with 10 mgs and 20 mgs of vardenafil respectively. The corresponding IIEF scores were less than 10 for placebo and 16 for the treatment group [183]. Based on the Brock study one would expect placebo and vardenafil group response rates less than 30% and 50% respectively with much lower IIEF-EF scores. The authors did not explain how they dealt with men who were not sexually active. A significant difference in sexually active men between treatment arms might blunt a therapeutic effect. A man may not attempt sexual intercourse because of incontinence or partner issues yet still have functional erections.

The use of LOCF in this study, though standard in pharmaceutical trials, could introduce a bias if the dropouts in one arm occur earlier than in another arm. As erectile function is known to improve with time, independent of treatment, if more men drop out early from one arm, their low IIEF EF domain score will be carried to the end of observation and hence lower the end-of-treatment IIEF score, even though they are likely to have improved. The dropout rates were similar between treatment arms: P (31%), N (35%), OD (32%). The dropout rates were largely driven by adverse events, protocol violation and consent withdrawal. Of note, in those categories alone there was a 20% difference between placebo and treatment arms (54%, 74%, 76% respectively). With such large dropout rates, it is important to understand when the dropouts occurred in each treatment arm, as they may have impacted the LOCF.

The primary efficacy variable was not met in the study. There was no difference between the P group and the vardenafil (N or OD) groups at the end of the single blind placebo washout phase. The proportions of patients with IIEF scores ≥22 were 28.9%, 24.1% and 29.1% for the P, N, and OD respectively (Figure 10). Almost 30% of the P group had an IIEF-EF domain score ≥22 and it is unclear why this is so. Data was collected at 3, 6 and 9 months but was not reported. It would have been useful for the authors to include the mean total IIEF-EF domain score in order to able to make comparisons with other studies.
Figure 9: study design for the REINVENT (Bayer sponsored vardenafil) post-RP study.

Figure 10: Primary end-point analysis in the REINVENT study.
Secondary outcomes included percentage of subjects with an IIEF EF domain score $\geq 22$ at LOCF at the end of the double blind treatment period (9 months) and at the end of the open label period (13 months) (Figure 11). Data were further analyzed for the percentage of patients with IIEF-EF score $>17$ and $>22$ at LOCF for each period of the study and per patient success using SEP 2 and SEP 3 were assessed for each period of the study. Authors did not include the data on the proportion of subjects with IIEF-EF scores $>17$ or $>26$ for all of the time points measured. This data is likely important to better understand the outcomes and for the design of future meaningful rehabilitation trials, thus it is hoped that the data will be made available at some point in the future.

The secondary endpoints demonstrated superiority of OD over P at all data points during the double blind period. The OD arm was superior to the N arm at “several visits and at double blind LOCF (9 months)” though no data was presented to accompany the p value of 0.0065. The superiority of on-demand therapy in the placebo-controlled trial is not surprising. Simply put, the OD arm used vardenafil for sexual relations while the N arm used a placebo for sexual relations. It would be expected that the OD group would record higher IIEF EF domain scores and SEP 2 and 3 rates at the end of the intervention phase.

All superiority of the vardenafil arms was lost during the two month open label period with IIEF-EF scores $\geq 22$ of 47.8%, 52% and 54.2% for the P, N, OD arms respectively. The accompanying SEP 3 scores were 57.1%, 59.8% and 62.6%. This is a remarkable study yet the results are in stark contrast to robust data from preclinical animal trials and the sildenafil trial. There was no benefit to rehabilitation with vardenafil at 11 and 13 months. The authors, in their conclusions, state that these data support a shift in the paradigm towards on-demand dosing of PDE5i post-RP, yet other than at the end of the intervention phase, the OD use was no more effective than the nightly dosing not the placebo.

Possible explanations for the lack of difference in response between the placebo and vardenafil arms after drug washout and at the end the open label period (13 months) include: (i) PDE5i play no role in penile rehabilitation and the animal model is not relevant to humans. The number of confounding factors in the NSRP patient is staggering and include patient age at time of surgery, surgeon experience, surgeon expertise, preoperative sexual function, nerve sparing status, partner/relationship issues and status, confounding medications, medical comorbidities, hormonal status, and endothelial function among others. Future studies should be designed and powered to control these confounding variables to obtain clearer answers; (ii) There are differences in the molecular action of sildenafil compared to vardenafil. In the absence of a head-to-head trial between different PDE5i in this population, this will be impossible to answer. However, all three PDE5i have been shown in animal studies...
at least to have a positive effect on erectile tissue and function preservation. On the other hand, there exists a randomized, controlled trial comparing all three PDE5i in the pulmonary hypertension literature demonstrating superiority of sildenafil over vardenafil in a number of end-points (primarily pulmonary artery oxygenation)[184]; (iii) The vardenafil was not dosed correctly for rehabilitation. Of note, doses of vardenafil used in pulmonary hypertension are 10-15mgs 2-3 times per day [185, 186]; (iv) Confounders existed unrelated to lack of efficacy of vardenafil including surgeon and nerve sparing quality variability related to the large number of centers and surgeons included in the trial; (v) It is also possible that the complexity of the trial design obscured any therapeutic effect.

4. INTRA-URETHRAL ALPROSTADIL SUPPOSITORY

The intra-urethral alprostadil suppository (IUA) was approved in 1997 and continues to play a small but definite role in ED management. Given its erectogenic capabilities, interest has existed in assessing its role in penile rehabilitation after RP. Interestingly, Moreland et al suggested that endogenous PGE1 (at least in an in vitro model) suppressed fibrogenic cytokine activity (in the form of TGF-β)[89]. Thus, it has been suggested that exogenous PGE1 may have some protective effects even aside from the production of erection.

Since the intracavernous injection study by Montorsi there have been no large prospective studies incorporating alprostadil in penile rehabilitation. Costabile and Raina have demonstrated the efficacy of IUA to treat ED after RP regardless of nerve sparing status[187, 188]. In a non-randomized, prospective observational study, Raina demonstrated the tolerability of a nine month regimen of three times weekly IUA after RP with a benefit over no treatment in “successful vaginal intercourse with or without erectile aids” (40% vs 11%) [188]. The non-randomized nature of the study limits the validity of the data.

McCullough et al conducted a randomized trial, the purpose of which was to determine if early nightly treatment with IUA after nerve sparing RP hastened return of erectile function (McCullough et al; manuscript under review). This study was conducted in the United States at three high volume prostatectomy centers. Approximately half of the patients had robotically assisted laparoscopic surgery and the other half standard open radical prostatectomy. All surgeries were bilateral nerve sparing. The study consisted of two-arms comparing nightly IUA administration to nightly sildenafil 50 mgs. Inclusion criteria were similar to the other prospective penile rehabilitation studies. Subjects were 69 years of age or less, sexually active in a stable relationship, had an erectile function domain score of at least 26, did not use PDE-5 inhibitors, had a Gleason score less than 8, a PSA level less than 20, and were scheduled to undergo a BNSRP. Post-surgical radiation therapy and androgen deprivation were exclusion criteria. At each visit, mean IIEF scores were calculated for study participants.

Subjects were consented one month prior to surgery, completed the IIEF questionnaire and had a stretched penile length (SPL) measured from the pubic bone to the coronal sulcus with a rigid ruler (V1). Patients were seen at the time of catheter removal (V2), and postoperative months 1 (V3), 3 (V4), 6 (V5), 9 (V6), 10 (V7), and 11 (V8). At V2, within one month after surgery, at the catheter removal visit, all men were randomized to either IUA (125 mcg) or Viagra (50 mg), in a 2:1 ratio and had measurement of SPL. IUA 125mcg was chosen as an initial dose to allow subjects to become familiar with the IUA technique and to minimize the discomfort of IUA administration. The first IUA administration was conducted at the clinical site for safety and tolerability assessment. Subjects were instructed to self-administer IUA or Viagra nightly during the study and were supplied with a one month supply of either drug. Subjects had to complete the sexual encounter profile (SEP) with each attempt at sexual intercourse throughout the trial.

At V3 (1 month), IUA subjects were up-titrated to 250 mcg. All subjects were provided with a two-month supply of IUA or Viagra for nightly administration and remained on that dose for the remaining 8 months. The IIEF, SPL, adverse events (AE), SEP, and medication compliance data was collected at V3-V6 and V8. At V6 (month 9) all nightly medication was discontinued and subjects were given no medication for one month. They attempted sexual activity during this time without using any erectogenic aids. At V7 (10 months), subjects were provided with six Viagra (100 mg) tablets and instructed to use each tablet on an empty stomach one hour before initiation of sexual activity over the ensuing month. At V8, eleven months after surgery, all subjects completed the Erectile Dysfunction Inventory of Treatment Satisfaction (EDIT) in addition to the IIEF, GAQ, SEP and had SPL measured.

The study was powered based on the 27% normalization of erectile function from the sildenafil rehabilitation trial and the 67% intercourse success rates published by Montorsi. The primary outcome was mean IIEF score at each visit and the secondary outcomes were SEP, SPL and EDIT.

A total of 227 men gave consent to enter the trial, 212 subjects started the study, while 156 subjects (97 IUA, 59 Viagra) completed the trial. Average age was 56.8±6.4 years for IUA and 55.6±5.9 years for Viagra. Dropout rates were 19% for Viagra and 30% for IUA. Most of the dropouts for IUA occurred between V3 and V4, when men were dose escalated to IUA 250. After visit 4, dropout rates were identical for both groups. Dropout rates in the IUA arm
were no greater than the REINVENT vardenafil rehabilitation trial despite the more invasive route of administration. As erectile function improves in time after RP, results are based on men available at each visit. LOCF was not used. The primary reason for dropout was the pain associated with the nightly administration of IUA 250.

Overall drug compliance as determined by ratio of dispensed to returned medication was 98% for Viagra and 79% for IUA. For each treatment arm, compliance did not change significantly from V3 through visit V6. At V8, compliance was virtually identical (94% for both IUA and Viagra). The percent of men attempting sexual intercourse and the mean number of attempts at each visit was not significantly different at V3-V6 and V8 between the treatment arms. Men who indicated that they were not sexually active were excluded.

As in the REINVENT trial, the primary outcome was not met. Though IUA trended towards favoring an earlier return of function by all the metrics used, by 11 months, differences in outcomes were not statistically significant. The mean IIEF scores by visit are shown in Figure 12. The IIEF scores increased in both groups respectively from a mean of 9.9/10.4 at the 1-month visit to 15.3/17.7 at the end of the study. At the month 3 and 6 visits there was a slight difference in IIEF EF domain scores in favor of IUA; these differences were not significant (p=0.58 and p=0.27 for months 3 and 6). The mean IIEF EF domain score differences were not clinically significant for the 2 groups at the end of treatment period or at the end of the study. At month 1, 3 and 6 visits the percentage of subjects responding yes to the GAQ was higher in the IUA group compared to the Viagra group; these differences were 17%, 8%, and 27%, respectively. The response at month 6 was statistically significant in favor of IUA. Intercourse success rates for IUA group were 16% higher at 3 months and 41% higher at 6 months when compared to Viagra; these differences did not reach statistical significance (Figure 12). Intercourse success rates correlated strongly with the IIEF EF domain score (r=0.80, p<0.0001). Men with intercourse success rates less than 50% averaged an IIEF score of 7.9 whereas those with success rate greater than 50% of attempts, averaged an IIEF EF domain score of greater than 20 throughout 3-11 months (p <0.0001) for both medications. These differences are not unexpected, as IUA does not require intact cavernous nerve to function while PDE5i response does, thus, at these early time-points when cavernous nerve neuropraxia is at play, PDE5i response is poor.

Stretched penile length generally decreased in length for both treatment arms. Though both treatment arms began and ended at virtually identical SPL, the IUA arm showed less loss of length at V5. Statistical significance was achieved at V5 (p=0.047). Figure 14. Total EDITS score after Viagra challenge was

![Figure 12](image)

Figure 14: Secondary end-point analysis (penile length) in the randomized study of intra-urethral alprostadil suppository versus sildenafil in men after radical prostatectomy.
not significantly different between arms. Over 75% of patients in both groups felt that their erections were not as hard as before surgery. The end-of-trial IIEF EF domain scores were similar to those in the sildenafil rehabilitation study and the percent of intercourse success were not dramatically different than the REINVENT trial. Despite aggressive rehabilitation, a loss of penile length was seen in both arms, occurring almost immediately. Previous longitudinal studies have demonstrated the frequently observed phenomenon [30-33, 189]. This is the first prospective longitudinal penile length study after RP in men undergoing penile rehabilitation and including only bilateral nerve sparing surgery. Absent of course was a control (no treatment) arm. The etiology of the loss of length remains uncertain but rates of length loss were not affected by the rehabilitation strategies.

5. STEROIDS

In an attempt to improve ED outcomes by modifying the acute post-operative inflammatory response, a 6-day course of methylprednisolone was used in a randomized, placebo-controlled study of 70 men undergoing bilateral nerve sparing RP [15]. The medication was started 16-22 hours after surgery. There was a statistically significant advantage to the placebo group at 3 months that disappeared by 6 months. At 12 months no differences were seen in SHIM scores or in positive responses to the question “Over the past 4 weeks, when you attempted sexual intercourse, how often was it satisfactory for you?” Post-operative complication and continence rates were not affected by the steroid administration. According to the authors, it is possible that the timing, short course of administration and low dose may have resulted in the absence of benefits in this study. A similar study was done with the intra-operative local administration of bethamethasone around the area of the NVB in 60 men [190]. Using similar outcome instruments, no difference in postoperative sexual function was seen and there was no increase in postoperative complications. There appears to be no benefit to short term systemic or topical applications of steroids in penile rehabilitation.

6. VACUUM THERAPY

The vacuum device is one of the oldest effective erectogenic aids. Though the effectiveness of vacuum devices is unquestionable in men with ED, its role in penile rehabilitation is unclear. It has been established that the use of the VED with a proximal constriction band results in penile hypoxia while it is being used [191]. The inflow of blood is predominantly non-arterial and is a result of decreased atmospheric pressure (vacuum) and not smooth muscle relaxation.. In a non-randomized prospective study of 109 patients both nerve sparing and non-nerve sparing, 74 patients were instructed to apply the vacuum device daily for 9 months compared to 35 men with no treatment[192]. Patients self-selected their treatment arm. The duration of the vacuum device application was not specified though the constriction band was used only for intercourse. 60/74 completed the vacuum device arm.

Men and their partners were mailed questionnaires. The results were inconclusive as 19/60 (32%) of the vacuum device group reported spontaneous erections and 10/60 (17%) reported vaginal penetration. In the “no treatment” group 13/35 (37%) reported spontaneous erections and 4/35 (11%) reported erections satisfactory for vaginal penetration. Follow up was done through mailed questionnaires. The vacuum device group reported subjectively that they had less penile shrinkage but no objective measurements were made. 76-86% of men were able to have sexual intercourse with the vacuum device regardless of the nature of the nerve sparing surgery. No long term follow up or PDE5i responsiveness was reported.

Kohler et al reported a randomized study of early intervention with vacuum device compared to no treatment after RP [193]. Thirty-three men undergoing RP were randomized to early intervention (6 months of treatment, starting 1 month after RP, group 1) or no early treatment control group (group 2). Men in the group 1 were instructed to use the vacuum device daily starting 1 month after RP; all used the Osbon ErecAid (Timm Medical, Eden Prairie, MN). The men were instructed to inflate the device for two consecutive 5-min periods after a brief release of suction in between inflations. The use of a tension band for intercourse was forbidden for the first study month (second month after RP). Thereafter, Group 1 was allowed to use the constriction band for intercourse if desired. By contrast, group 2 were not allowed erectogenic aides for 6 months then were given instructions to use the vacuum device after 6 months and to do so whenever they wished to attempt intercourse with the constriction rings. The use of PDE5i was not allowed in the first 6 months in either group, but after the sixth month both groups were allowed to use PDE5i if they desired.

The men were evaluated with the IIEF-5 (SHIM) questionnaire, and with questions on spontaneous erections and adequacy of erections for intercourse. Stretched penile lengths were also measured. Data were acquired preoperatively and at 1, 3, 6, 9 and 12 months after RP. The primary endpoint of the study was the proportion of patients with moderate to severe ED (SHIM score ≤11) after randomizing to groups 1 and 2. Secondary endpoints included penile size, including significant penile shortening, for which 2-cm was used as the threshold, progression of SHIM scores over time, and occurrence of spontaneous erections in the early period after RP. As this was a pilot study, no rationale for the endpoints, study
size or the randomization schedule was given. Four patients withdrew from group 1 and one withdrew from group 2. One patient in each group had a unilateral nerve sparing while the rest had bilateral nerve sparing.

The results were inconclusive. At last follow up (mean of 9.5 months) there was no significant difference between the groups in SHIM score or in the percentage of men with moderate to severe ED. Disappointingly, no spontaneous erections adequate for intercourse were reported in either group. The penile size changes that were reported underscore the vagaries of this endpoint. The vacuum device group actually gained length whereas the no treatment group lost length.

IN SUMMARY

In summary, the committee believes that the term ‘penile rehabilitation’ is easy to understand by patients and should be retained, although some clinicians may prefer to use the term ‘erectile tissue preservation’. The committee defines rehabilitation as the use of a medication, combination of medications, devices (alone or in combination with medication) in the early stages after RP. The goal of rehabilitation is to maximize preservation of all components of the local erectile mechanism and optimize recovery of erectile function.

The ICSM recommends that based on the strong animal and basic science evidence, understanding the strengths and weaknesses of the existing human studies and the negative consequences of long-term ED after RP, clinicians should discuss with the patient that penile rehabilitation has significant potential benefits for the patient/partner and should be considered after RP. This was a unanimous recommendation of the committee and is based on expert opinion thus receiving a grade C because of supportive animal data, combined with conflicting and generally weak human data. The committee appreciates that the animal model may not be fully representative of the human model, or may be representative of only certain forms of nerve sparing surgery. The committee believes taking all of the human data into account, including the two RCTs, two non-randomized studies and also the data evaluating the positive impact of PDE5i on endothelial function and possibly corporal smooth muscle integrity health, that despite the data from the REINVENT study that there remained a signal that PDE5i use after RP had some potential benefit. While the data supporting ICI after RP is weak, the committee believes that the erection induced by ICI may be of benefit possibly mediated through cavernosal oxygination and likely other hitherto unknown factors and pathways.

The ICSM further recommends that key patient factors be taken into consideration when deciding on penile rehabilitation for an individual patient. These factors include but are not limited to: cost to the patient and the health care system, time commitment for patient and clinician, exposure to medications and their adverse effects, the potential benefits of sequential follow-up, early return to sexual intercourse, and potentially maintenance of penile length. The committee appreciates that many patients have no health insurance coverage for medication utilization after RP. However, ICSM feel strongly that this decision should be made by the patient/couple and that the cost be placed in perspective of the long-term sequelae of permanent ED. The ICSM also appreciates that rehabilitation is labor and time consuming for both the patient and clinical staff and that patients be given realistic expectations regarding this prior to commencing rehabilitation. The ICSM suggests that a comprehensive discussion be held with patients regarding the adverse effects of all therapies employed in the rehabilitation program. It is also appreciated that consistent and regular follow-up with patients has potentially significant psychological benefits including dissemination of realistic expectations, offering perspective and psychosocial support. Furthermore, the early institution of erectogenic therapy permits the early resumption of sexual intercourse with a decrease in confidence erosion so often seen in patients who have delayed recovery of EF after RP. The ICSM understands the concept of penile length loss prevention through rehabilitation is highly controversial and based solely on anecdotal information, however, the majority of the committee felt it was reasonable leaving this statement within the recommendation.

The ICSM can give no specific recommendations regarding the structure of the optimal rehabilitation regimen. Numerous confounding variables that at present remain undefined of the ideal rehabilitative approach were discussed including: defining the best time to start rehabilitation after RP, frequency of medication utilization, specifically, daily versus on-demand exposure, the best dosing schedule (low-dose versus maximum dose), duration of rehabilitation after its commencement and strategies used (PDE5i, ICI, transurethral prostaglandin suppository, vacuum therapy), but no definitive evidence exists favoring one rehabilitation strategy over another. This is a unanimous committee recommendation. It was clear that this was disappointing to many clinicians in the audience based on feedback during the presentation of the recommendations by the committee. Unfortunately, no trial has
been conducted and likely will never be that will address all of the significant potential confounders.

RECOMMENDATION 7

Grade C

It is recommended that clinicians discuss with the patient that penile rehabilitation has significant potential benefits for the patient/partner and should be considered after RP.

RECOMMENDATION 8

Grade C

It is recommended that key patient factors be taken into consideration when deciding on penile rehabilitation for an individual patient.

RECOMMENDATION 9

Grade D

No specific recommendation can be given regarding the structure of the optimal rehabilitation regimen.

INTRODUCTION

Only one pharmacological product has been approved for Female Sexual Dysfunctions (FSD) in the European Union and none in the United States since the last International Consultation (2004). This appears to be related more to the standards for clinical trials in women than to the efficacy of the drugs themselves. The focus of this chapter is on essentials of research design and measurement in female sexual dysfunctions. Accordingly, our recommendations rest upon classical procedures in experimental design and classical measurement theory. Therefore, consideration of rating the quality of level of evidence is not germane for this chapter.

As part of that process, we will review current recommendations, evaluate their appropriateness for regulatory approval, and discuss discrepancies and potential changes that may improve ability to demonstrate efficacy for a specific construct.

I. REGULATORY CONSIDERATIONS

1. REGULATORY GUIDELINES: FOOD & DRUG ADMINISTRATION (FDA)

Introduction of a new device or drug requires regulatory approval by a designated government entity. Unfortunately, as of 2009 only one regulatory body, the FDA, has issued any guidance on standards for clinical trials in women with sexual dysfunction. The FDA’s Draft Guidance of May 2000 (FDA-DG or DG, http://www.fda.gov/downloads/Drugs/GuidanceComplianceRegulatoryInformation/Guidances/ucm071655.pdf) outlines Female Sexual Dysfunctions as “currently” consisting of the same four recognized components as in DSM-IV, decreased sexual desire, decreased sexual arousal, persistent difficulty in achieving or inability to achieve orgasm, and dyspareunia (no broader or more detailed definition for sexual pain syndromes). The FDA-DG states that “the definition of FSD continues to evolve” while not recognizing the Diagnostic and Statistical Manual (DSM-IV) criteria for these disorders. Similar to DSM-IV, however, it specifies that, for a diagnosis of FSD, “these components must be associated with personal distress, as determined by the affected woman.” Unlike DSM-IV, it does not recognize interpersonal difficulties as an alternative requirement, to personal distress.

The FDA-DG allows sponsors to target for treatment development any one of, or combination of, the four named components. It suggests some exclusion criteria “to increase the likelihood of demonstrating a treatment effect in clinical trials of FSD:”

- Relationship difficulties with a sexual partner
- Use of concomitant medications that could affect sexual function (e.g., certain antidepressant medications)
• The presence of medical conditions that could affect sexual function (e.g., depression, anxiety, the first few weeks of the postpartum period)
• Sexual dysfunction on the part of the woman’s partner

2. EMEA

The European Medical Authority (EMEA), while not issuing any guidance on FSD, has in the documentation of its approval of a testosterone transdermal system (TTS) (European Public Assessment Report (EPAR), 2006, effectively established precedents for standards of treatment development in hypoactive sexual desire disorder (HSDD). (www.emea.europa.eu/humandocs/PDFs/EPAR/intrinsa/063406en1.pdf) The EPAR details the discriminant validity of the sponsor’s proprietary patient-based measures of sexual desire (desire subscale of the Profile of Female Sexual Function© [PFSF©] and distress related to a deficiency of desire on the Personal Distress Scale© [PDS©]), in comparisons of post-menopausal women with HSDD to those without FSD, and then focuses on three measures of HSDD as leading to its acceptance of the TTS: satisfying sexual events, sexual desire as measured in the PFSF, and distress related to sexual desire as measured on the PDS. These measures remain proprietary and unavailable in sufficient detail for use except by the sponsor of the TTS, Procter and Gamble.

3. MEASURES

Satisfying Sexual Events (SSE): The DG recommends recording the number of sexual events/encounters daily “using diaries” for 4 to 8 weeks before treatment is initiated, and collecting such information weekly for the duration of the intervention. A count of satisfying sexual events is to be the primary endpoint. Satisfaction is to be determined by the patient herself. Partner diaries are allowed but not recommended as primary endpoints.

Sexual Distress: The Draft Guidance recommends measuring personal distress to ensure appropriate patient selection for trial participation but states that this dimension of FSD “should not serve as the primary endpoint for establishing effectiveness.”

Other Measures: Changes in vaginal/genital physiology are not accepted as main endpoints and must be linked to satisfying sexual events to be accepted. Neither is Health Related Quality of Life to be used as a primary endpoint.

Patient Reported Outcomes (PRO) Measures: The DG recommends that any new measures developed be thoroughly validated prior to use in definitive clinical trials. The USA Food and Drug Administration (FDA) issued its draft guidance in 2006 on PRO measures used as effectiveness endpoints in clinical trials (http://www.fda.gov/CDER/GUIDANCE/5460dft.pdf). [1] A PRO is a measurement of any aspect of a patient’s health status that comes directly from the patient. Thus data generated by a PRO measure can provide evidence of a treatment benefit from the patient perspective. PRO instruments need to demonstrate ability to measure the claimed treatment benefit and to be specific to the intended population and the characteristics of the condition or disease treated. The advent of this guidance had specific benefit to the field of female sexual dysfunction. Previously the FDA had relied on observable outcomes, such as daily calendar reports of intercourse frequency. It can be argued that intercourse frequency, relying on the relationship with a partner, may not directly reflect the domain of female sexual function that a clinical intervention seeks to change. The FDA guidance document notes that PRO-based evidence of improvement in symptoms may not be sufficient to substantiate a claim which may also need to demonstrate how any change in (for example sexual desire) translates into other specific endpoints (such as intercourse frequency).

The guidance recognized that for some treatment effects the patient is the only source of data. This, for example, applies to sexual desire where there are no observable physical measures of this concept. Self-completed questionnaires by patients directly capture the patient’s baseline and perceived response to treatment and are not affected by inter-observer variability. However, the PRO may be affected by inter-patient variability if the instrument is not easily understood and completed by patients. PROs may also be developed to define entry criteria to study populations, and evaluate adverse events.

The adequacy of the PRO instrument as a measure to support efficacy claims depends on the development of the PRO and demonstrated measurement properties. The FDA encourages sponsors to determine whether an adequate PRO exists to assess and measure concepts. If it doesn’t then a new PRO can be developed. A single item PRO can on occasion provide a reliable and valid measure (e.g. pain severity). Multiple domains are usually necessary for general concepts. Documentation is needed of the instrument development process, revealing the means by which domains were identified and named, how individual items are associated with each other, associated with each domain, and how domains associate with each other and the general concept of interest. In some measures domains can be aggregated into an overall score. The FDA will compare the patient population used in the instrument development process to the study populations enrolled in clinical trials to determine whether the instrument is appropriate to that population with regard to patient age, sex, ethnic identity and cognitive ability.
The guidance specifically states that the PRO instrument item generation process is incomplete without patient involvement. Item generation generally incorporates the input of a wide range of patients with the condition of interest to represent appropriate variations in severity and patient characteristics such as age or sex. Adequate numbers of patients are needed to support the opinion that the specific items and instrument are adequate and appropriate to measure the concept. Detail is needed regarding item generation techniques used, including theoretical approach used, population study, pools of items, selection and reduction of items, cognitive debriefing interviews, pilot testing, importance ratings and quantitative techniques for item evaluation such as factor analysis and item-response analysis. The method of data collection and all procedures and instructions and modes of administration must also be detailed. The rationale and appropriateness of the recall period must be established and measures taken to ensure that entries are made into patient diaries according to the study design. Response options need to be adequate, appropriate, associated with clear instructions and avoid potential ceiling or floor effects as well as not biasing the direction of response.

The FDA will review PRO instruments for reliability, validity, ability to detect change and interpretability. The socio-demographic and medical characteristics of any sample used to develop PRO instruments should be appropriate for future clinical study settings.

Measurement properties to be reviewed in clinical trials include:

- **reliability** (test - retest; internal consistency; inter-interviewer reproducibility for interviewer administered PROs only)
- **validity** (content - related; construct - related; predictive validity; discriminant validity)
- **ability to detect change** (calculation of effect size and standard error of measurement)
- **interpretability** (smallest difference that is considered clinically important such as minimum important difference; responder definition).

Modification of an existing instrument requires additional validation studies to confirm the adequacy of the modified instrument’s measurement properties. When an instrument developed in one language or culture is adapted or translated for use in another language and culture, then evidence is needed that the translation processes were adequate to ensure the validity of responses.

In summary, the FDA guidance on PROs represents an advance for the field of clinical trials for sexual dysfunction. The guidance clearly states that the PRO may be used as an endpoint, elevating the patient’s perception to that of an observable outcome. The FDA guidance has also spurred further development of instruments. The method outlined by the FDA does help ensure that instruments will adequately reflect the concepts being measured in any given population. However, the necessity for an integration of that guidance, which also incorporates important recommendations/corrections from sexual medicine professionals, is still awaited. [2,3]

4. PROBLEMS WITH CURRENT GUIDELINES

This Draft Guidance remains unaltered despite much criticism from many academic experts in the field of FSD. These objections are of four main types.

One criticism is to the primacy of SSE despite its absence from the criteria for the various forms of FSD recognized in practice and by DSM-IV. While a decrease in SSE is considerably "downstream" in consequences of the DSM-IV-recognized symptoms defining FSD, in fact, the rate of SSE is markedly decreased in the various types of FSD [4,5,6]. The mean decrease is about 70 to 80% in the various Boehringer-Ingelheim (BI) samples compared, with wide variation from patient to patient but with approximately 70-75% sensitivity and specificity vs women with no FSD. D. Shames, Director of the involved FDA division has stated that the primacy of SSE was established so that improvement could not be claimed based solely on subjective feelings of the subject/patient. It also serves to "level the playing field" between the various types of FSD in terms of the main standard set for proof of efficacy.

A second objection is to the absence of the DSM-IV recognized symptoms of FSD as primary outcome variables, e.g., improvement of sexual desire for women with HSDD. The FDA took the latter particularly into account in its presentation in response to the International Society for the Study of Women’s Sexual Health (ISSWSH) in 2006 and published the next year. [7]. Measuring sexual desire is explicitly recommended as a main endpoint for clinical trials of HSDD, but not to the exclusion of SSE as another primary measure.

Thus, it would not be unreasonable for sponsors to seek claims in terms of the main symptom that defines each of the other types of FSD, e.g., a measure of sexual arousal for women with sexual arousal disorder. However, such measures will apparently not be recognized by the FDA unless they meet the validation criteria recommended by the FDA in its Draft Guidance on Patient Reported Outcomes (PRO) of February 2006. Some measures meet these criteria, but not all are available for use in clinical trials. A path to validate currently available measures is also given which has been followed for at least one measure of a primary symptom of FSD, i.e., the desire domain of the Female Sexual Function Index [8,9,10,11].
A third objection is to the exclusion of distress as a main endpoint, but the FDA has not in practice excluded a well-validated measure of personal distress related to FSD as either a co-primary or a secondary endpoint.

A fourth objection is to the FDA emphasis on daily recording of symptoms of FSD, e.g., of sexual desire in women with HSDD. Recent evidence shows that women with HSDD do not recognize a 24-hour retrospective period as valid for assessing their desire, and that instead they find one to four weeks as a meaningful period for retrospective assessment. The finding was the same for pre- and post-menopausal samples. [12,13]

Given these criticisms, there could be value in an iterative process involving coordination between the two regulatory agencies, FDA and EMEA, and including external input.

5. STUDY DURATION

The FDA's draft guidance requires a six-month treatment period to establish efficacy; the two TTS studies that led to EMEA approval were of this duration, so a six-month treatment period is now the recognized transatlantic standard.

Objections can be raised to this, too. Surely it would be a rarely persistent patient who would comply with a new treatment, its inconvenience and side effects if she felt no improvement until six months had passed, leading to considerable likelihood of selective attrition of placebo-arm patients from clinical trials. Thus, a practical standard for onset of action should be recognized as closer to 1-2 months than 6 months. A practical standard for proof of efficacy would inform a similarly short duration of no longer than 12 weeks, as in typical clinical psychopharmacology indications (depression, anxiety, etc.). This would help not only to conform to practical considerations in routine clinical practice but also to separate the issues related to treatment response from those related to maintenance of efficacy and to long-term remission and recurrence. Three-month extension trials (following a 12-week acute efficacy trial), relapse prevention trials, long-term safety studies (when indicated, such as for hormonal therapies), and trials involving a comparator agent (when available) would add to drug information, but do not appear necessary for regulatory approval.

This recommendation is not for a relaxation of regulatory standards, but to establish standards for the separate goals of demonstration of induction of effect and for proof of maintenance of efficacy.

6. SAFETY OF LONG-TERM TREATMENT AND WITHDRAWAL

Data are accumulating that FSD are highly chronic. The mean duration of HSDD was over 5 years at entry into the fibanserin phase III trials of premenopausal women with HSDD. [4] Thus, determination of long-term efficacy and safety, including the safety of treatment withdrawal, should also be assumed to be regulatory concerns.

With the announcement of two one-year studies and a large two-year controlled study of 549 women, (some on placebo) of TTS for postmenopausal women with HSDD, http://clinicaltrials.gov/ct2/results?term=Intrinsa+female, it might be assumed that concerns for the safety of long-term hormonal therapy in postmenopausal women expressed by the FDA in 2004 (http://www.fda.gov/OHRMS/DOCKETS/ac/04/briefing/2004-4082B1_02_A-FDA-Intrinsa-Overview.htm) have led to a recommendation for studies of this size and duration.

Similarly, with publications arising from the fibanserin ROSE study at the European Society for Sexual Medicine – International Society for Sexual Medicine (ESSM-ISSM) meeting in Brussels in December 2008 and the International Society for the Study of Women's Sexual Health in February 2009, it is reasonable to assume that one or more regulatory agencies have recommended that sponsors perform a clinical study sufficient to determine the effects of drug withdrawal after six months of treatment for FSD (at least in HSDD and based on CNS activity) http://www.em-consulte.com/article/175759, http://www.docguide.com/news/content.nsf/news/852571020057CCF68525751A005D6357.

Finally, additional guidance from other government regulatory agencies was not available at the time this chapter was written in 2009.

II. CHOICE OF STUDY MEASURES AND ENDPOINTS

1. PROBLEMS WITH CURRENT ENDPOINTS: SEXUAL PSYCHOPHYSIOLOGY

Sexual psychophysiology is an emerging field of investigation with the number of publications increasing 10-fold over the last 30 years.[14] Sexual psychophysiology can be defined as the application of psychophysiological methods to the study of sexual arousal, with special emphasis on the interplay between subjective (cognitive and affective) and physiological determinants of sexual arousal.[15] A common finding in psychophysiological research is that correlations between subjective and genital responses are lower in women than in men.[16] The discordant pattern most frequently found in women is that genital responses occur while subjective sexual arousal is low or absent.

As well, there has been comparatively little research on the effects of the experimenter on results. A number of studies have explored differences
between volunteers and non-volunteers for sexuality studies and found differences in sexual experience, frequencies of sexual activity, sexual guilt, exposure to erotic materials, and sexual attitude. [17] These findings suggest that psychophysiological studies are particularly susceptible to volunteer bias. Thus, psychophysiological measures cannot currently be recommended as suitable endpoints for clinical trials, consistent with the FDA guidance.

Rellini and Meston found that only the self-report questionnaire, the FSFI, significantly predicted which women with female sexual arousal disorder improved at post treatment.[18] Event logs, vaginal photoplethysmography, and continuous subjective sexual arousal measured during exposure to erotic videos did not demonstrate or predict women’s improvement at post-treatment. Nevertheless, these results provide strong evidence that validated self report questionnaires such as the FSFI are the most sensitive endpoints to detect treatment-induced changes in women’s sexual dysfunction.

There is little correlation between other biologic measures such as sex steroids, specifically androgens, and self-report measures of sexual functioning. Low levels of androgens, specifically DHEA-S, have been linked to low sexual desire in only one study [19]; however, treatment of distressing low desire with testosterone in women without demonstrated low androgen levels did increase desire over placebo. [20,21,22,23] Elevated levels of sex hormone binding globulin (SHBG) appear to mitigate the increase in desire associated with testosterone treatment, and may be used as an exclusion criteria in studies involving sex steroids. [24] In addition, peripheral measures of neurotransmitters have not been shown to accurately reflect central levels, nor to be correlated with sexual dysfunctions or response to non-hormonal, centrally-mediated treatments.

2. SEXUAL DISTRESS

Current definitions of sexual dysfunction include criteria that there is deficiency in a parameter of sexual function and that this causes personal distress or interpersonal difficulty (DSM-IV). Objective and subjective measures of domains of sexual function have been the focus of study for some decades. A number of instruments which measure the low sexual function component have been validated and have been translated into different languages. [25,26,27,28,29] However these measures did not include items about personal distress. Consensus in definitions has led, in the last decade, to the development of measures of distress.[30,31] When both components (low sexual function and sexual distress) are measured in epidemiological studies, prevalence of sexual dysfunction is greatly reduced. [32,33] However, there is a differential effect of age on aspects of sexual function and sexual distress. For example with increasing age (and reproductive aging) the proportion of women who experience low desire increases, but the proportion of women distressed by low desire declines.[34] Thus, if low desire and sexual distress are combined into the aggregate definition of hypoactive sexual desire disorder, no association with age is detected. [34] Recent Australian epidemiological studies have investigated the relationship of psychological, socioeconomic, physiological and relationship factors to low sexual function and sexual distress components of FSD. [35,36] In a cross-sectional population based study of 1002 women aged 20 to 70, utilizing the Sexual Function Questionnaire (SFQ) and the Female Sexual Distress Scale (FSDS), relationship factors were found to be more important to low desire than age or menopause, whereas physiological and psychological factors were more important to low genital arousal and low orgasmic function. [32] Sexual distress was associated with both psychological and relationship factors. Sexual distress was positively associated with depression and inversely associated with better communication of sexual needs when results were adjusted for age, and other factors. In an 11 year, longitudinal study of mid-aged women using the Short Personal Experiences Questionnaire, a decline in all aspects of sexual function was reported over the duration of the study.[36] Sexual distress (measured by FSDS only once, postmenopausally) was associated with higher depression scores and negative feelings for the partner. Sexual distress was predicted by prior negative feelings for the partner and a greater decline in total scores of sexual function.

Sexually-related distress can be assessed by clinician interview and by patient self-report. Reliability and validity have been consistently demonstrated with the FSDS and PDS as a measure of the central nervous system construct of distress. Measurement of distress as an efficacy measure has been demonstrated.[37]

III. OTHER ISSUES IN FSD ASSESSMENT

The primary focus by regulatory agencies on event measures rather than on whether the construct is comprehensively conceptually appropriate to the specific sexual disorder is based on a desire for quantitative behavioral outcome measures. For example, questions about maximum intensity of sexual desire and frequency of sexual desire collected on a daily basis may not be conceptually relevant to HSSD; neither the daily time frame nor the measurement of intensity are closely linked with the construct of HSSD. Similarly, definition of successful and satisfactory sexual events or encounters over time requires a subjective interpretation of sexual experiences by the woman potentially including sexual intercourse, oral sex, and partner- or self-stimulation, and other associated outcomes such as orgasm and
emotional intimacy. Data clearly show other contextual factors influence reporting such as relationship status in sexual desire, and physiological and psychological factors in genital arousal and orgasmic function, that might need to be controlled-for in criteria for exclusion and inclusion in clinical trials, ultimately affecting generalizability. Such data seem to be even more difficult to interpret than numerical scores on self-report questionnaires, which have been established in control subjects and in target populations. Particularly in women with HSDD, the construct of low desire is only indirectly related to the number of sexual events, satisfying or not, as most if not all sexual events in women with HSDD are partner-initiated. Counting of satisfying sexual events reflects a behavioral outcome, rather than a biological or cognitive event (sexual desire), and may not correspond to the sexual problem about which the woman is distressed. [38] Attempts to quantify the minimum important difference (MID) for an SSE diary in 788 women with HSDD using anchor- and distribution-based estimates suggest a range of mean MID estimates between 0.04 and 0.46 SSEs per week. [39] Measurement of SSEs also fails to count other conceptually appropriate events such as receptivity to partner approach and subject initiation of sexual activity.

In addition, the FDA draft guidance for clinical development of drug products for treatment of FSD (http://www.fda.gov/downloads/Drugs/GuidanceComplianceRegulatoryInformation/Guidances/ucm071655.pdf) requires recording of these events in daily diaries which do not have either face validity (daily measures in women of sexual desire or activity) nor have they been developed using the FDA's own guidance regarding PROs (http://www.fda.gov/downloads/Drugs/GuidanceComplianceRegulatoryInformation/Guidances/ucm071975.pdf). Unfortunately, diaries are often inaccurate; this is particularly true of paper diaries that record behavioral events, which may be completed retrospectively without investigator knowledge, and thus, are subjected to recall bias which daily diaries are intended to avoid. [40] However, even when completed on time, for example, with electronic diaries, repeated daily measurement of the distressing sexual problem (e.g. low desire) may increase distress or may not accurately reflect the experience of the women (e.g. she may not have previously experienced an awareness of sexual desire daily). Also, daily measures may themselves act as an intervention, potentially inflating treatment and placebo effects or magnifying distress.

Validated self-report questionnaires have been standardized in target populations, and permit privacy that may lead to more accurate reporting. (See report of Committee 6; Clinical evaluation and symptom scales: sexual dysfunction assessment) Structured interviews allow for follow-up questions that may better define the problem, but require training and monitoring to establish inter-rater reliability, and avoid clinician bias. Currently, standardized expert interviews have been developed by industry, but have not been psychometrically validated. Concomitant use of self-report measures and clinician evaluation may provide the most accurate assessment. Such an approach has been successful in demonstrating differences between study drug and placebo in other central nervous system-mediated disorders, such as major depression and pain disorders.

Partner assessments have been utilized in post-marketing erectile dysfunction (ED) and premature ejaculation (PE) studies, particularly analyzing the burden of disease, medication adherence, and response to treatment. A woman's sexual difficulties can be contingent on ED in her male partner, and PE in male partners has also demonstrated co-morbid sexual difficulties in the woman, and was associated with greater dissatisfaction and emotional distress. [41,42,43,44] No such studies have been published in women, but FSD would likely also be associated with dissatisfaction and distress in the partner. In addition, FSD trials usually exclude women whose partner has any reported sexual dysfunction. In planning studies to include partners of women with sexual disorders, care would need to be taken to avoid making desire discrepancy between partners into a sexual disorder, and to avoid using partner assessments as a study endpoint.

**IV. RECOMMENDATIONS FOR STUDY MEASURES AND ENDPOINTS**

1. Primary endpoints should directly measure the construct of interest sampled over an interval of time appropriate to the construct, through measures such as:
   a. A validated, self-report measure of sexual functioning to include domains/subscales related to phases of the sexual response cycle (specifically sexual desire, arousal, orgasm and sexual pain – all processes mediated via the nervous system), and/or questionnaires or structured interviews assessing specific phases, and able to measure change over time with an intervention
   b. A validated measure of sexual distress
2. Recall period should be 1 – 4 weeks; daily diaries are not recommended
3. Translations of self-report questionnaires must be linguistically/culturally validated with cross-cultural construct validation established.
4. Hormonal status should be considered to include separate evaluations/stratification of premenopausal vs. post-menopausal women, monitoring of menstrual cycle in premenopausal women, analysis of effect of hormonal therapies.
5. Secondary endpoints may include physiologic measures, satisfying sexual events (this may be least important for HSDD), partner assessments, relationship satisfaction, etc.

V. DEFINITIONS OF THE SPECIFIC DISORDERS WITH APPLICABILITY TO THE RESEARCH QUESTIONS

All research designs in sexual dysfunction clinical trials must have participant inclusion and clinical trial outcome measures that reflect DSM IV-TR sexual dysfunctions. These have been outlined by Committee 2.

With regard to the DSM-IV-TR and its relevance to clinical trials, one of the major goals of the DSM-IV-TR is to allow for the differentiation between sexual complaints (short-lived, transient disruptions) from sexual dysfunctions (persistent problems that are distressing) and warrant treatment. The challenge remains to make more objective the essentially subjective line in the sand of what constitutes a complaint versus a dysfunction. Although Diagnostic and Statistical Manual for Diagnosis (DSM-IV-TR) [44] diagnoses and/or criteria are now often used uncritically by researchers and the legal profession, the DSM-IV-TR does not provide any indication of the huge variability in the level of empirical support for the reliability and validity of different diagnoses.

Similarly, the validity of the classification system is questionable given marked variations occurring across time (e.g., age, stage of life, etc.) and across cultures. Further, DSM-IV does not reflect differences in cultures when establishing norms of behavior and this remains a clinical judgment and may also be reflected in difficulties in validating clinical research across cultures.

There is a great deal of overlap or comorbidity of sexual disorders in women. The Female Sexual Function Index (FSFI), despite not initially meeting development criteria for a Patient Related Outcomes (PRO) measure [1,45], but often used as an outcome measure in clinical trials, shows high correlations between sexual constructs. For example, there was a surprisingly higher correlation between the FSFI arousal (psychological) and desire constructs than FSFI arousal and lubrication which are supposed to be measuring the same construct. (1,45) This also points to the notion that desire and arousal (psychological) may be the same construct in women or too interrelated to effectively tease out and measure independently. Clinical trials of sildenafil to treat Female Sexual Arousal Disorder (FSAD) are clear examples of the problem of overlap of disorders. These trials attempted to include postmenopausal women with only FSAD, but had a significant number of subjects who also met the criteria for HSDD or Female Orgasmic Disorder (FOD) (> 50% overlap) [46,47,48,49]. Some clinical trials of testosterone to treat HSDD in postmenopausal women also showed overlap between HSDD and FSAD or FOD with inclusion criteria that HSDD preceded the onset of other disorders. [20,21,22 23] Often in clinical and research settings, women are unable to differentiate the two constructs of desire and arousal, which begs the question—is it really the same construct we are measuring? More data are needed regarding the separation or overlap of sexual desire, sustained desire, receptive desire, and cognitive/psychological arousal.

VI. OBTAINING A REPRESENTATIVE STUDY POPULATION – ISSUES IN GENERALIZABILITY

1. SAMPLING A REPRESENTATIVE STUDY POPULATION

General Principles. Sample selection for clinical trials of candidate treatments for sexual dysfunction in women is driven by the specific objectives of the clinical trial in question, the degree of sample representativeness required to achieve these objectives, and the requirement for experimental integrity that permits unambiguous attribution of study effects to study treatments. Inclusion criteria for research participants must ensure (a) representation of the clinical phenomenon of interest at levels appropriate to the objectives of the study (e.g., study of safety, tolerability, or efficacy), and (b) representation of participant sample characteristics matched to the target population to which it is wished to generalize clinical trial results, which defines the external validity of the study. [50,51,52]

Exclusion criteria are determined by the requirement to ensure safety of study participants and by the need to avoid clinical trial sampling procedures from introducing confounding factors (e.g., recruiting women who are involved in concurrent treatment efforts that may be productive or interfering, or who are experiencing intractable relationship difficulties rendering their sexual dysfunction refractory to pharmacologic intervention) that would impair ability to attribute treatment effects or lack of effects to the treatment under study. The presence or absence of such confounding factors in the sample population, together with trial design and measurement parameters, help define the internal validity of the clinical trial, or the degree to which it is possibly to unambiguously attribute clinical trial treatment effects to the treatment per se. [50,51,52] There is often a need to balance requirements for internal validity (achieving a pristine experimental design and sample recruitment strategy that permits unambiguous attribution of treatment effects to the intervention of interest) and external validity (ability to generalize from the
Sample Selection in the Context of Clinical Trials. Sample selection in the context of clinical trials is driven by the specific objectives of the Phase I, Phase II, or Phase III clinical trial. Phase I trials focus on assessing safety and tolerability of a study compound beyond data obtained in animal studies. While sampling for Phase I trials of candidate compounds in women may seem merely to require passive participation of physiologically normal women subjects, sampling for such trials may prove to be more complex than first apparent. Examination of safety and tolerability in clinical trials of treatments of sexual dysfunction in women will require healthy female participants, whose hormonal status (e.g., oral contraceptive use, menopausal status, hormone replacement therapy use), pregnancy status or pregnancy intentions, comorbid conditions and concurrent medication use permits generalization of Phase I safety and tolerability results to the intended treatment populations. Moreover, sample selection representativeness requires recruitment of participants who are likely to complete the study across the Phase I time interval and multiple potentially invasive procedures involved in single dose, multiple dose, and pharmacology studies, as systematic attrition of intolerant subjects or those who suffer adverse effects can introduce interval validity violations that will render safety and tolerability findings of limited or no value.

Phase II clinical trials focus on identification of an effective dose range for a candidate treatment of a female sexual dysfunction, and early in the Phase II trial a wide array of inclusion and exclusion decisions must be considered in the selection of an appropriate research sample. Following the general principle that sample selection is driven by the specific objectives of the research in question, it will prove critical to sample women who experience a moderate level of the clinical condition in question, as women with an insignificant or an overwhelming level of the condition will be unlikely to show any effective dose treatment response vs. placebo. Similarly, with respect to exclusion criteria, women experiencing lifelong sexual dysfunction, women whose partner relationships appear overwhelmingly to be a cause of their sexual dysfunction, and women for whom a specific medical or pharmacological issue appears to contribute significantly to sexual dysfunction, would not be appropriate candidates for a Phase II study of a candidate treatment. Selection of participants unlikely to attrit during the course of the trial remains a concern. Phase II sample selection should be guided by the need to create “greenhouse conditions,” in part via selection of a sample with appropriate levels of the dysfunction at focus and lacking characteristics that would render the dysfunction refractory to treatment, for identification of an efficacious dose of a pharmacologic treatment for a female sexual dysfunction. In seeking to do so, the tension of balancing internal validity with external validity is evident. In seeking this balance, many of the sampling issues of core concern in Phase III research, including sampling the diagnostic entity at focus at appropriate levels and exclusion of appropriate potential confounders without unduly restricting generalizability of results, come clearly into focus early in the Phase II trial process.

Phase III clinical trials aim to demonstrate the efficacy of a candidate compound for the treatment of a female sexual dysfunction within a representative sample of those experiencing such dysfunction and who might reasonably constitute a treatment target population. Accordingly, sample representativeness in relation to the population of women suffering from the dysfunction, balanced by the need for exclusion criteria sufficient to ensure experimental precision, are paramount concerns in Phase III research. Inclusion criteria for Phase III research are guided by the need to capture participants who represent the diagnostic entity under study, with representative severity of dysfunction (neither too little nor too much), duration of dysfunction, and distress attendant upon the dysfunction. At the same time, it is necessary to exclude those for whom the trial might prove unsafe and, to ensure internal validity, exclusion of those whose hormonal, comorbid illness or medication, and partner relationships might prove confounding factors that obscure ability to attribute research results to the study compound. Again, a careful balance between representativeness and precision is thus required. In Phase III trials, involving the active treatment of a woman’s sexual dysfunction that may be situated in and affect her partnered relationship, partner willingness and potentially partner consent must be considered. Enrollment of partners as clinical study participants may also be a wise choice to permit detection of positive or negative effects of treatment of the index patient on her partner [53].

2. ADDITIONAL CONSIDERATIONS IN SAMPLE SELECTION

Contextual and Interpersonal Factors. Within the general need to select samples that are appropriate for study of the research question at hand, and to balance sample representativeness with exclusion criteria sufficient to ensure internal validity, it is necessary to consider contextual and interpersonal factors that are relevant to both concerns. External validity may require representation of contextual and interpersonal characteristics in research sample participants (e.g., participants drawn from ethno-cultural groups that tend to inhibit female sexual expression; women with childbearing responsibilities; women with a burden of comorbid illness, or other stressors; women with sexual dysfunction whose partners
Symptom Duration, sexual dysfunction. Research that seeks to identify boundary conditions concurrent relevant conditions may be sampled in protocols, participants with a representative range of treatment efficacy within internally valid research use to smoking to concurrent psychotherapy to these or other characteristics ranging from alcohol to which it is wished to generalize may well have sexual dysfunction in the treatment target population of candidate compounds should exclude women sampling for research seeking to demonstrate efficacy and is a potential treatment-sensitive endpoint. Accordingly, avoidance of exceedingly high or low levels of distress may be advisable in sampling for clinical trials in sexual dysfunction.

Hormonal Status. In all research on female sexual dysfunctions, it is critical to systematically incorporate women’s hormonal status into sampling strategies on the basis of anticipated hormonal status moderation of effects of a candidate compound. At a minimum, it would be anticipated that pre, peri, and postmenopausal status women may differ on the basis of hormonal milieu and anatomic and physiologic aging in response to candidate treatments; as such, sampling and research designs must reflect this reality. In addition, it is likely that hormonal contraception (oral, transdermal or injection routes of delivery), and potentially ovarian cycle phase, may moderate treatment effects and sampling; research design, and assessment of covariate assessment and control must be integrated into research strategies in this area to address related external and internal validity concerns.

Overlap and Comorbid Conditions. A number of overlapping and comorbid conditions may be both representative of women with a particular sexual dysfunction and confounding factors that could serve to obscure clinical trial results. It is likely that women with sexual dysfunction may experience medical illnesses, psychiatric conditions, and medication regimens that may contribute to their dysfunction, and sampling for research seeking to demonstrate efficacy of candidate compounds should exclude women with such cofactors. At the same time, women with sexual dysfunction in the treatment target population to which it is wished to generalize may well have these or other characteristics ranging from alcohol use to smoking to concurrent psychotherapy to relationship distress. Within a progressive approach to increasing external validity after establishing treatment efficacy within internally valid research protocols, participants with a representative range of concurrent relevant conditions may be sampled in research that seeks to identify boundary conditions of efficacy of a pharmacologic treatment of a female sexual dysfunction.

Symptom Duration, Symptom Severity, and Symptom Distress. For a variety of clinical, scientific, and regulatory reasons, it is clear that symptom duration, and as alluded to earlier, symptom severity, and symptom distress need to be considered in sampling strategies. Symptoms that are life long may be refractory to treatment, and symptoms that are highly intermittent are unlikely to show treatment effects within time-limited clinical trials. Similarly, symptoms that are exceedingly severe, or exceedingly minor, as measured via screening or interview metrics are unlikely to be sufficiently responsive to treatment in the context of a clinical trial. Finally, opinion generally holds that distress attendant to symptoms of sexual dysfunction is both necessary for diagnosis of such dysfunction and is a potential treatment-sensitive endpoint. Accordingly, avoidance of exceedingly high or low levels of distress may be advisable in sampling for clinical trials in sexual dysfunction.

The Partner as a Subject. It is well recognized that sexual dysfunction is very often embedded in the context of a couple relationship. Not only may it be advisable for partner willingness and partner consent to be assessed, but it may also prove valuable in exploring treatment effects to examine treatment impact on the female participant as well as on her partner. Placebo-controlled clinical trials in sexual dysfunction have indicated that female partners of treated male patients may experience substantial positive benefits of partner treatment and exploration of the reverberating effects of treatment of women with sexual dysfunction on the index patient and her partner is certainly warranted [54,55] 3. NATURE OF CONTROL GROUP

Selection of a control group for clinical trials in female sexual dysfunction should be guided by the same imperatives as sample selection for those randomized to treatment conditions: representativeness of the clinical parameters under study as appropriate to a Phase I, Phase II, or Phase III study, balanced by the need for internal validity and experimental clarity. Research of this nature may involve crossover or repeated measures designs in which an individual woman participant serves as her own control, with consequently increased statistical power and appropriate consideration of drug washout periods; it may involve a placebo-control group in which a single sample of appropriate representativeness is randomized to treatment or control condition, or it may involve a randomized controlled trial involving randomization of appropriately representative participants to a placebo group, an investigative compound, and a comparator (when available) to determine the efficacy, equality, or superiority of a candidate treatment of a female sexual dysfunction.
Special sensitivity and effort to avoid systematic attrition of control arm participants who may not experience symptom relief and who may bear the burden of side effects is needed to avoid compromising the internal validity of the clinical trial.

### VII. ISSUES IN STATISTICAL ANALYSIS

#### 1. PLACEBO-CONTROLLED TRIALS

Large placebo-response in FSD trials makes it difficult to demonstrate significant drug-placebo differences. Large placebo responses (>50%) are likely to lead to failed trials.

Some concern may be raised for measures with placebo response over 40%, too, but a 42% placebo response on the primary endpoint for a trial of sildenafil for FSAD did not prevent significant statistical separation from placebo. A subgroup of patients with FSAD + HSDD showed poor drug-placebo separation but the placebo response was only 2% higher (44%). [47] Thus, subpopulation assessment may provide direction for future trials, particularly in terms of inclusion and exclusion criteria.

Low placebo response may obviate such problems; e.g., in the primary endpoint of a trial of a melanocortin receptor agonist in FSAD, the published main endpoint, a sexual satisfaction scale from 0 (extremely dissatisfied) to 5 (extremely satisfied), showed 82% of patients satisfied with bremelanotide vs 10% with placebo after twenty attempts at sexual intercourse. Earlier timepoints, after four and twelve attempts, were similar for placebo (12 and 15% satisfied, respectively) but showed increasing rates over time with bremelanotide (52 and 78%, respectively), p=0.01 for all of these comparisons. [56]

Placebo response in excess of 50%, however, can severely limit the assay sensitivity of a clinical trial. The ultimate example would be 100% placebo response, of course, which would allow no differentiation from active treatment. As an illustration of this problem, a daily diary measure of maximum intensity of sexual desire in premenopausal women with HSDD was used as a co-primary endpoint in the libanserin phase III project. Although percent change from baseline was not a pre-specified endpoint and individual percent patient changes were not evaluated, the crude group placebo response on this measure exceeded 50% in all trials, at approximately 60-70% per trial, and the diary desire measure was the least robust endpoint in the series of trials. [57]

**Relationship to measure, recall period, etc.** A given measure tends to have a specific recall period, of one, seven, thirty days, etc. Controversy exists on what is an adequate period for a patient to make sense of her pattern of sexual symptoms, but women with HSDD have newly been debriefed to indicate unequivocally that they do not accept a one-day recall period, but do endorse a one to four week recall period related to sexual desire. [12]

In the same libanserin studies as described just above, with a crude overall 60-70% response to placebo on the daily desire measure, the FSFI desire self-ratings, with a 4-week recall, showed 33% or less mean crude overall effect in the placebo groups. On other endpoints, e.g., changes in sexual distress (seven-day recall period) and proportion of patients rating themselves as improved on a global impression question (recall period: 4 to 24 weeks), placebo response was similarly low. The credibility of the e-Diary’s one-day recall results is thus questionable, as it is such an outlier in terms of placebo response. (Figure 1)

**Relationship to Number of Treatment Arms.** A supposition sometimes made is that the lower the proportion on placebo (the higher number of active arms; the higher the proportion on putatively “active” drug), the higher the placebo response. Too few large-scale trials in FSD have been done to establish this effect in FSD. The BI development program used 2-arm, 3-arm, and 4-arm trials (50, 33, and 25% on placebo, respectively). Of well-powered phase III trials, one out of two 4-arm trials had high placebo response; neither of two 3-arm trials had an excessive placebo response, and neither of the two-arm trials had a high placebo response. The two TTS Phase III and three Phase IIIb/IV trials in surgically or naturally menopausal women were all done with a two-arm design (50% on a single level of TTS, 50% on placebo) and were uniformly positive with moderate placebo response.

#### 2. DOSE-FINDING

**Duration.** Duration of treatment in dose-finding studies must be consistent with onset expected and with practical clinical realities: if an agent shows no obvious onset of efficacy within one, or at most two, months of use, poor (or no) compliance thereafter, and thus poor efficacy should be expected. The maintenance dose should be achieved reasonably early, at least within the first month; consuming more time for titration of dose may be impractical.

**Sample Size.** In general, sample size should be large enough for adequate power of the trial to confirm whether further development of a treatment is worthwhile or not. Trials based on main endpoint separations and variance values consistent with less than 75% power cannot inform such decisions with much accuracy. Dose-finding done early in development with small numbers of subjects (n/treatment of 20-75) may help guide future development in dosage but can mislead by Type I and II errors as to whether the treatment actually works. An alternative
is to perform several trials each with moderate statistical power and look for patterns of confluence.

If done late in development, dose-comparisons multiply costs and patient burden in seeking the minimum effective dose because a large number of patients may be given inactive doses. This is likely to impact compliance and subject retention negatively.

**Controls.** Dose-finding not controlled with parallel double-blind placebo may mislead by overly positive results due to a high “placebo” effect. A positive control, if any were available, is not an adequate substitute for placebo because superiority over a positive standard is highly unlikely, and similarity to a positive standard may mislead because both agents may not have exceeded a placebo if one had been included. However, using a dose of the agent at what is demonstrably a no-effect level in Phase I studies may help surmount the difficulties of using a placebo. These include rejection by some ethics review boards, and poor enrollment due to low expectations of obtaining personal benefit.

**Fixed vs Flexible Dosing.** Fixed dose design can create a barrier to efficacy if side effects arise early and the onset of efficacy comes late, factors often leading to excessive subject dropout, especially in non-progressive conditions such as FSD. Yet, flex-dosing mixes in time effects, potentially obscuring dose effects. A forced up-titration to a fixed dose may be the best compromise to determine the minimum effective dose. Yet flex-dosing is the only way to optimize the dose for all patients in a treatment group, thus maximizing opportunity for drug-placebo separation and to best simulate effects to be expected in clinical practice.

Rescue down-titration may add value to salvage fixed-dose trials by helping lower dropout rates.

**Maximum Dose.** In early dosing studies of patients with FSD, it may be more germane to be guided in the maximum dose not only by toxicology results or side effects in an indication with high patient symptomatology (depression, etc), but more so by the side effect profile in normal female subjects, who tend to approximate closely the tolerability profile of women with FSD.

**Timing of dosing.** Sedative agents should be given at bedtime; activating agents should be given in the morning. Doses of agents which cause nausea, etc should be administered with meals if that does not impair absorption. In general, dosing instructions should seek to minimize side effects in a practical way.

The number of doses per day is another practical issue. Trials should keep the regimen practical for patient compliance, not exceeding twice daily dosing unless strongly informed by short half-life issues.

**Intermittent Dosing.** Trialists and sponsors should consider intermittent dosing if the indication amounts to an episodic disorder; e.g., in arousal, orgasmic,
sexual pain disorders; that is, if symptoms relate chronologically to sexual activity or if the agent works upon first dose. This schedule appears to have less potential for treatment of desire disorders.

**Pharmacokinetics (PK).** A short half-life may dictate dosing before sexual activity, or at the time of day just before sexual activity is most likely. If the half-life is much less than 8 hours, it may still be effective for FSAD if taken just before sex at bedtime but may require exclusion of, or special dosing alarm/reminder system for, women whose pattern is for sexual activity in the morning. The possibility of cumulative effects must also be considered, even for short half-life agents. For agents with long half-lives, cumulative effects (positive and negative) may overshadow first-dose effects, so trial designs must take this into account with slow increases in doses and emphasis on chronic rather than acute efficacy and safety.

Drug interactions must be considered for agents that are CYP-450 metabolized, especially for those with active metabolites.

**Pharmacodynamics (PD).** Pharmacodynamic studies early in drug development can obtain useful preliminary answers to several vital questions:

- Which come first, side effects or efficacy?
- How long must the patient be treated before a dose is found to be effective, or can be assured to be ineffective?
- Can an expected (early-onset) side effect be used to guide dosage for a late-onset drug?

Side effects and their severity may depend on the rapidity of upswing in plasma concentration, not just on the absolute Cmax; slowing absorption (even if only with food) may make a medication more tolerable and allow the patient to persist in compliance until she obtains efficacy.

Carefully chosen surrogate endpoints potentially can guide dose-finding in later studies, e.g., if an agent is sedating, prospective measures of sedation, attention, and/or cognition are likely to give stronger dose differentiation than simply a general inquiry about how the subject feels. Similarly, self-rating scales can be modified to a shorter recall period to fit the restrictions of early (phase I trials), e.g., a 4-week recall can be shortened to 1 week. [31]

3. **DURATION OF TREATMENT**

Three months may be adequate to test for induction of effects on feeling states (sexual desire, sexual distress) but may not be long enough to alter a couple’s dysfunctional pattern of sexual inactivity and/or dissatisfaction, whether it was a consequence of the FSD or not. Thus, this duration may be suitable for Phase II trials, but not for Phase III studies, in which sexual activity, and in particular the frequency of satisfying sexual events, is likely to be required as a primary endpoint. Several trials have shown concordance of improvement in feeling states and satisfying sexual activity over this period [20,21,22,23,58,59,60,61].

Female Sexual Disorders are rarely of short duration. Thus, controlled testing of maintenance for six months or longer may be useful to confirm maintenance of effect. A parallel trial with placebo for over a year is in process for the TTS (www.clinicaltrials.gov) but it may be more practical, particularly for retention of subjects on placebo, to use a randomized crossover from open-label “active” treatment to drug vs placebo after several months to obtain plateau maintenance effects. This has been used successfully in a 48-week design in premenopausal women with HSDD. [37] When considerations of withdrawal are relevant, this design may be particularly useful.

4. **EFFICACY MEASURES AND THE CURRENT PROCESS AND PROBLEMS**

All measures of a particular construct associated with the sexual disorder should have convergent validity. When well-validated measures fail to converge statistically with novel measures, concerns about the suitability of the novel measure arise.

Excessively high placebo response may be measure-specific, as explained above. Excessively low placebo response may also occur, even for measures that discriminate FSD patients well from normal women. Poor response on such a measure can suggest lack of efficacy if the active treatment does not separate from placebo on the measure. However, if it is an outlier among measures, the presumption instead should be that the measure is insensitive to change with treatment, as no history of ability to detect treatment responsiveness is currently available, because all the treatments are novel. This currently appears to be a particular problem for measures in FSD trials as data on treatment responsiveness of validated instruments is not published (e.g. proprietary tools used in TTS trials). This can occur because of irrelevance to patients or because of design flaws in the measure, if other measures in the same trial do show separation between active treatment and placebo, e.g., crude overall group placebo response was about 5% on a daily e-Diary question on intensity of sexual distress (not a thoroughly validated measure) in a set of Phase III trials of premenopausal women with HSDD, whereas crude overall group placebo response on the well-validated FSFI-R (measuring frequency but not intensity of sexual distress) was about 15-20% in the same women at the same time, and crude overall group desire improved 26-33% on the well-validated FSFI desire domain. Thus, the credibility of the e-Diary distress item results is questionable. (Figure 1)
This points to a major potential problem of daily measurement: that the measurement itself influences ratings. Whether the level of placebo response varied so greatly between measures (daily desire, 60% response or more; daily distress, 5% response, both in the same placebo group) because of the frequency of measurement, and/or because of the power of suggestion invoked by the measure, the large disparity between measures suggests a serious problem with daily measurements of feelings related to HSDD. Self-ratings with a 7 to 30 day recall period, the FSFI and FSDS-R, generally showed less than 40% crude overall group placebo response in the same program. This demonstrates the importance of less frequent measurement, which has been argued on theoretical and practical grounds. [62]

5. SAFETY MEASURES AND ADVERSE EVENT MONITORING

Spontaneous reporting of adverse events is the standard method, but it is known in general to give lower incidence rates than prospective, elicited reporting. The prime example in this field is that the first selective serotonin reuptake inhibitor (SSRI) antidepressant, fluoxetine, was originally described in the package insert as associated with a 1.9% rate of sexual dysfunction. Prospective, elicited reporting of sexual dysfunction with now-standard rating scales such as the Changes in Sexual Functioning Questionnaire (CSFQ) have shown rates of FSD more than 15-fold higher. [63]

The FDA's new standards require prospective, elicited reporting of suicidality. The FDA has also mandated prospective, laboratory-based determination of whether an agent causes infertility. As appropriate, determination of relevant endogenous sex hormone levels should be used to inform long-term safety, e.g., carcinogenesis and cardiovascular disease. Thus, certain classes of compounds may require a longer treatment period to determine safety.

VIII. ADDITIONAL ISSUES IN FSD TRIALS

**Comparator trials.** No gold standard treatment for comparison exists, although tibolone, the Eros device, the testosterone transdermal system for postmenopausal HSDD, or behavioral treatments may serve as models to inform calculation of a sufficiently powered trial (not over-powered or under-powered).

**Statistically significant change vs. clinically meaningful effect.** Standards for statistical differences and clinically important differences must be determined a priori or anchored by a global measure of change: efficacy and effectiveness. Achieving a statistically significant difference between a new treatment and placebo is insufficient to define the value, or effectiveness, of the new treatment. The latter can be done only by finding a clinically meaningful difference between the two treatments. This can best be done by comparing the proportion of responders between the treatments.

**Confluence of arbitrary responder values and clinical data to determine responders.** Few normative population data are available to help establish responder criteria for adequate sexual function in pre- and post-menopausal women, but a value of 25, 30, or 50% of normal functioning might be chosen arbitrarily as a responder value for various endpoints. Data from comparisons of women volunteers with a given FSD diagnosis vs volunteers without sexual complaints suggest that such values would be clinically meaningful.

For the FSFI desire domain, the minimum score is 1.2 and the maximum is 6.0. A 20% improvement based on the maximum score would be 1.2. A 50% improvement based on the baseline score would be 0.9, but patients can improve by increments no smaller than 0.6, so 0.9 would amount to 1.2 anyway. The value of +1.2 to define a responder on this measure corresponds with the value determined by anchoring methods (see below).

For the FSDS-R, an improvement of 6 points has been recommended by the author of the scale, L. Derogatis, as a responder value, which corresponds for this 13-item, 52-point scale to approximately a one-half point change per item. It corresponded, in the fibanserin Phase III program, to a 20% improvement toward the scale maximum for functionality, i.e., zero. [4]

**Confluence of anchoring methods to determine responders.** Alternatively, anchoring a responder value in terms of a patient global impression question can be used.

For the TTS Phase III project in surgically menopausal women with HSDD, to define responders on the desire measure, the desire domain of the Profile of Female Sexual Function (PFSF), a value was chosen by anchoring for optimal sensitivity and specificity on the Patient Benefit Evaluation (PBE), i.e., 9.0. Comparing to the baseline mean on the PFSF, 21.3, a responder would be one with a 42% increase in desire.

In the TTS project, responders on the sexual distress measure, the Personal Distress Scale (PDS), were defined the same way, resulting in a responder value of -20 versus the baseline mean score of 65.05; this represents an improvement of 31%.

In the fibanserin Phase III project in premenopausal women with HSDD, responders on the FSFI desire domain or on the FSDS-R distress measure were defined similarly, but the anchoring used the mean difference (on the desire measure or distress
measure) between those self-rated on the PGI-IMPROVEMENT as unchanged vs those minimally improved. The logic here is that a responder is one who achieves the minimum clinically important difference (improvement) between no treatment and treatment. The responder value was the same when calculated as the difference between those self-rated as minimally improved vs those much improved. This method of analysis seeks to determine the minimum clinically important difference between optimal and suboptimal improvement with treatment.

By either the PGI-anchored method of defining a responder, or by anchoring for optimal sensitivity and specificity on the PBE, the responder value was 1.2 for the FSFI-desire domain, and -6 (+1, depending on trial and method) for the FSDS-R. Use of independent data sets on women with HSDD not in a clinical trial, or in different clinical trials derived the same responder value.[11] Seeking and finding such a confluence of values helps assure the clinical meaningfulness of the definition of a responder.

On the 2-to-10 FSFI desire domain score (of two items, each rated 1-5), which in its standard analysis is multiplied by a factor of 0.6, an improvement of 1.2 represents a change of 2.0 in the raw score, i.e., exactly two scale points. The baseline mean in the filbanserin program was 1.8 for the FSFI desire domain. Thus, the PGI-anchored responder value represents a 67% improvement.

FSDS-R mean values of about 30 have been found for untreated premenopausal and postmenopausal women with HSDD or FSAD (vs scores of 3-4 in women with no sexual complaints) [4]. Thus, a decrease of 6.0 points would represent a 20% improvement for patients on the mean.

In any case, a reasonably large ratio of efficacy with active treatment over placebo is required not only for statistical significance but also for clinical relevance. This may alternatively be registered on effect size (mean difference divided by the common standard deviation at baseline) of at least 0.2 (small) to 0.5 (moderate), a statistically significant difference in the proportion of responders (usually >10%; e.g., anchored on the difference between no change and minimal improvement or between minimal improvement and much improvement on the patient’s global impression of change), or an (adjusted) odds ratio close to or exceeding 1.5. In the FSAD trial of Berman et al. [47] for instance, a subgroup with both FSAD and HSDD was included. Their adjusted odds ratio (OR) was 1.09 or 1.14 (primary endpoints question 2, and question 4), which demonstrated that inclusion of such dually–diagnosed patients formed the efficacy issue within the overall analysis, not a high placebo rate. The ORs for FSAD-only patients were impressive, with values of 7.98 and 10.95 on the two respective questions (p<0.001).

An example that involves comparing the proportion of responders is use of the testosterone transdermal system for HSDD in post-surgically menopausal patients. In the two trials of TTS in such patients, the % responders on PFSF desire, defined by anchoring (at a cut point of 8.9) to optimize sensitivity and specificity using a patient benefit evaluation question (yes or no meaningful benefit from the treatment) to define responders vs nonresponders, was reported in the SM1 and SM2 trials as favoring TTS over placebo significantly at 45.7/34.8% and 42.2/25.1%, respectively. For PDS distress, similarly defined, responders were also significant in both trials: 51.3/34.6% and 49.2/33.9% respectively.

The level of improvement required to define a responder on PSFS desire and PDS distress based on the TTS FDA advisory committee slide set of December 2004 was 42% for PFSF Desire (>8.99/mean baseline of 21.3), -31% for PDS distress (<-20/mean baseline of 65.05).

**Remitters.** A higher standard, but the one with the utmost clinical meaning, would be for a new treatment for FSD to produce a meaningfully higher rate of remission than placebo. Treatments for FSD cannot be expected to produce a high rate of remission, given that FSD may often, or perhaps even usually, be not only biologically mediated in part but also mediated and/or perpetuated by psychosocial factors. However, all new treatments should be evaluated not only for ability to induce response but also for ability to induce remission. Clinically meaningful superiority to placebo on the rate of remission should be an achievable goal.

On the FSFI desire domain, for instance, the cutoff between women with HSDD and normal women has been found to be >3.0 on the derived version of the domain. That is, achieving a score of 3.6 would be required for remission. The baseline means in the filbanserin program were 1.8, so an improvement of 1.8 would represent a 100% (mean) improvement. The PFSF-DsR, the baseline value in the filbanserin program was about 30, and the established cutoff between HSDD and no FSD is 15. [4,30] This cutoff, representing a 50% group mean improvement, could be used to designate remitters.

**Ethical Issues.** Ultimately, somatic treatments will be prescribed mostly by clinicians not expert in FSD. Thus, an ethical issue arises as to how well they can screen/diagnose patients as candidates for such somatic treatments. To fill this need, acceptably simple (and brief) screening/diagnostic tools for non-expert clinicians must be well validated before approval of such agents. [64] A method for such validation is a one-way crossover study in which results of two diagnostic interviews are compared after a substantial sample of patients are screened using the new screening/diagnostic tool by a non-
trained, non-expert clinician, followed by diagnosis by an clinician expert/experienced in diagnosing FSD who is not permitted access to the non-expert’s diagnostic decision.

**FSD impairs quality of life.** However, it is, of course, non-life-threatening. Thus, the burden of proving a very high level of safety must be assumed by sponsors of treatments for FSD. No treatment for FSD should be recommended that has not stood the test of a large (multi-thousand-patient), long-term (at least 1-2 year) prospective evaluation of safety in the target population, using appropriate safety measures and appropriate controls, without causing life-threatening side effects or being associated with a rate in excess of placebo of laboratory abnormalities known or expected to be associated with long-term health risks, be they as specific to FSD as prolactin levels or as nonspecific to FSD as cholesterol levels. Thorough, perspicacious, scientifically valid risk management practices and studies must be assumed by sponsors after marketing, also, because of the significant multiple-effect to be expected for patient exposure compared to even large programs of clinical trials.

**Disclosure of results.** For the advancement of the field of treatment of FSD, it is incumbent on sponsors to disclose trial results. Proprietary concerns must be acknowledged and accepted. However, ordinarily in the past an ineffective treatment was seldom acknowledged in public. This can easily prevent or retard research funds from flowing from continuing fruitless mechanisms of action into useful directions.

Trial results (at least in the US) have become subject to disclosure in www.clinicaltrials.gov to be considered for publication in peer-review journals. This new standard has opened doors to disclosure. However, this remains to be seen, as the policy has been in effect only since 2007.

**Post-conduct issues.** Selective publication of positive results obscures difficulties to be expected in replication of trial results, and in effect, magnifies the efficacy of an agent. Thus, this is strongly discouraged in favor of full disclosure of all results in each phase of investigation of a new agent.

Post-hoc analysis of “evaluable patients” rather than intent-to-treat (ITT), and publication of the latter without the former, or failure to provide fair balance between conflicting analyses in publications, are also strongly discouraged. Like selective publication of positive results, these practices unfairly magnify efficacy expectations.

Issuing press releases before submitting results to peer-review publications, while a temptation for sponsors, serves only to negatively affect the view of the FSD scientific community and regulatory bodies alike about the utility of a new agent, and is to be discouraged.

**REFERENCES**

**VIII. CONCLUSIONS**

Fine-tuning outcome measures to directly assess the specific FSD construct under evaluation should lead to improved ability to demonstrate efficacy when such an effect exists. Future clinical trials should include clear population definitions, direct and indirect measures of the specific FSD construct, and procedures to allow generalizability of diagnosis and treatment to the general/target population.

REFERENCES
Understanding the anatomical, physiological, neurobiological and endocrine mechanisms behind sexual function, dysfunction and responses are of paramount importance. The interaction of these with psychological mechanisms is crucial in the field of sexual medicine. In this context, it is important to highlight that in women changes in physiology do not necessarily induce sexual dysfunction, while sexual problems may occur despite a normal sexual physiology.

The sexual response cycle has traditionally been described by the stages of sexual desire, arousal and orgasm. Since the early descriptions of these stages by Masters & Johnson [1] and later, Kaplan [2], the stages have been challenged [3]. Substantial advances have also occurred in the understanding of physiological aspects of sexual function and dysfunction, driven by more and more sophisticated methods of their measurement. Particularly, the application of neuro-imaging methods during the last years has significantly improved our knowledge of central mechanisms related to women’s sexual function and dysfunction. In this context, research on peripheral mechanisms and the interaction between central and peripheral mechanisms have given us a better understanding of feminine desire, arousal and orgasm. There is also an increased awareness of the interaction between physiological responses and psychological/behavioural factors and their influence on sexual function.

Due to ethical constraints and experimental limitations much of our knowledge has been obtained from animal studies, but an increasing amount of evidence is arising from human investigations.

In this context, the aims of this chapter are to describe:

1. Central and peripheral anatomical and physiological aspects of female sexual function and the influence of hormonal milieu, neurobiological factors and interaction with psychological factors;

2. Pathophysiological processes impacting on women’s sexual health. Since the 3rd International Consultation on Sexual Medicine has a number of chapters devoted to comprehensively describing the role of both animal models for studying women’s sexuality and (committee 7) the importance of the hormonal milieu on women’s sexual health (committee 23), the current chapter will not include any large debate about those items. Furthermore the pathophysiological processes are only described briefly as other chapters cover pathophysiological aspects of FSD more extensively (committee 9 and 25).

The chapter reviews existing literature with a focus on the most recent data and includes earlier studies if they are relevant for dealing with the concept of women’s sexual arousal and orgasm. The chapter includes animal studies when no human studies exist.

In accordance with the consultation criteria, wherever possible the basic principles of evidence-based medicine have been used in the evaluations on the included studies. We have primarily included papers which have been through a peer review process. However, the current guideline (ICUD guidelines) for grading level of evidence is often difficult to apply on animal and laboratory studies investigating basic anatomy and physiology.

When describing the physiological fundament of arousal and orgasm it is noteworthy that it is difficult to find out a comprehensive definition for female sexual arousal [4]. It has to be subdivided into an objective
and a subjective part, and is in the literature often based on what is considered dysfunctional. Thus, sexual arousal could be described as “a combination of objective and subjective signs; the bodily reactions as vulvar swelling, vaginal lubrication, heavy breathing and increased sensitivity of the genitalia combined with the subjective experience of feeling pleasure and excitement”. Orgasm, in contrast, may be defined as “a variable, transient peak sensation of intense pleasure, creating an altered state of consciousness, usually accompanied by involuntary, rhythmic contractions of the pelvic striated circumvaginal musculature, of the with concomitant uterine and anal contractions and myotonia that resolves the sexually induced vasocongestion (sometimes only partially), usually with an induction of well-being and contentment” [5].

B. DEVELOPMENT AND DETERMINATION OF SEXUAL PHYSIOLOGY AND ANATOMY

Understanding the physiology of adult female sexual behavior requires knowledge of events that occur early in development and the understanding of the neural control of female sexual behavior includes consideration of those brain regions essential to motivation, consummation and reward. The basic principles of the neural control of sexual behavior apply to an impressively broad range of species, from fish, lizards and birds to rodents, guinea pigs, dogs, rabbits, sheep and non-human primates. The importance of the biological mechanisms regulating reproduction in animals is much greater than that in humans. Stereotyped sexual behavior and coitus occurs normally only in estrous, whilst human copulation can occur during the entire ovarian cycle, and even during pregnancy and in the postmenopausal condition, demonstrating relative freedom from hormonal control [6] and is influenced by cognitive, cultural, and social factors as. Nevertheless, there is still value in understanding the basic cellular mechanisms establishing the physiological and neuronal parameters upon which other variables act to influence human female sexuality. Often only studies in animals can provide this insight by allowing observation, experimentation and hypothesis testing to occur. Reviewed here is the current understanding of the biological principles of sexual behavior at the most fundamental level.

I. SEX DETERMINATION AND DIFFERENTIATION

In mammals, sex is determined by a single gene on the Y chromosome, the Sry, for sex determining region of the Y chromosome, with codes for the protein tdf, for testis determining factor. The tdf is a transcription factor which initiates a cascade of gene expression and protein products that will direct the development of the bipotential gonadal anlage towards a testis [7]. In the absence of the Sry gene, this same gonadal anlage will become an ovary. The brain is also sexually differentiated in males and females by gonadal steroid hormones and this process occurs during a restricted developmental window termed the sensitive period. In rodents the sensitive period is during the last few days of gestation and first week of life and the critical hormone for masculinization is estradiol derived from testicular androgens. In primates, including humans, the sensitive period is largely prenatal, beginning in the 2nd trimester, and the critical hormone for masculinization is testosterone. At first consideration these differences might make it seem that rodents and humans are so different they are not worth comparing, but what really matters is the cellular mechanisms by which the steroids are acting to differentiate the brain. Estrogens and androgens often converge on the same cellular mechanisms and only by identifying those mechanisms can we determine whether there is a commonality is steroid hormone action in the brains of humans and animal models.

II. FEMALE SEX BEHAVIOR IS CONTROLLED BY A HORMONALLY RESPONSIVE NEURONAL NETWORK

Sexual behavior is a simple phrase for a complex set of actions that includes motivation to seek partners, evaluation of critical stimuli, motor execution of the behavior and rewarding physiological processes that reinforce the behavior so it will be repeated again. Each component of the behavior involves multiple brain regions but we can identify specific critical nodes that are essential for gating information in order to produce a functional behavioral output. Not surprisingly, neurons in each of the critical brain regions express high levels of steroid receptors, thereby creating a hormonally sensitive neuronal network (Figure 1). The fundamental core of the network is those regions that control motor execution of the behavior. In rodents, the female adopts a sexually receptive posture, referred to as lordosis, which allows the male to mount and intromit. We know that the ventromedial nucleus (VMN) of the hypothalamus is an essential brain region for the executing of this process; if it is damaged or destroyed the female will not exhibit sexual receptivity. The estrogen receptor expressing neurons of the VMN then project to the estrogen sensitive neurons of the midbrain central grey and those neurons project on down to the spinal cord and activate the motor neurons innervating the critical muscle groups on the back. The sensory information associated with mating is then received at the spinal cord and passed on back up the line to activate the same regions as well as those associated with reward, such as the...
ventral tegmental area and the nucleus accumbens. The VMN receives critical input from the amygdala, which has in turn received olfactory information, an important evaluative signal in the rodent world. The preoptic area (POA) is an additional critical hormonally sensitive region that shares reciprocal connections with the VMN and other brain regions relevant to mating. The POA is considered the critical area for male sexual behavior, but influences female behavior as well, in part by exerting an inhibitory influence over its expression (see for review [8]).

Because the motor patterns involved in male versus female sexual behavior are so notably different, particularly in our animal models, there is a tacit assumption that separate neuronal networks exist within the brain to specifically regulate the expression of each. However there has been no male versus female circuit identified to-date, and it maybe that the reality is the neuronal underpinnings of male versus female sex behavior are largely the same but critical nodes are weighted differently. The weight of a particular node is a function of the number of neurons, the phenotype of the neurons and the synaptic connections of the neurons. In other words, the sex differences we observe in the brain are the weighting that pushes the network towards one or the other behavioral output.

III. THE ORGANIZATIONAL / ACTIVATIONAL HYPOTHESIS OF SEXUAL DIFFERENTIATION OF THE BRAIN.

It was 50 years ago this year that an iconic paper was published by Phoenix, et al. [9] which provided a framework upon which all subsequent research into sexual differentiation of the brain has been hung. Referred to as the Organizational / Activational Hypothesis, this simple postulate states that early actions of gonadal steroids act to organize the neural architecture regulating sexual behavior and that secretion of gonadal steroids in adulthood will activate this previously organized substrate to permit sex-specific sexual behavior in response to appropriate stimuli (Figure 2). The difference between males and females is achieved by differences in the hormonal profile early in development and this is achieved by copious production of testicular androgens in the late gestation fetal male contrasted with the quiescent ovary in the female. The onset of testicular steroidogenesis in the fetus marks the beginning of the sensitive period for sexual differentiation of the brain. Shortly after birth the testis ceases androgen production and both males and females are devoid of circulating gonadal steroids until the onset of puberty weeks (rodents) or years (primates) later. Two critical predictions of this postulate are that reversing the hormonal milieu of adult males and females neonatally will permanently alter their behavior in adulthood and that reversing the hormonal milieu of adult males and females will not reverse adult behavior.

The role of estradiol in the masculinization of sexual behavior in the rodent is undisputed but has recently been challenged as being the sole mediator of the differentiation process [10,11]. Converging evidence suggests that androgens are also a key mediator under normal circumstances, and although the entire process of differentiation can be completed with exogenous estradiol treatment, the natural course of events involves androgens as well. This highlights the complexity of hormonal modulation of the differentiation process and emphasizes the need to understand the mechanisms of hormone action as opposed to just what the hormones are. This is particularly important when we consider the hormonal modulation of sexual differentiation in primates, where the evidence for a critical masculinizing effect of androgens is undisputed, and a role for estrogens considerably more controversial (see for review [12]). Consistent with the importance
of androgens and a lesser role of estrogens, human males with a mutated gene for the estrogen receptor or the aromatase enzyme are phenotypically and psychologically male whereas genetic males with a mutated androgen receptor that renders them completely androgen insensitive, are psychologically female. This does not negate the value of animal models to understand sexual behavior in humans, as the cellular mechanisms initiated by estradiol versus testosterone frequently converge. Whether this is the case for sexual differentiation of the primate brain is currently unknown. So, what are the cellular mechanisms by which steroids induce permanent changes in the developing brain?

IV. MECHANISMS ESTABLISHING SEX DIFFERENCES IN THE BRAIN RELEVANT TO SEXUAL BEHAVIOR

As discussed above, sex differences in the brain occur at the critical nodes regulating sexual behavior and are considered the neuronal underpinnings of male versus female sexual behavior. The cellular mechanisms by which steroids act on the developing brain to induce sex differences can be categorized into four key processes:

1. cell birth
2. cell migration
3. cell death
4. cell differentiation.

The latter process includes the neurochemical phenotype and synaptic patterning of the cell, both of which are essential to its role in the integrated neuronal network and are a major component of the weighting towards male versus female sexual behavior. The second major component is cell death. Some nodal points in the network are larger in the male versus female brain or vice versa. In each instance where this occurs, it has been determined that males and females begin with the same number of neurons, but they then selectively die in one sex of the other. For critical nodes in the control of sex behavior, the most celebrated sex difference is the size of a subnucleus in the preoptic area called the sexually dimorphic nucleus, or SDN. The number of neurons in this region is 5-7 times greater in males.

Figure 2: Sexual Differentiation of the Brain: Organizational and Activational Effects.

The brain is a bipotential organ that adapts a masculine or feminine phenotype as a function of developmental exposure to gonadal steroid hormones. In males, the embryonic testis produces high levels of testosterone which acts on the brain to organize it as male, which then determines the brains responsiveness to steroid post-puberty to direct sex specific behavior. The organizational effects occur during a developmental sensitive period that is operationally defined in rodents as the onset of testicular androgen secretion and the offset as the loss of sensitivity to exogenous testosterone in females. In humans, the sensitive period begins in the second trimester and appears to be largely completed by birth (E = embryonic, PN = postnatal day, T = testosterone, E2 = estradiol). Courtesy of McCarty M.
Similar sex differences are found in other nodes in the sex behavior network but none are as dramatic as that of the SDN. The cellular mechanisms of the differential cell death are only just beginning to be understood but involve the steroid hormone estradiol inducing or repressing the process of apoptosis, also called naturally occurring cell death (see for review [13]). An analogous nucleus has also been found in the sheep and human brain and associated with sexual preference in both cases [14], but there is little evidence for a roll for this subnucleus in sexual behavior per se.

Returning to the issue of synaptic patterning of the cell, here the evidence is far greater that the number of inputs to a particular region exerts an important effect on the execution of sexual behavior. Quantifying synaptic patterning is a difficult and tedious process and to be done correctly requires the use of electron microscopy. A series of detailed and elegant studies in the 1980’s by a group of Japanese neuroendocrinologists established a firm foundation from which others have built (see for review [15]). The process is now considerably simplified by focusing on one particular type of synapse, the dendritic spine synapse. Dendritic spines are small protrusions off of neuronal dendrites and are the principle site of excitatory (glutamatergic) input. The beauty of dendritic spines is that they can be quantified at the light microscope level or indirectly by measuring an essential protein for spines, called spineophilin. In the preoptic area of rodents, males have two to three times more dendritic spine synapses per unit of dendrite than females and this sex difference is established during the first few days of life by the higher gonadal steroids produced in males. The cellular mechanism underlying the increase in dendritic spines synapses in males is a surprising one, the increased production of a prostaglandin called PGE, which initiates a cascade of signal transduction that promotes the formation and maintenance of spines [16]. Prostaglandins are well known for their role in inflammatory processes and induction of fever. Whether prostaglandins mediate masculinization of sex behavior in primates is currently unknown, but if they do, it has important implications for the potential effects of medications designed to inhibit prostaglandin production, which includes multiple over-the-counter analgesics such as aspirin.

There is an equally profound sex difference in the VMN, the major brain region controlling female sexual behavior. Here too, males have two to three more dendritic spine synapses, and the dendrites themselves are longer and branch more frequently than in the female brain. This sex difference is also a function of gonadal steroids that are higher in males during the first few days of life, the critical period. However the mechanism establishing the sex difference is distinctly different in this brain region, involving a rapid non-genomic activation of a membrane kinase that promotes the release of glutamate from nerve terminals which then induces the formation and maintenance of dendritic spine synapses [17]. Key proteins that suppress the outgrowth and branching of neurites are also suppressed in the male brain, allowing for more exuberant growth [18]. Both these cellular processes coordinate to influence the weighting of excitatory input to this key brain region for female sexual behavior.

### IV. SUMMARY

The cellular processes establishing the dynamics of the neuronal networks controlling sexual behavior are still being established but some generalized principles are becoming clear. One fundamental principle is that there are indeed multiple processes. By having multiple mechanisms involved in differentiating the male from the female brain at distinct nodes throughout a neuronal network, there are many more potential points of variation. Genetic differences in specific kinases, enzymes and/or receptors can all be important contributors to the manner in which hormones exert organizational influences. As a result, the phenotypic variability is far greater than that that would be achieved by a single unifying mechanism of hormone action. There is no male brain versus female brain, instead we have a mosaic of overlapping and varying degrees of masculinization and feminization within one brain and the potential that any individual male or female are highly similar in some nodes on the network but highly divergent at others, and which nodes those are will vary from one person to the next. Ultimately, the variety of cellular mechanisms of steroid hormone action in the developing brain contributes to individual variability in adult sexual behavior.

**Box 1**

- Majority of knowledge on sex differentiation of the brain is obtained from animal studies
- The brain is sexually differentiated early in development in response to gonadal steroid hormones
- Masculinization and feminization are regulated by separate cellular mechanisms in different brain regions
- Adult sexual behavior is controlled by a hormonally response neural network
- Variability in the mechanisms of hormone action on the developing brain contribute to variability in adult sexual behavior.
C. CENTRALLY-BASED PHYSIOLOGY OF WOMEN'S SEXUAL FUNCTION

The central nervous system mechanisms that govern female sexual behavior are largely unexplored in humans. Most descriptions are based on neurophysiological investigations in rodents. In particular, lordosis, has served as an important animal model for neural control of female sexual behavior [8,19-23]. As for sexual development, mating habits of many mammalian species, human copulation is characterized by relative emancipation from hormonal control [24] and a highly flexible and resourceful sexual behavioral repertoire [25]. There is strong evidence, especially from neurological patients, that human sexual behavior is guided by the cerebral cortex [26-28]. Given the vast differences in cerebral development between humans and virtually any other animal species, it is questionable if rodents should serve as a model for all aspects of female sexual behavior. Indeed, taxonomic differences between primates and non-primates in mating-related functional neuroanatomy have been shown [29].

Human brain function can be assessed relatively easily using neuroimaging techniques like positron emission tomography (PET) and functional magnetic resonance imaging (fMRI). These research methods, which have become widely available over the last decade, are potentially powerful tools for exploring the woman's brain with regard to sexual function [30].

I. NEUROIMAGING METHODS

1. NEUROVASCULAR COUPLING

PET and fMRI are functional neuroimaging methods that measure metabolic or vascular parameters. The physiological basis of these methods is postulated to reflect the fact that local changes in metabolic demand are coupled with local blood flow and blood oxygenation changes [31].

a) Positron Emission Tomography

The principle behind PET is the use of radioactive positron-emitting isotopes. These isotopes are tagged to molecules of a biological compound of interest, which are introduced into the human body by intravenous injection. The most widely applied radioactive "tracer" for neuroimaging purposes is \(^{15}\)O-H\(_2\)O (oxygen-15 labeled water) and its distribution is a measure of regional cerebral blood flow (rCBF) [32].

b) Functional Magnetic Resonance Imaging

By far the most popular neuroimaging technique is BOLD (blood oxygenation level-dependent) fMRI, which uses a rapid dynamic series of MR images to assess changes in MR signal intensity over time caused by changes in brain activity. Changes in MR signal occur because blood flow responses to neural activity exceed metabolic demands [31]. This leads to an increase in the local concentration of oxygenated hemoglobin compared to deoxygenated hemoglobin, which, because of their different magnetic properties, increases the local MR signal [33].

2. VISUAL SEXUAL STIMULATION (VSS) AND NEUROIMAGING

The stimulus most used to elicit sexual arousal in PET and fMRI studies is VSS, using erotic or sexually explicit photos or film excerpts. A few factors have to be taken into account when interpreting brain responses related to the processing of VSS in general and sexual arousal in particular:

a) Although experimental studies support that men generally respond more to VSS than do women, there is substantial variability in this effect; A potential source of variability is the type of stimuli used which may not be of equal interest to both men and women whose preferences can depend upon the activities and situations depicted [34,35];

b) The activities and situations depicted. VSS type and length varies substantially between studies, ranging from 3-second photos of nude people presented to 3-minute XXX-rated film excerpts;

c) Considerable variation is seen with respect to the "control stimuli", which should match the VSS for elements like luminance, number of subjects depicted in the excerpt, and emotionality. It has been shown that sound is not critical to a VSS to elicit a sexual arousal response in women. Thus, many studies have used silent VSS and control video to avoid the variable of having different types of audio stimuli [36].

d) Correlations between measures of sexual arousal and brain activity are not always performed.

II. VSS-INDUCED BRAIN RESPONSES. WOMEN'S AROUSAL PHASE.

Initial studies of sexual arousal were first undertaken in men [37,38]. Subsequently, similar fMRI studies have also been conducted in healthy women by several different research groups and these studies document activation in multiple cortical and subcortical areas of the brain during VVS.

Park et al performed a study dedicated solely to sexual arousal in healthy female volunteers [39]. This fMRI study, which included only 6 subjects,
found involvement of extrastriate visual areas in the occipito-temporal cortex, the lateral prefrontal cortex, the insula, the cingulate cortex, the inferior temporal lobe, the thalamus, and the basal ganglia. This activation pattern was based on the comparison of brain responses to “erotic video” versus “documentary video”. All subjects perceived significantly more sexual arousal during the erotic video, but no correlations were computed between perceived sexual arousal (PSA) and brain activity. They pointed out that many of the sites of activation were the same as previously demonstrated in male subjects during sexual arousal [38]. Recently, a very similar result was reported in a cohort of 9 healthy women that served as healthy controls for women suffering from major depression [40]. Unfortunately, the experimental paradigm, data analysis, and data reporting employed in both studies were clearly suboptimal.

Maravilla and Yang [30] also studied a group of healthy heterosexual women without sexual difficulties and found activation in many of the same areas described by Park and colleagues [39] (figure 3A). In addition, there was activation in the amygdala and hypothalamus, areas not described by Park et al [39] but subsequently shown to occur by other fMRI investigators (though more prominently in men than in women, see section C.II.3) [41,42]. Importantly, the study by Maravilla and Yang [30] demonstrated decreased activation in bilateral temporal lobe with the VSS arousal stimulus, at sites that have been associated with moral judgement or embarrassment (figure 3B). This group hypothesized that this decreased activity was due to lowering of activity in sites that normally exhibit active inhibition to a sexual stimulus. Such inhibitions may keep us from acting out in response to sexual stimuli at inappropriate times or in inappropriate situations. However, with sexual arousal during appropriate situations, these inhibition areas may have decreased activity, thus allowing one “permission” to act on sexual urges. A possible inhibitory influence of the temporal cortex over sexual arousal has been shown in men [38,43], and was recently confirmed in women [44]. They demonstrated that the entorhinal cortex (part of the temporal cortex) was more activated in women with hyposexual desire than in healthy heterosexual women, when watching VSS stimuli. See Table 1 and figure 4 for summary of brain areas activated during sexual arousal.

1. EFFECT OF STIMULI-MODE ON MEASURED BRAIN RESPONSES

VSS duration and mode (pictures vs. video) is likely to influence brain responses. Maravilla and Yang [30] and Arnow et al. [44] used long periods of VSS (>1 minute film excerpts). Karama et al. [42] did the same using a mixed male-female subject cohort
where female subjects were analyzed separately. In all three studies the erotic video induced increased BOLD signal in the extrastriate visual cortex, the inferior parietal lobule, the orbitofrontal cortex, the anterior cingulate cortex, the ventral striatum, and the amygdala, compared to a control video. In men, largely the same pattern of activation is found with similar VSS periods [37,45]. Differences between studies (like the midbrain activation in Arnow et al. [44] (which was not found in the other two studies) may have been due the fact that the control stimuli were quite dissimilar (“neutral” vs. “sports”). Moreover, the menstrual phase, which is very likely to affect cerebral function (see later section), was not taken into account by Arnow et al [44] and Maravilla and Yang [30], whereas Karama et al. [42] only included women outside their ovulatory period. PSA was assessed in two studies [42,44], and vaginal photoplethysmography (VPP), an objective measure of sexual arousal, in one [44]. only Arnow et al. did a whole-brain correlational analysis between BOLD signal and PSA, which confirmed the activation pattern found with the VSS-sports contrast [44]. Karama et al. restricted their search volume to the hypothalamus [42]. Nevertheless, no significant correlation between PSA and hypothalamic activity was found in either study. The VPP measurements had rather distinct temporal dynamics in Arnow’s healthy control group, showing increased vaginal blood flow towards the end of the experiment.

Figure 4: Surface rendered brain from same study as in 3 showing areas of activation mapped onto representative brain for better spatial appreciation showing same areas of activation as viewed from surface of brain. Courtesy of Maravilla K & Yang C
However, this objective measure did not explain much of the variance in BOLD signal [44].

Hamann and colleagues [41] exposed their (male and female) heterosexual subjects to relatively brief 4s-presentations of erotic (nude individuals or couples) and neutral photos. They focused their analyses on the hypothalamus and both amygdalae. PSA ratings were highest for the couples stimuli, but no correlations with BOLD signal were computed. In none of the apriori defined regions did women have a stronger BOLD signal during the erotic stimuli over the neutral stimuli. However, as described before, longer VSS periods with videos consistently activated the female amygdala [30,42,44], and in one instance also the hypothalamus [30]. This suggests that in heterosexual women the amygdala, and probably also the hypothalamus, are not sensitive to brief periods of still VSS. Outside these regions of interest, women had increased BOLD signal in the extrastriate visual areas, the inferior parietal lobule, the anterior cingulate cortex, and the ventral striatum, which they shared with men [41]. This pattern showed substantial overlap with that found using longer periods of VSS using film excerpts [30,42,44].

2. SPECIFICITY OF VSS-INDUCED BRAIN RESPONSES

Sexual arousal has a distinct quality, which should be reflected somehow in terms of brain function. However, many, if not most, of the VSS-induced brain responses are readily found in any given “emotional” neuroimaging experiment. Consider, for example, the most consistent and robust VSS-induced brain activation in the extrastriate visual areas of the occipito-temporal cortex [30,42,44]. This is a well-known (epi)phenomenon in visual paradigms that reflects visual attention processes [46] and that occurs most readily when emotionally laden stimuli are used [47,48]. Likewise, a wide range of tasks activate the anterior cingulate cortex, especially those that require enhanced attention and/or response selection [49,50]. These activations are hallmarks of visually-induced emotional states, but not of sexual arousal per se.

Two interesting mixed male-female cohort studies have attempted to control for the “contaminating effects” of general emotional arousal and attention [51,52]. These studies did not consider the female subjects separately, but their results are relevant to this discussion. Stark et al. designed an experiment with erotic, neutral, and disgusting pictures. The contrast between erotic and neutral pictures resulted in a large cluster of activation in the extrastriate visual areas and the inferior parietal lobule, as well as smaller effects in the hypothalamus, ventral striatum, midbrain, and amygdala. However, when compared to disgusting pictures, which also possess high emotionality, erotic pictures only rendered activations in the ventral striatum, hypothalamus, and midbrain significant [51]. Moreover, the ventral striatum was found to be the main region related to sexual pleasure across groups and stimuli [51]. Walter et al. followed a similar line of thinking, including non-erotic bodily and non-bodily emotionally-laden stimuli. In addition, their rating scales discriminated between sexual intensity, general emotional arousal, and valence. They showed that when VSS was controlled for general emotional arousal and bodily content, only the ventral striatum, caudal anterior cingulate cortex, and superior parietal lobule were significantly correlated with sexual intensity [52]. Figure 5. These studies underscore the importance of sophisticated experimental designs to get closer to the heart of sexual arousal.

3. GENDER DIFFERENCES IN VSS BRAIN RESPONSES

Clearly one of the most exciting discoveries about human sexual brain function obtained with neuroimaging is that VSS (brief, photos) produced greater neural activations in men than in women in the hypothalamus and both amygdalae, even when women reported greater arousal [41]. Male-biased VSS-induced activation in the hypothalamus [42] and amygdala [53] have been reported by other studies. It is fascinating that similar sexual behavioral output, i.e. similar levels of sexual arousal reported by male and female subjects, is associated with fundamental neurobiological differences. Figure 6 & 7. One explanation is that in men visual stimuli have fast access to primordial systems underlying the sexual response, and that this reflects men’s higher propensity to identify cues for sexual opportunity [41], especially in the visual domain. In both the amygdala [30,42,44] and the hypothalamus [30] women showed significant activation only with longer VSS samples, providing further support for the idea that in men this ancient system is more tuned towards sexual cues. A recent fMRI demonstrated that very brief (33ms) VSS, which can not be processed consciously, reliably activated the male amygdala [54]. This would support the theories that women in general take a more thoughtful approach with regard to sexual encounters, as opposed to the more instinctive nature of the male sexual response.

4. SOME CONCLUSIONS FROM FEMALE VSS STUDIES

Consistent effects across studies were found in the extrastriate visual areas, the inferior parietal lobule, the anterior cingulate cortex, and the ventral striatum. However, only the ventral striatum can be convincingly linked to female sexual arousal [51,52]. An important key to female sexual arousal may be buried deep inside the primordial brain in areas like
Figure 5: Common and interacting regions in sexual and emotional processing.

(a) Red voxels indicate regions with a significant interaction in processing of sexual arousal and valence, as revealed by the contrast [positive > negative bodily-emotional pictures] > [positive > negative non-bodily-emotional pictures] at p < 0.05, corrected, k>10. Significantly stronger effects in the first contrast were found in the perigenual anterior cingulate (pgACC) and bilateral occipital cortex (LOC). Blue voxels indicate significant regions for the conjunction of the contrasts [bodily > non-bodily-emotional pictures] and [non-bodily-emotional > non-bodily neutral pictures] at p<0.05, corrected, k>10. In resulting regions, including amygdala, dorsal medial prefrontal cortex DMPFC, LOC, tectum and thalamus, activity during non-bodily emotion processing was found to be lower than during processing of bodily stimuli but higher than during neutral picture presentation, reflecting rather general effects of emotional intensity.

(b) Bar diagrams plot mean percentage signal changes for bodily, non-bodily-emotional and neutral conditions in these common regions. With permission from [52]
Figure 6: Regional activation maps. Activation contrast for the couples stimuli versus fixation (a–c) and the couples stimuli versus neutral contrast (d–f) (P < 0.005, minimum five contiguous voxels). White circles indicate the approximate location of the a priori regions of interest (ROIs); the left and right circles and upper and lower circles show the left and right amygdala ROIs on the coronal and axial views, respectively. The medial circles show the hypothalamic ROI, which is not visible on the axial views at z = −20. Color bar indicates maximal Z values. Note that color scale bars vary from image to image. The right hemisphere is on the right of the coronal images and bottom of the axial images.

(a) Left, coronal image (y = 0) showing greater bilateral amygdala and hypothalamic activations for males versus females for the couples versus fixation contrast. Right, axial view (z = −16) of the same contrast, showing additional right cerebellar activation.

(b) Couples versus fixation contrast for males, at the same coronal and axial views. (c) The same contrast and views for females. (d) Left, coronal image (y = 0) showing greater bilateral amygdala activations for males versus females for the couples versus neutral stimuli contrast, within those regions showing greater activity for males versus females for the couples versus fixation contrast (at P < 0.10). The region of greater hypothalamic activation for males is not visible at this coronal level. Right, axial view (z = −20) of the same contrast, showing primarily left-sided amygdala activation.

(e) Couples versus neutral stimuli contrast for males, at the same coronal and axial views. (f) The same contrast and views for females, showing an absence of differential activity in the ROIs. With permission from [41]
the hypothalamus and the amygdala, which seem to be less sensitive to VSS in women than in men.

A major issue is that seemingly opposite emotional states, such as pleasure and pain [55], or sexual pleasure and disgust [51], show remarkable neurobiological overlap. For VSS-based neuroimaging experiments, which often make use of rather rigid paradigms this may be particularly relevant: under those circumstances sexual arousal does not necessarily imply sexual pleasure per se, but could just as easily cause feelings of guilt, shame or frustration. Technical limitations of neuroimaging in terms of temporal and spatial resolution, suboptimal experimental paradigms and/or analyses further complicate matters.

IV. CLITORIS STIMULATION, CLITORALLY-INDUCED ORGASM AND BRAIN ACTIVATION

1. EXPERIMENTAL DESIGN

Georgiadis et al. [56] reported the results of a series of [15O]-H2O PET experiments in women experiencing sexual clitoral stimulation and clitorally-induced orgasm. They included 12 healthy heterosexual volunteers whose male partners manually performed clitoral stimulation during the experiments. During the PET experiments, rectal pressure (RP) was measured and subjective ratings of sexual arousal (PSA) were obtained to verify women’s reported orgasms. An overview of the experimental tasks that were performed is given in figure 8. The temporal resolution of this PET experiment was roughly one minute, which means that the acquired activity reflected all peri-orgasmic events.

2. SOMATOSENSORY PROCESSING OF CLITORIS STIMULATION

Compared to a passive non-sexual resting state, increased rCBF during sexual stimulation of the clitoris was found in bilateral primary somatosensory cortex (SI), the left secondary somatosensory cortex (SII), and the left supplementary motor area [56].

SI is somatotopically organized, and Penfield in his classical experiments found the genitals to be represented in the paracentral lobule on the interhemispheric surface, ventral to the “foot-region” [56]. Recent neuroimaging studies in men indicate that this location may not be correct, and that the genital portion of SI is on the dorsal convexity of the postcentral gyrus [57-59]. Georgiadis et al. [56] showed that this is also the case for the clitoris. SII, located in the inferior parietal lobule, serves a variety of higher level sensory modalities [60,61]. Sensory stimulation in the pelvic region readily activates SII, for instance during distension of the anal canal.

Figure 7: Average fMRI signal change for males and females for couples, opposite-sex and neutral stimuli (vs. fixation baseline), for ROIs in the left amygdala, right amygdala and hypothalamus. Couples = couples stimuli; O.S. = opposite-sex stimuli; Neutral = neutral stimuli. Error bars indicate s.e.m. With permission from [41]
Figure 8: (A) Scan order and time span of the experiment. Scans (black lines) lasted 2 min. Consecutive scans were made with an 8 min interval (grey line). (B) Main effects of the present study. The glass brain shows an F-map (P < 0.05, corrected), giving an overview of the brain regions involved in any of the experimental conditions. This F-map is also depicted in colour scale, superimposed on sagittal sections of a standard single-subject T1-weighted MR image (SPM99). The location of the section relative to the midline is indicated in the bottom right corner of each section (negative value for x, left hemisphere). Bar graphs in the top right corner of each section indicate how the response in the centre of significant brain clusters varied during the four conditions. This average signal change for each parameter relative to the mean normalised activation over all scans is expressed as a percentage.

[62,63], or non-erotic stimulation of the penis [59,64]. In addition, VSS activates the inferior parietal lobule, which contains SII, in both men [43,45], and women [41,42,44], possibly as a result of the sensory input caused by genital arousal [45]. Interestingly, women with vulvar vestibulitis syndrome had more SII activation in response to pressure on the posterior vaginal vestibulum than did healthy controls. This is suggestive of augmented central processing of sensory afferent information in these patients who experience vaginal pain [65]. Thus, it seems that SII activation reflects the context of the sensory stimulus, "weighting" the salience of somatosensory stimuli before they enter the realm of consciousness.

3. CLITORIS STIMULATION AND ORGASM DECREASE BLOOD FLOW IN AMYGDALA AND TEMPORAL CORTEX

Relative to the non-sexual resting state, there were rCBF decreases in the inferomedial temporal lobe including the amygdala during clitoral stimulation and during orgasm (Figure 9). Activity levels in the left parahippocampal gyrus and anterior temporal pole decreased even further from clitoral stimulation to orgasm [56]. In the section on VSS it was stated that the temporal lobe probably exerts a tonic inhibition on sexual arousal [30,66], and that successful release of this inhibition may be imperative in the event of sexual opportunity. This was confirmed by a highly significant inverse relationship between PSA ratings and temporal lobe blood flow [56]. Clinical findings of temporal lobe lesions causing hypersexuality [67], and temporal lobe epilepsy-associated sexual (or even orgasmic) auras [68,69] provide further support.

The female amygdala readily responded to VSS, though only to long periods of VSS [30,42,44,68]. However, Georgiadi et al. found clear deactivation in the amygdala in response to sexual genital stimulation in men and women alike [56,58,70]. Euphoric mental states such as cocaine rush [71], but also romantic love [72] are also characterized by attenuated amygdala (and ventromedial temporal lobe) activity. These 'rush' states share characteristics with the rush experienced during sexual genital stimulation. This switch in amygdala activity may be crucial for sexual encounters to take place. This is also supported by the findings that patients with chronically enhanced amygdala activity, for instance as a result of war- and combat-related Post Traumatic Stress Disorder [73], experience more sexual difficulties than healthy controls [74].

4. ORGASM DECREASES PREFRONTAL BLOOD FLOW

Orgasm induced strong rCBF decreases in the left orbitofrontal cortex (OFC) and ventromedial prefrontal cortex (vmPFC), in both men and women [56,58,70]. The prefrontal cortex is called OFC where it overlies the orbita, and vmPFC where it borders the midsagittal plane. In women, the largest blood flow decrease in the vmPFC was measured between the non-sexual resting state and orgasm. For the OFC, however, the most prominent blood flow decline was between clitoral stimulation and orgasm (Figure 10) [56].

The PFC in general is instrumental in social behavior and executive function. The vmPFC constitutes a crucial part of a neural network underlying self-monitoring and self-referential thought [75]. Deactivation in a network of midline cortical structures, including the vmPFC, is a rather common phenomenon in neuroimaging studies, and is most prominent when scans during passive, low arousal states are compared with scans during goal-directed behavior that usually entail higher arousal levels [76]. Thus, the vmPFC deactivation is unlikely to represent orgasm-specific neurobiology.

The OFC deactivation certainly connects to sexual consummation in a much more specific way. Subjects recorded the highest OFC blood flow levels not during the non-sexual resting state, but during clitoral stimulation and failed orgasm attempts, during which they perceived high sexual arousal (Figure 10) [56]. The OFC consists of functionally distinct lateral, middle, and medial parts [77]. The peak of the orgasm-related OFC deactivation was located on the border of lateral and middle OFC. The middle OFC is believed to specifically encode hedonic experience, as it becomes activated with increasing satiation and subjective pleasantness, and deactivated with feelings of satiety [78,79]. The lateral OFC is strongly linked to urge suppression, shown both by functional neuroimaging studies [80,81], and by studies evaluating the effects of OFC damage [82,83]. Georgiadis et al. suggested that the activity level of the OFC reflects conscious control over the sexual urge: high control during clitoral stimulation (because orgasm was not allowed) resulted in increased rCBF, whereas decreased rCBF during orgasm could indicate the release of that conscious control. The failed orgasm attempts, too, were associated with increased rCBF in the OFC [56], providing strong evidence that OFC activity levels significantly determine sexual behavioral outcome. Possibly, the loss of conscious control and the release of tension that people report when they describe an orgasmic experience [84] relates to this decreased OFC activity.

A major limitation of the PET technique is the restricted temporal resolution, which prohibits parceling out the blood flow responses related to different peri-erotic events is not possible. Therefore, exploring the precise function of the OFC in female sexual behavior, and how it relates to psychosexual disorders, will be an important research direction in the near future.
Figure 9: t-Contrasts: clitoral stimulation and orgasm vs. rest. The significance threshold in this figure is $P < 0.001$, uncorrected. For each comparison, a t-map of rCBF changes is depicted (glass brain: left side of the figure). These rCBF increases (red scaling) and decreases (blue scaling) are also superimposed on horizontal sections of a standard single-subject T1-weighted MR-image (SPM99). The top row shows the result for stimulation vs. rest, the bottom row for orgasm vs. rest. The location of each section relative to the anterior commissure (AC) is indicated in the bottom right corner of each section (negative value for $z$, ventral to AC).

5. ORGASM-RELATED ACTIVITY OF THE CEREBELLMUM

The left anterior lobe of the cerebellar vermis and adjacent deep cerebellar nuclei activate during orgasm, in men and women alike [56,58,70]. Women showed a strong positive association between blood low in the left anterior vermis and rectal pressure luctuations [56], a measure of pelvic and abdomi- nal muscular contractions. Other investigators have demonstrated similar cerebellar activation in women performing voluntary pelvic motor contractions in a non-sexual context [85,86].

The vermis takes part in axial motor control, but also in autonomic regulation and affect [87]. Indeed, orgasms are characterized by substantial cardio-vascular and respiratory arousal [84], and vast emo- tional changes [88]. Yet, the precise nature of the cerebellar contribution to orgasm remains unclear. Table 2 shows different brain areas which are acti- vated/deactivated during rest, clitoral stimulation or orgasm.

6. PAUCITY OF SUBCORTICAL EFFECTS

VSS often induced significant activity in subcortical parts of the brain. Georgiadis et al. [70] found significant subcortical effects only through correlational analysis with the PSA ratings. A positive correlation between the subjects’ PSA and rCBF was found in the ventral rostral midbrain and the right head of the caudate nucleus. It is quite possible that this correlation represents increased activation of
dopaminergic cell groups in the midbrain and their striatal target cells.

Despite this nice correlation, it is quite striking that no other subcortical effects were found. In particular, the hypothalamus plays a major part in the sexual response of female rodents [8], while in women hypothalamic function predicts sexual orientation [89,90] and indicates visual sexual stimulation [30]. Moreover, elevated levels of the pituitary hormones oxytocin and prolactin have been associated with orgasm [91,92]. Perhaps, the neuronal events that might occur in the hypothalamus during sexual consummation did not require a metabolic increase that sufficiently increased rCBF, or maybe the temporal resolution of the PET experiment was too limited to detect short-lasting events occurring in the hypothalamus. The same explanation could hold true for the absence of activation in the ventral striatum, a region that has been specifically linked to sexual arousal [51,52]. Improvements in terms of subcortical activations are to be expected with the use of neuroimaging techniques with better sensitivity for detecting short-lasting events, like fMRI.

7. GENDER DIFFERENCES IN BRAIN RESPONSES DURING SEXUAL CONSUMMATION

When directly compared to activation patterns for penile stimulation, women showed significantly more activation in left fronto-parietal regions, most notably in the posterior parietal cortex and the supplementary motor area [70]. Given that these regions are important for making a mental representation of another person’s actions [93], differential activity in these regions as a function of gender may reflect behavioral gender differences related to perspective taking and empathy [94]. By contrast, women’s brain responses during orgasm did not differ significantly from the male counterpart [70]. This suggests that men and women use different cerebral strategies to reach orgasm. Future research may elucidate how these difference can best be understood, and if this intriguing theory is tangible.

V. SEXUAL AROUSAL AND ORGASM FUNCTION IN SPINAL CORD INJURED WOMEN - BRAIN ACTIVATION PATTERNS

Although spinal cord injury (SCI) is a common cause of anorgasmia, irrespective of the level of the lesion, some 50% of women with lesions above the tenth thoracic level report that they still achieve orgasm [95]. This is truly astonishing, because clitoral sensation is lost in these patients. One way for women with complete transection of the spinal cord to reach orgasm is via vaginocervical stimulation [96]. The vaginocervix receives innervation from the parasympathetic vagal nerve (cranial nerve X), which enters the central nervous system in the caudal brainstem (in the nucleus of the solitary tract), therefore bypassing any SCI. Thus, salient genital information may still reach the brain. Similarly, sensory information from the internal genitalia may be conveyed by the sympathetic nerves [95].

Komisaruk et al. [97,98] performed neuroimaging studies of women with SCI at or above the T10 level who were able to achieve arousal and even orgasm with cervical self stimulation. Using a custom-made self-stimulation device, subjects were able to stimulate their vaginocervix to eventually induce orgasm. In a first (PET) study, the authors reported rCBF increases in the lower brainstem during vaginocervical stimulation, possibly representing the nucleus of the solitary tract [98].

However, this result was based on only three subjects (one without SCI), and the authors did not explain how brain responses were modeled and statistically analyzed. In a subsequent fMRI study, the same authors included five women with complete SCI [97]. It confirmed the conclusion from their earlier PET findings, in that the lower brainstem was consistently activated across subjects in response to vaginocervical stimulation. Orgasm-related activity was reported to be consistent in the middle cingulate cortex, the insula, the hypothalamus, and the amygdala. Orgasm, however, was achieved by only three volunteers. The authors concluded that cerebral sexual activation response in these SCI women was mediated through an alternative paraspinal pathway via the vagus nerve.

Unfortunately, these studies suffered from suboptimal experimental design, analysis, and execution. No information about the data analysis procedure or the significance of the effects was disclosed.

Therefore, it was not obvious why certain “activations” were labeled as consistent effects, and others were not. Surely, the number of subjects (five for stimulation; three for orgasm) was too small to identify any meaningful group effects.

Another potential problem is MR scanner instability and subject motion, especially when data are collected over longer periods of time as was the case in Komisaruk et al. [97]. These slow signal drifts are usually removed during data analysis, but this also erases any real biological effects that develop slowly (like sexual arousal). Alternatively, these drifts may induce random artifactual activity if not corrected for [99]. Obviously, other factors like the type of genital stimulation (clitoral vs. vaginocervical) and the subject cohorts (healthy vs. SCI) may also explain the different findings compared to the studies of Georgiadis et al. [70].
D. FACTORS INFLUENCING BRAIN PATTERNS DURING SEXUAL STIMULI IN WOMEN

I. SEXUAL ORIENTATION

1. HYPOTHALAMIC FUNCTION DEPENDS ON SEXUAL ORIENTATION

The putative role of the hypothalamus in sexual orientation [100-102] has been confirmed at a functional level in humans. Using neuroimaging ([(15)O]-H2O PET) and volatile sex-specific odors; pheromones, it was found that sexual orientation predicted hypothalamic responses. More specifically, heterosexual women activated the ventromedial hypothalamus and preoptic area when smelling an androgen-like substance, whereas heterosexual men smelling an estrogen-like odor activated the (more posteriorly located) dorsomedial and paraventricular nucleus [90]. Lesbian women, interestingly, showed partial congruence with heterosexual men in the dorsomedial and paraventricular hypothalamus [89]. Similar congruent activity has been found between homosexual men and heterosexual women in the preoptic area and ventromedial hypothalamus [103], suggesting a coupling between hypothalamic function and sexual preference, irrespective of gender. Even when anatomical distinction between adjacent hypothalamic areas is quite challenging given the relatively limited spatial resolution of the PET technique (ca. 10mm), it seems safe to conclude that sexual orientation and sex-specific behaviors depend heavily on hypothalamic structure and function.

2. SEXUAL ORIENTATION BIASES BRAIN ANATOMY AND CONNECTIVITY

Neuroanatomical gender differences have been found in large parts of the brain [104], but most notably in the amygdala, hippocampus and prefrontal cortex [105-107]. These regions are important for memory and learning, executive function, and emotion, and, together with sexual dimorphism of basic structures like the hypothalamus, might explain why women behave differently from men.

In a very interesting recent paper [108] it was demonstrated that individuals who prefer male sexual partners have symmetrical cerebral volumes, whereas those who prefer female sexual partners possess a rightward cerebral asymmetry. Moreover, sexual preference determined the functional connectivity patterns of the amygdala, a putative part of the emotional and memory system. Heterosexual women (and homosexual men) showed more widespread connections from the left than from the right amygdala, whereas the opposite was the case for homosexual women (and heterosexual men). More specifically, in heterosexual women the connections were primarily with the contralateral amygdala and anterior cingulate cortex, in homosexual women with the prefrontal cortex, caudate and putamen [108].

II. HORMONAL MILIEU

Hormonal fluctuations during the menstrual cycle not only influence mood, cognition, memory, and arousal [109,110] but also sexual interest [111]. Heterosexual women in their follicular phase showed less metabolic effort in the right lateral orbitofrontal cortex and the caudal anterior cingulate cortex when performing a cognitive task involving male faces than when they were in their luteal phase. Because task performance remained unchanged, the authors proposed that most efficient neural processing of sexually salient stimuli occurs when pregnancy is possible [112]. Likewise, testosterone administration during the early follicular phase shifted memory processes in the hippocampus and inferior temporal gyrus towards the encoding and retrieval of male faces [113], indicating relatively automatic processing of sexually salient stimuli under the influence of testosterone. Prefrontal activation dominates the response to female faces in this group, suggesting less automatic processing of sexually irrelevant stimuli [113].

Hormonal influences have been studied using fMRI and have been shown to correlate with measurable changes of brain activation responses with general (non-sexual) arousal. Gizewski et al. demonstrated that VSS induced more brain responses in women during their midluteal phase than during their menses. The increase in activation was most apparent in the anterior cingulate, left insula and orbitofrontal cortices [114]. Similarly, Goldstein et al. [109] performed fMRI during the early follicular phase and again during the late follicular phase (midcycle or ovulatory phase) and documented significant differences in activation of hypothalamic–pituitary–adrenal (HPA) circuitry. Pictures consisted of negative valence/high arousal images versus neutral/low arousal visual stimuli. The fMRI results were validated by concomitant electrodermal activity (EDA) measurements. Significantly greater magnitude of BOLD signal changes were found during the early follicular phase, most notably in the amygdala, hypothalamus, hippocampus, orbitofrontal cortex (OFC), anterior cingulate gyrus (ACG), and brainstem - a network of regions implicated in the stress response. Arousal (EDA) correlated positively with brain activity in amygdala, OFC, and ACG during late follicular but not in early follicular phase, suggesting less cortical control of amygdala during early follicular phase, when arousal was increased. This is the first evidence suggesting that estrogen, which is elevated in early follicular phase, may attenuate arousal in women via cortical–subcortical control within HPA circuitry.
Premenopausal women had greater global brain signal than menopausal women in response to VSS [115]. (Figure 11). Archer et al. [116] studied a group of surgical menopausal women compared to a control group of age-matched premenopausal women. Brain activation was studied by fMRI during erotic and neutral videos. The menopausal women were studied at three time points; while not on hormone therapy, while on estrogen (E_2) therapy, and while on E_2 plus testosterone (T) therapy. Compared with premenopausal women, untreated postmenopausal women had significantly decreased areas of brain activation during both erotic and neutral video stimulations. Administration of E_2 increased global brain-activation patterns during both neutral and erotic visual stimulations, with erotic video viewing causing a limited increase in limbic system activation. Combined E_2 and T therapy was associated with a greater activation of the central nervous system (CNS), with more limbic system activated during the erotic video. Brain-activation patterns of the postmenopausal women were similar to the premenopausal group only during the E_2 and T treatment phase. These studies suggest that both E_2 and T act independently and in a complimentary fashion to increase the central arousal response in women. They also illustrate the potential of fMRI to document response to treatment.

Together with similar central effects of T observed in men [66] this underscores the importance of gonadal hormones in mediating the sexual response. It also illustrates that in female neuroimaging studies of any kind the menstrual phase has to be considered if there is any possibility to do so.

### III. HYPOACTIVE SEXUAL DESIRE DISORDER

Arnow et al. [44] conducted fMRI studies in a group of women with hypoactive sexual desire disorder (HSDD) compared with a control group of women with no history of sexual dysfunction. This study was notably not only in the unique study population, but also in the study design since fMRI measures were correlated with simultaneous vaginal photoplethysmography recordings and subjects were studied at three different time points for validation of reproducibility. The study used a standard VVS block design previously described comparing control video of sporting activity versus sexually stimulating couples activity. Results showed significantly greater subjectively reported arousal response in the group without a history of sexual dysfunction. They observed many similar areas of brain activation correlated with sexual arousal in both groups but only a limited number of brain regions showed significant differences of activation between the groups, when comparing erotic versus neutral videos.
control video stimulus. Notably there was increased activation in the HSDD group compared with control subjects with normal desire in 3 areas;

1) medial frontal gyrus [Brodmann area (BA) 10];
2) the right inferior frontal gyrus (BA 47);
3) the putamen on both sides.

The entorhinal cortex on both sides was the only area that displayed reduced activation. The authors concluded that the increase in activation in the medial frontal and the right inferior frontal gyri suggested that the HSDD group was directing more of their attention to self evaluation of their responses which may have been distracting and interfered with the normal sexual arousal response [44]. Interestingly, this study also compared simultaneous vaginal photoplethysmography (VPP) with the fMRI and found no between group differences in VPP-fMRI correlated activation, nor was VPP correlated with subjective arousal response [117]. Also of note is the fact that these investigators performed the fMRI study 3 times in each subject and a repeated measures ANOVA analysis on the activation sites detected in the erotic–sports paradigm across the three sessions did not reveal any significant activation differences across sessions [44].

This validated the reproducibility of the fMRI techniques and the paradigm used for this study as well as having major implications for fMRI as a research methodology, in general.

**E. SUMMARY**

The last years introduction and increased use of neuroimaging methods have enabled us to explore cerebral activation and deactivation during sexual stimulation and to hypothesize on the importance of different brain areas for functional and dysfunctional sexual function. The cerebral sexual response has been shown to be modulated by hormones, age and sexual orientation. Furthermore the research shows that it is crucial that the neuroimaging methods as well as sexual stimulation are standardized in order to obtain better and clearer results and be able to compare studies. In Appendix 1 a suggestion for a guideline for female sexological brain activation studies is given.

**BOX 2**

- The hypothalamus and amygdala are crucial for sexual orientation and early pre-consummatory stages of the female sexual response, albeit to a lesser extent than in men.
- Amygdala and parts of the temporal lobe deactivate once sexual consummation commences, and this may be part of a brain mechanism that enables sexual interaction.

- The ventral striatum is specifically related to sexual arousal.
- The left orbitofrontal cortex is the seat of sexual self-control. It is deactivated during orgasm, but activated when orgasm fails.
- Clitoral sensory information is predominantly processed in neocortical somatosensory and motor areas. This type of genital central processing is much more prominent in women than in men.
- Menstrual cycle phase, age, and sexual orientation clearly influence brain activity patterns, and should be taken into account if possible.
- Vaginocervical stimulation may induce orgasm in spinal cord injured women, because this information is conveyed by the vagal nerve, which enters the central nervous system in the lower brainstem. fMRI data provide some support for this concept.
- Aging does not change the brain activation pattern in terms of anatomic sites activated with arousal but may affect the magnitude of activation in selected areas especially the paralimbic system, temporal and parietal regions.
- Lack of arousal in HSDD may in part be related to subject self reflection on performance causing distraction from “letting go” and responding to the moment.

**F. GENITAL ANATOMY AND PHYSIOLOGY OF WOMEN’S SEXUAL FUNCTION**

**I. FUNCTIONAL ANATOMY**

The female genitalia can be subdivided into the internal genitalia (vagina, cervix, uterus, fallopian tubes and the ovaries and external genitalia (vulva) including mons pubis, clitoris, the labia majora and minora which are the structures surrounding the urogenital cleft [118] (Figure 12). This chapter describes the structures involved directly in the physiological sexual response.

1. **MONS PUBIS**

is the hair-covered area over the pubic bone and forms the anterosuperior limit of the urogenital cleft and ends posteriorly at the anterior margin of the perineal body [119].
2. LABIA MAJORA

are the two prominent, fatty lateral boundaries of the urogenital cleft. Anteriorly they meet creating the anterior commisur in front of the glans of the clitoris, posteriorly forming the posterior commissure. Each labium has external pigmented hairy, slightly wrinkled skin and internally a smooth surface lined with multiple sebaceous glands. The labia majora often meet and close the vaginal introitus.

3. LABIA MINORA

are smaller and may vary in size (length 61 ± 17 mm, Mean ± SD, range 28-100 mm; width 22 ± 9 mm, range 7-50 mm.). Anteriorly they split into two layers forming the clitoral prepuce and the clitoral frenulum. They consist of no subcutaneous fat, elastic skin and contain erectile tissue and appear from smooth surfaced to extensively corrugated [119,120].

Little attention has been paid to the neural innervation of the labia minora. Malinovsky et al. [121] reported that the types of sensory nerve endings could be divided into 4 main groups namely:

i) free nerve endings and arborizations;

ii) spray-like nerve endings;

iii) 7 types of ‘claw’ like endings;

iv) Pacinian corpuscles (only a few).

The exact functions of this innervation are still under study but the free nerve endings subserve pain while the Pacinian corpuscles subserve pressure and vibration, whilst the possible roles of the different types of ‘spray and claw nerve endings’ are unknown but they are unlikely to be only for pain.

4. THE CLITORIS

is unique in that the only known function is the generation of sexual pleasure when stimulated by touch or vibration.

Its gross structure is like an iceberg in that only a fifth is visible on the surface while the rest is hidden beneath the skin and deeper. According to O’Connell et al. [122] internally, it is a triplanar complex of erectile tissue comprising a midline shaft of some 20 cm long and 1-2 cm wide dividing internally into a pair of crura some 5-9 cm in length (Figure 13A & B). The erectile tissue consists of trabecular smooth muscle and collagen connective tissue encircled by a thin fibrous capsule surrounded by large nerve trunks [119,123]. Externally, the shaft is covered by the prepuce and is capped by a glans some 20 mm in length and 30 mm wide [124,125]. Linked into the structure are two vestibular (clitoral) bulbs on either side of the vaginal introitus closely applied the urethra. The erectile compartments consist of the clitoris and the clitoral bulbs. The functional and histological distinction of the trabecular vascular tissue of the clitoris and the bulbs are alike indicating this type of tissue to be erectile vascular tissue [122,126,127], very similar to the erectile tissue found in the penis. It has been further demonstrated [128] that autonomic innervation of the clitoris and the clitoral bulbs show striking similarities further supporting their observation that these are responsive erectile structures. The function of these bulbs is unclear; one speculation is that when filled with blood they support the vaginal wall during the thrusting of coition. Whether they create any erotic pleasure when stimulated by pressure has not been examined.

5. PERIURETHRAL GLANS.

The term ‘periurethral glans’ [129] describes and delineates a triangular part of the vaginal vestibule that surrounds the urinary meatus, extending from below the clitoral glans to the vaginal introitus and laterally to the beginnings of the labia minora. Contrasts exist, since the same area has been described in one study as part of the corpus spongiosum of the female which is far more widespread than in the male [130] and others have described the periurethral glans/corpus spongiosum/pars intermedia/root of the clitoris as the same structure [131].

During coitus, the thrusting of the penis causes the area to be pushed into and then dragged out of the vagina. As the area is an innervated mucous membrane, this induced movement will create pleasurable erotic stimulation. When women are asked to list hierarchically their most pleasurable erotic sites the periurethral glans area of the vaginal vestibule is rated second after the clitoris. The area, its mobility and density of innervation could be the answer as to why a sub-group of women can have orgasms.

---

from simple penile coital thrusting alone (so-called 'vaginal orgasms') [131]. Remarkably, the area has not been the focus of any biothesiometric study and is generally overlooked as a potentially important source of erotic pleasure during coitus for women.

6. THE VULVAR VESTIBULE

includes the vulvar area comprised between the inferior part of the clitoris, the medial part of the labia minora and the fourchette [131,132].

7. VAGINA

In the unaroused condition the vagina is a potential space with its anterior and posterior walls collapsed and resting together but they do not adhere because the walls are covered with a thin film of fluid (see, in this context, the specific section dealing with vaginal lubrication). Its shape is complicated so no single structure can describe it. The cross-section is similar to either a 'H' or 'W' while the longitudinal axis is like a greatly stretched out 'S' (length range 6-12 cm). Its entrance (introitus) is usually gated by the labia minora (see section above ) while its back culminates in a cul-de-sac the anterior wall of which is penetrated by the cervix of the uterus usually at right angles to the vaginal longitudinal axis [119,133].

The layered structure of the vagina consists of the luminal stratified squamous epithelium (a multicellular layer with new cells continually created in the basal layer by oestrogen-stimulated mitosis which then migrate to be shed off (desquamated into the lumen), a lamina propria layer containing connective tissue, blood vessels, nerves and receptors, collagen, elastin fibres and finally a layer of smooth muscle [129,134-136] (Figure 14). The organ is set in the pelvis surrounded by powerful striated pelvic musculature while at the introitus two superficial striated muscles, the ischiocavernosus and bulbocavernosus can contract around the penis during orgasmic arousal [137].

a) Microcirculation in the basal condition.

The vaginal microcirculation is supplied with blood from at least 3 main arteries and drained by numerous veins. Like all microcirculations it consists of a circuit of arteries→arterioles→met-arterioles→capillaries→venules→veins.

The vaginal vessels are richly innervated by adrenergic, cholinergic and vipergic nerves together with neuuropeptides like substance P (a sensory transmitter), neuropeptide Y (a vasonconstrictor) and calcitonin gene related peptide (CGRP), a possible sensory transmitter and a peptide influencing capillary permeability) and Nitric Oxide (NO) [134,138-144]. The exact functions of the various innervations have yet to be ascertained [145].

Like other microcirculations it has a preferred path for most of the blood flow during quiescence (and for the vagina that is quite often) which means that most of the time the capillaries are closed due to
contraction of the pre-capillary sphincters. When the local area around one of these becomes hypoxic the released metabolites (\(pCO_2\), lactic acid, \(K^+\), ATP) cause sphincter relaxation and the supplied capillaries open up washing away the metabolites and refreshing the local area with oxygen and nutrients. This intermittency of the microcirculation is known as 'vasomotion', it is seen in a number of other genital tissues such as the testis [146] but has only recently been observed and quantified in the vagina by photoplethysmography [147]. The degree of vaginal vasomotion is a sensitive and useful index of genital arousal. Thus, during basal conditions, a high vasomotor tone of the arterial supply through central sympathetic activation and a high level of vasomotion keep the blood flow to the vagina at minimal levels. A corollary of this is that the surface \(pO_2\) of the vagina wall is basally at a low, hypoxic level [136].

Recently Allers et al. described slow oscillations in vaginal blood flow in both rats and humans as a marker of sexual arousal [148,149]. They are influenced in rats by the central nervous system namely the PVN (Paraventricular Nucleus) and modulated by the autonomic nervous system [149]. They also demonstrated that in humans and rats the oscillation appear independent of vaginal vasocongestion. VSS induced an increase in the total power of slow oscillatory activity in vaginal blood flow in healthy human volunteers but no increase was observed in women with Female Sexual Arousal Disorder (FSAD). They concluded that slow oscillations in vaginal blood flow are correlated with subjective physiological arousal and display diminished responsiveness in women with FSAD and may be used as a model when studying female sexual arousal [148]. Relations, if any, between vaginal vasomotion (147) and the slow oscillations have not been discussed.

8. THE CERVIX

The cervix pierces the anterior vaginal wall normally at approximately right angles the longitudinal vaginal axis. In the basal non-stimulated state, the cervix can rest on the posterior vaginal wall. Its central canal is some 3 mm in diameter and 2-3 cm in length and is lined with a greatly folded epithelium of columnar cells creating crypts (some 10,000) that look like glands and are often mistaken for them. The cells secrete mucus under the influence of oestrogens (increasing the production) and progesterone (decreasing the production). Around mid-cycle the mucus is viscous like egg white and it provides the optimum environment for sperm movement and survival. At other phases of the cycle the mucus is thick and relatively hostile to sperm movement and survival.

The innervation of the cervix is poor so that some minor surgery can be carried out without anaesthesia but it has the second highest concentration of VIP in the female genital tract. The functions of this VIP have not yet been elucidated but it is unlikely that it is involved in increasing cervical blood flow during arousal because fMRI imaging does not indicate the
organ becoming vasocongested [127]. It is more likely to be involved in the neuroimmunology of the cervix acting as an anti-inflammatory agent [150].

II. ARTERIAL SUPPLY

Women’s genitalia have a rich arterial blood supply [118,132]. The labia are supplied from the inferior perineal and posterior labial branches of the internal pudendal artery as well as from superficial branches of the femoral artery. The clitoris is supplied by the ileohypogastric pudendal arterial bed. After the internal iliac artery has given off its last anterior branch, it traverses Alcock’s canal and terminates as the common clitoral artery, which gives off the clitoral cavernosal arteries and the dorsal clitoral artery (Figure 13B). The proximal (middle) part of the vagina is supplied by the vaginal branches of the uterine artery and the hypogastric artery. The distal part of the vagina is supplied by the middle hemorrhoidal and clitoral arteries.

III. PERIPHERAL NEUROPHYSIOLOGY

The female genitalia are richly innervated [125,134,143,151,152]. Knowledge of the innervation is clinically important. Firstly it is essential for our understanding of the physiology and pathophysiology of arousal and orgasm. Secondly in our understanding of possible disruption of neural pathways during surgery and other iatrogenic procedures [153].

The uterine nerves arise from the inferior hypogastric plexus formed by the union of the hypogastric nerves (sympathetic T10-L1) and the splanchnic fibers (parasympathetic S2-S4). This plexus has three portions: vesical plexus, the rectal plexus and the uterovaginal plexus, which lies at the base of the broad ligament, dorsal to the uterine vessels and lateral to the uterosacral and cardinal ligament. This plexus provides innervation via the cardinal ligament and uterosacral ligaments to the cervix, upper vagina, urethra, vestibular bulbs and clitoris, for review see [145].

At the cervix sympathetic and parasympathetic nerves form the paracervical ganglia. The larger one is called the uterine cervical ganglion. It is at this level that injury to the autonomic fibers of the vagina, labia and cervix may occur during hysterectomy. The pudendal nerve (S2-S4) reaches the perineum through Alcock’s canal and provides sensory and motor innervation to the genitalia.

Consequently the anatomic structures involved in the female genital sexual response are innervated by autonomic and somatic nerves

1) the pelvic nerve issuing from level S2-S4 of the spinal cord (parasympathetic);

2) the hypogastric and lumbosacral chain issuing from level (T12 – L2) of the spinal cord (sympathetic);

3) the pudendal nerve (somatic) with cell bodies of the motoneurons located in the Onuf’s nucleus (S2 – S4);

4) the vagus nerve issuing from the nucleus tractus solitaries.

Sensory stimuli relevant to sexual function are conveyed by afferent pathways consisting of pudendal, pelvic and hypogastric nerves and the lumbosacral sympathetic chain. They relay information to the dorsal horn, medial central and lateral gray matter of the lumbosacral spinal cord, and the vagal afferent fibers convey sensory information from the genital apparatus to the nucleus tractus solitarius (NTS) [154].

A great variety of neurotransmitters/mediators and receptor types have been demonstrated in nerves in the female genitals in both animal and human studies (see [135,139] for references). The functional implications of each transmitter are not fully understood.

IV. PHYSIOLOGY OF AROUSAL

During sexual stimulation the female sexual arousal response is elicited by sensory stimulation as well as central nervous activation resulting in increased blood flow to the genitals. This culminates in a series of vasocongestive as well as neuromuscular events leading to physiological changes.

Berman et al. [155] demonstrated that sexual stimulation resulted in a significant increase in clitoral, labial, urethral and vaginal blood flow. High resolution MRI studies of the female genitalia have detailed the living anatomy of the female genitalia and have demonstrated the changes that occur with arousal and engorgement [126,127]. Studies by Yang et al [128] correlating in vivo MR imaging of genitalia together with gross and histologic examinations of cadaveric specimens have demonstrated five vascular compartments comprising the external female genitalia; the clitoris, clitoral bulbs, labia minora, urethra, and vestibule/vagina. (Figure 15A) These compartments are composed of erectile as well as non-erectile tissues with erectile tissue demonstrating the greatest volume change with engorgement during sexual arousal [127,156] (Figure 15B).

1. EXTERNAL GENITALIA

a) Labia

During sexual arousal the labia become engorged with blood increasing in size by as much as two to threefold [1,157] and their sensitivity to touch is enhanced. Because they are the gateway into the vagina, painless initiation of coitus by penile thrust-
ing requires their lubrication. If their resistance to insertion is greater than the buckling pressure of the penile erection, usually quoted as an axial pressure equal to or greater than 550gm [158], penetration will be difficult and ‘insertional dyspareunia’ may occur making the initiation of coitus uncomfortable for both partners. Masters and Johnson [1] proposed that their lubrication during arousal was due to the ‘spill over’ of excess vaginal lubrication. However, a pilot study [159] that used tampons in the vagina to prevent any fluid leaking out onto the labia found that sexual arousal still caused labial lubrication, strongly indicating that the labia could actually form their own lubricative fluid presumably by plasma transudation similar to that produced by the vagina during arousal (see details in the subsequent section on vaginal lubrication).

As the labia minora become engorged with blood during arousal - unlike the labia majora [157] - they have been experimentally used as an indicator of genital sexual arousal, the increase in engorgement being monitored either by the increase in labial temperature using a thermistor [160] or by thermographic imaging [161]. (Figure 16)

b) Clitoris

As described above the clitoral shaft is composed of two corpora cavernosa surrounded by a capsular fibrous sheath (tunica albuginea). Under basal conditions the blood vessels in the clitoris have a high tone (through sympathetic activity) and are mainly closed [162] but show evidence of vasomotion [163] the random opening and closing depending on local tissue needs (as described previously). The neural innervation is through vipingic nerves releasing Vasoactive Intestinal Peptide (VIP) dilating the arterial supply [129,164] and NO, formed by the enzyme nitric oxide synthase (NOS), found in the nerves (nNOS) and lining endothelium of the corpora cavernosa (eNOS) relaxing the smooth muscle of the cavernous sinuses [165-173]. During sexual arousal the central reduction of sympathetic tone and the release of the two vasodilator neurotransmitters create an increase in the blood flow to the clitoris and relaxes the smooth muscles of the cavities in the clitoris so that they become filled with blood and the organ becomes vasocongested. Unlike the penis, which when it becomes fully erect cannot be bent, the clitoris, because it has no subalbugineal layer between its tunica and the erectile tissue [174], even when fully-filled only becomes swollen or tumescent and not rigid. Genital MRI techniques have been used to dynamically study and quantitatively the clitoral engorgement response in women during VSS [126,127,156,175] Dynamic genital MRI techniques have documented and measured the engorgement response in vivo during arousal and showed increased width of the clitoris during arousal [127]. (Figure 15B).

Surprisingly, the vibration sensitivity of the clitoris is known to decrease during and immediately after arousal [176] a feature similar to the tumescent
penis [177]. No satisfactory explanation for the genital decreases in response to vibration has yet been proposed.

Data regarding the correlation between the measured degree of physiologic engorgement and the subjective level of arousal have been mixed. There has been a non-significant trend suggesting correlation between these two measures but further studies are needed to validate this [156]. A preliminary uncontrolled, randomized, blinded crossover MRI study of the genital response following ingestion of sildenafil vs. placebo in a group of women with (FSAD) demonstrated a non-significant trend toward improved engorgement with sildenafil [175]. MRI studies documented an increase in clitoral volume following sildenafil compared with placebo in 6 of 12 subjects, no significant change in either imaging session in three subjects while in three subjects, there was a robust clitoral response in both MR sessions. This indicates that MR measurements of clitoral volume can provide an objective measure of engorgement change following a vasoactive medication in women with FSAD, but larger scale studies are needed.

2. INTERNAL GENITALIA

a) The urethra

The female urethra is only 4 cm long but in its wall are venous sinuses that are filled with blood. They are part of the closing pressure of the urethra thus aiding in maintaining urinary continence. In the lining of the urethra are found, triangular- shaped paracrine cells that are thought to have mechanoreceptor properties and are rich in serotonin (5-hydroxytryptamine). This neurotransmitter is known to potentiate the sensitivity of nerve endings [178]. Stretching of the urethra occurs during coitus [179] or during digital stimulation of the anterior wall and this may well activate these mechano-receptor cells to release serotonin sensitising the nerve endings in the urethra and thus creating pleasurable sensations [179]. The urethra is thus converted from a urinary tube into a genital sex organ.

b) Vagina: microcirculation in the aroused condition

At the beginning of sexual arousal the blood supply to the vagina is minimal due to the high sympathetic vasomotor tone and vasomotion as detailed in the previous section. Then, usually within seconds of an acceptable or consensual sexual stimulus, the central sympathetic tone is reduced and the arterial supply is enhanced through the action of released neuronal VIP and some NO via the sacral anterior nerve roots [181] and vasomotion decreases as more closed capillaries are recruited [147]. Fairly rapidly the recruitment of the capillaries becomes maximal and the vagina becomes fully vasocongested (along with the labia and clitoris) vasomotion is absent and the woman will subjectively perceive that her pelvis ‘feels full and congested’. While consensual sexual stimulation is obviously the preferred behavior it is known that vaginal vasocongestion, lubrication and even orgasm can be induced in some women even by non-consensual unwanted sexual stimuli [182].

c) The aroused vagina and the formation of vaginal lubrication

As described above, within the sexually aroused vagina, the capillaries of the micro-circulation are filled with blood and the increased hydrostatic pressure inside them forces out a plasma transudate (ultrafiltrate) into the interstitial space around the blood vessels. Continued formation of this neurogenic transudate fills up the interstitial space and then passes through and between the cells of vaginal epithelium to leak onto the surface wall of the vagina as the vaginal lubrication. The final fluid is a modified plasma filtrate because the cells of the vagina can transfer Na⁺ ions vectorially from the lumen back into the blood [183] and add K⁺ ions by secretion and the cell shedding [136,184,185]. Thus the ionic concentrations of these ions are much different to those in the plasma, vaginal basal fluid having a higher K⁺ and a lower Na⁺ than plasma throughout the menstrual cycle [186].
However, during arousal the greatly enhanced transvaginal flow of filtrate from blood vessels to the vaginal lumen has a much reduced contact time with the vaginal cells and their ability to transport Na\(^+\) is of limited capacity so that the transport of Na\(^+\) back into the blood is saturated and much Na\(^+\) escapes into the vaginal transudate. Thus the arousal lubrication fluid has a much higher Na\(^+\) concentration than the basal fluid approaching that of plasma [185]. (Figure 17) The fluid formed on the surface of the vaginal wall is more than just a modified plasma transudate because it feels slippery to the touch and has obvious lubricant properties. Exactly what these substances are is not known but it is thought that they may include glycerol manufactured by the vaginal cells [187] and sialoproteins secreted into the vagina by the cervical epithelium [187]. On cessation of the sexual arousal the vaginal Na\(^+\) together with osmotically drawn fluid is transferred back into the blood [179,187] resetting the vagina to the basal ‘just moist’ condition.

In a number of fluid transporting tissues water channel proteins called ‘aquaporins’ (AQP’s) are found, they facilitate the transport of water and other small molecules like glycerol. There are some 13 members of the AQP family; AQP 1,2,4,5 and 8 are specific for water transport while AQP 3,7,9 and 10 transport are less specific transporting water and small molecules. AQPs have been localized in rat vagina. Park et al [188] found that AQP1 was primarily expressed in capillaries and venules, AQP2 in the cytoplasm of the epithelial cells and AQP3 was associated mainly with the plasma membranes of the epithelial cells. Stimulation of the pelvic nerve, known to induce increased vaginal blood flow, caused the translocation of AQP1 and 2 from their cytosolic site to the membrane compartment but AQP3 was unchanged. The authors interpreted their results to suggest that the AQPs could play a role in the fluid movements of vaginal lubrication. A later study, again in rats, reported that estrogen deprivation decreased the expressions of vaginal AQP2 and NOS but they were restored by 17- beta estradiol treatment. While these animal results are interesting, as yet, there is only a poster study [189] reporting that the distribution of AQP 1, 2 and 3 in premenopausal human vagina has the same distribution as that in the rat. Any possible role of these water channels in human vaginal lubrication has yet to be determined.

d) The uterus

Masters & Johnson [1] reported that the uterus increased its size by 50-100% during sexual arousal and then returned to normal after its cessation when monitored by palpation suggesting vasocongestion. Later studies with MRI imaging did not confirm this swelling [190]. During high levels of sexual excitement and at orgasm the uterus contracts...
PuTATIVE EROTIC STRUCTURES

3. THE ANTERIOR VAGINAL WALL AND ITS PUTATIVE EROTIC STRUCTURES

The anterior vaginal wall, when stimulated by deep pressure, is known to generate a more sexually pleasurable feeling than either of the lateral or posterior vaginal walls. This is not due to it having a greater innervation than the other vaginal areas as it has been reported that vaginal nerve density is relatively homogenous [143,187].

Closely associated with this wall, however, are 3 anatomic components that are reputed to create the sexual feelings when stimulated. These are:

a) the urethra (see description in previous sections);

b) the so-called ‘G-Spot’;

c) Halban’s fascia.

As these structures are all packed into a relatively small space in and along the anterior wall it is obvious that any deep pressure on the anterior wall will likely activate all three, it will be nearly impossible to isolate and stimulate just one. It may thus be more sensible to talk of the ‘antero wall erogenous complex’ [191]. This is also why the claim of Chua Chee Ann [179,192] to have found a new erotic site of the anterior vaginal wall, described by him as the “anterior fornix erogenous zone”, which when stimulated by digital pressure created vaginal lubrication and orgasm must be looked at with a high degree of scepticism especially as it was claimed without any evidence that the stimulus acted locally and did not reach the brain.

a) The ‘G spot’

Ernst Grafenberg in 1950 described a site on the anterior wall of the vagina that when stimulated by deep pressure became swollen and or enlarged protruding into the vaginal lumen and was highly effective in causing orgasm in women when stimulated [193]. Two authors, Whipple and Perry, of a popular, non-peer reviewed book [194] named the site the ‘G spot’ in recognition of Grafenberg and this appellation has stuck although it is more of a zone than a spot [195]. Several papers (actually, more than 250) have been published as to whether the area exists and its possible connection with female ejaculation (see [191] for references). Despite the passage of nearly sixty years controversy still surrounds the ‘G spot’ because

1) of its inexact anatomic placement- in the short female urethra its position is unsettled. Some places it at the junction of the bladder with the urethra [196] while others place it at the middle [193] or possibly even the distal part of the urethra [197].

2) its putative structure – some suggest it to be the ‘female prostate’ paraurethral or periurethral glands/ducts [see 131,198,199] for references).

b) Halban’s fascia

Attention was drawn to this genital structure as a source of sexual pleasure in the report of Minh et al. [200] The fascia is in the space between the bladder and the anterior wall of the vagina and is filled with connective tissue, blood vessels, nerves and neuroreceptors. Strong stroking pressure on the anterior vaginal wall transfers the stimulus to the fascia inducing highly pleasurable sensations that can lead to orgasm. Recently a report suggested that the greater the thickness of the fascial space (called the urethrovaginal space in this report) the greater was the ability of women to have an orgasm from penile thrusting alone [201]. They had no proposal as to why such a relationship should exist. Unfortunately, the authors erroneously confused the anatomical site that they described also as the ‘human clitoris-urethrovaginal complex’ as the ‘G-spot’.

4. NIPPLE/BREAST STIMULATION

While genital stimulation is very effective in creating female sexual arousal the stimulation of the fe-
male nipple/breast can significantly enhance sexual arousal. Levin & Meston [202] noted that the role of nipple stimulation during lovemaking was just the subject of opinion-based comment rather than any evidence-based study. They gave a short questionnaire on nipple stimulation during lovemaking to 153 sexually experienced women undergraduates and 149 males. The major findings were that 81.5% of the women (and even 51.7% of the males) reported that stimulation of their nipples/breasts caused or enhanced their sexual arousal while 78.2% of the women (and 39% of the men) agreed that when sexually aroused stimulation of their nipples further increased their arousal. During lovemaking, 59.1% of the women (and 17.1% of the men) had asked for their nipples to be stimulated. Only 7-8% of the population questioned reported that nipple stimulation decreased their arousal [202].

No evidence exists exploring the role of skin in the arousal response

5. SEXUAL PHYSIOLOGY - THE REFLEXES GENERATED FROM VAGINAL STIMULATION

An overlooked subject is the generation of a number of genital reflexes claimed to be activated by vaginal pressure or stretch stimuli. They have been reviewed previously by Levin [203]. The earliest report of reflexes from the vagina was by Ringrose [204] who mechanically stimulated the vaginal wall with a wooden tongue depressor and observed a number of reflex muscle contractions. Because they did not appear to have any obvious physiological function they were ignored. A subsequent study [205] revealed that the reflexes could not be elicited in women up to 12 hours after they had been raped. No studies have been undertaken since to establish whether this finding could be of significant forensic importance. Lavoisier et al. [206] reported that the vaginal insertion and withdrawal of a balloon induced an increase in the velocity of blood supply to the clitoris and inferred that the same scenario would occur during coitus facilitating clitoral arousal. By far, the most extensive studies of female vaginal reflexes have been those of Shafik and his co-workers [207-210] which are listed in Table 3 together with their proposed function. The reflexes were all elicited by inflating an intravaginal balloon and the authors have assumed that this is equivalent to the mechanical stimulation of the penis in the vagina during coitus thus claiming that the recorded reflexes are physiological and occur during coitus. Such an assumption may be questionable and it still needs to be established whether the reflexes will be useful in the diagnosis of FSD.

VI. SEXUAL PHYSIOLOGY - MRI STUDIES OF INTERCOURSE

Pelvic MRI studies have been done of couples during intercourse [190,211,212]. Studies were done with couples in the missionary position and in posterior position to study the living anatomy of intercourse and to determine if previous theories about anatomic relationships are correct. In the missionary position, the penis is observed by MRI to be boomerang-shaped and reaches the anterior vaginal fornix with preferential contact along the anterior vaginal wall. Prior to penetration the vagina is parallel to the pubococcygeal line and has a normal anterior convexity. After penetration, the anterior vaginal wall is lengthened and the posterior bladder wall is pushed upward and anterior while the uterus is pushed upward and posterior. With a posterior position the penis reaches the posterior fornix and there is preferential contact along the posterior vaginal wall. Both the bladder and the uterus are pushed anterior in this position [212].

VII. THE PERIPHERAL PHYSIOLOGY OF ORGASM

Changes occur in the striated pelvic muscles, the smooth muscle of the uterus and vagina and circulation of the genitalia at orgasm. These have been reviewed extensively by Meston et al. [213] and only a brief account with updating is given below.

1. STRIATED PELVIC MUSCLE CHANGES

The striated muscles of the female pelvis are categorized into superficial and deep musculature. Surprisingly, despite extensive studies, a simple, clear and unambiguous description of this musculature is remarkably difficult to make. As van Houton [137] has remarked this is because of ‘unhelpful generalisations, confusing and overlapping terminology and misleading metaphors’.

Classical accounts describe the superficial muscles (urogenital diaphragm) as the ischiocavernosus, the bulbocavernosus and the deep and transverse perinei, while those of the deep pelvic floor, often described as the ‘pelvic diaphragm’, consists of the coccygeus (ischio-coccygeus) and the levator ani which contains the iliococcygeus and pubococcygeus muscles. The pubococcygeus is itself said to be made up of the pubourethralis and puborectalis muscles together with other smaller muscles (puboperinealis and puborectalis) a strange concept where a muscle is said to be constructed from other muscles. However, it is adequate for the present purposes to accept this simplistic picture. According to Graziottin & Giraldi [132, 214], the function and dysfunction of these pelvic muscles have an important impact on female sexuality. Hypoactivity of the muscles (low tone) leads to poor sexual function and lack of pleasure during coitus and orgasm while hyperactivity (high tone) is associated with the pain disorders of dyspareunia (namely, either coital or non-coital pain) and vaginismus (namely, difficulties in allowing entry into the vagina despite wanting it) a leading cause of unconsummated marriages in women [215].

Like all striated or voluntary muscles those of the pelvis have both afferent (sensory) and efferent (motor) innervation. Their innervation is by the pudendal nerve [216] and is the neural path for nerve impulses creating the rhythmic contractions of these muscles that occur in most women at and during orgasm. Masters and Johnson [1] described the pelvic contractions as an intrinsic part of the orgasmic process but Kinsey et al. [217, 218] regarded them as the ‘after-effects of orgasm’. The actual number of the contractions varies with the duration and intensity of the orgasm [1,219] and their frequency, strength and pleasurable power all decrease after the first few. It is thought that neurally-controlled genital muscular events that occur at orgasm are mediated at the spinal cord level which is involved in integrating the afferent impulses from the muscles and the efferent discharge from the supraspinal origins.

It has often been stated that the contraction of the pelvic muscles is mandatory (indispensable) as an indicator for the occurrence of the female orgasm [1,220]. However, claims have been made by women that while they have orgasms they do not have pelvic contractions [219]. Unfortunately, as no laboratory measurements of the pelvic musculature have ever been made in such cases we cannot be sure whether they really don’t possess these contractions rather than they don’t perceive them, perhaps because they are weak or that they have low interoceptive awareness. Attempts to relate aspects of the physical nature of the vaginal contractions to the pleasure felt during their activity have not been successful. Masters and Johnson [1] stated that the stronger the orgasm the greater was the number of contractions experienced, mild orgasms had 3 to 5 contractions, normal orgasms 5 to 8 contractions and the most intense 8 to 10 contractions but there has been no confirmation of this claim. Recordings of the intraluminal vaginal pressure during orgasm have not shown any linkage between the orgasmic contractions and the intensity of pleasure [221].

a) Purpose of the pelvic muscle contractions

In the male the purpose of the involuntary rhythmic contractions of the pelvic muscles at orgasm is clearly to eject forcefully the semen from the urethra, without them only a dribbling emission occurs. The role(s) of the muscular contractions in the female at orgasm is less attributable. Some five possible functions have been suggested namely:

i) to eject glandular secretions from the urethra (viz female ejaculation);

As a significant number of women do not appear to have such urethral ejections it is unlikely to be a significant or major function of the muscles that needs to be preserved.

ii) to create sexual pleasurable feelings;

When the muscles are contracted voluntarily they do not create sexual pleasure (but such voluntary contractions can facilitate the induction of arousal/orgasm in some women).
iii) to restore the vasocongested pelvic tissues to their basal state;

Orgasmic contractions from a single orgasm only partially restore the vasocongested tissues to the pre-aroused basal state of vasomotion [147].

iv) to stimulate the male to ejaculate;

By creating increased pressure on the thrusting penis the sexually-excited male is pushed over his threshold of ejaculatory containment and delivers his semen into the vagina thus the female captures the spermatozoa of her chosen male inseminator. Most women also vocalize nonverbally at each pelvic contraction [222].

v) to end sexual arousal;

As women are multiorgasmic a single orgasm with the concomittant contractions does not necessarily end their sexual arousal.

Thus none of the suggested functions hold up well on examination except perhaps that of stimulating the male to ejaculate. Another explanation is simply that both the female and the male pelvic muscles arise and develop from the same embryonic structure. While they are essential for the forceful ejaculation of male semen they have no apparent functional purpose for the female, but as they do no harm in their occurrence they are of no consequence and take too much energy and trouble to remove so they have been ignored and remain. They are an example of a 'biological spandrel', a structural feature that has a specific function in one sex but of little or no apparent use in another [223].

2. VAGINA

Because the vagina is a compliant organ and is set in a surround of powerful pelvic striated musculature (see previous section) the motility of its coats of smooth muscle per se has been poorly characterized. Its innervation by vipersic nerves suggests that the muscle will become relaxed during arousal and coitus probably to avoid occluding its blood vessels and thus reduce its lubrication and aid in the tenting process. At orgasm, the contractions of the striated muscles will impinge on the vagina causing passive increases in its intraluminal pressure. How much the vaginal smooth muscle contributes to the activity is uncertain as no study has measured the vaginal smooth muscle and the striated at the same time during orgasm. When Gillan and Brindley [224] recorded what was presumably the electrical activity of the vaginal smooth muscle using steel wire electrodes or silver discs sucked onto the vaginal wall an increase in its electrical activity was induced by clitoral vibration but at orgasm the continuous activity was replaced with intermittent activity associated with the orgasmic contractions. Shaflk et al. [225] also studied the electrical activity of the vaginal wall but the slow waves and the intermittent action potentials they recorded were observed in women who were not sexually aroused. The action potentials were concomitant with increased intraluminal vaginal pressure and represent the spontaneous vaginal motility described previously (see [187] for references). The function of these basal contractions were assumed to be for 'housekeeping', clearing the vagina of cellular debris, secretions and blood and possibly as maintenance to activate vaginal blood flow during sexual quiescence.

3. UTERUS

Although orgasmic contractions of the uterus have been described, unlike Kinsey et al. [217] who regarded them as having a sucking effect, Masters and Johnson [1] proposed controversially that they were expulsive and not involved in up-sucking material from the vagina (see section on sexual arousal and reproduction). Their experimental evidence for this conclusion was that blood was ejected forcibly when an orgasm was induced at menstruation and that no fluid was taken up at orgasm when a fluid-filled cap was placed over the cervical os. Others have criticized these experiments and argued that neither of these conclusions rules out uterine up-sucking. Unfortunately, remarkably few measurements of this uterine activity during orgasm have been recorded and published and those that have, electrical measurements by Masters and Johnson [1] and intrauterine pressure measurements by Fox et al. [226], are technically difficult to analyze and interpret and leave much to be desired [163]. Although a number of studies have been made on uterine contractile activity in relation to sperm transport they have all been undertaken in the sexually non-aroused condition (see section on arousal and reproduction).

What actually creates the uterine contractions is still under debate as discussed previously.

Masters and Johnson [1] and Kinsey et al. [217] differ significantly in their descriptions, both in the appearance and in the placement of the uterine contractions. According to Kinsey et al. [217] 'the upper end of the uterus goes into rhythmic contractions of considerable frequency whenever there is sexual arousal' but Masters and Johnson [1] claimed that 'specific uterine patterns do not develop unless the individual subject undergoes an orgasmic experience'. In conclusion, there are simply too few published recordings/data to resolve these unanswered problems [203].

4. CERVIX

The only change that appears to occur in the cervix is a minimal dilatation of the os immediately after orgasm lasting for 20-30 minutes [1]. It was suggested that this could facilitate spermatozoal transport through the endocervical canal. The mechanism for this dilatation has never been investigated but as the
The cervix has the second highest concentration of VIP in the genital tract; it is possible that its relaxant action on the sparse smooth muscle present could be involved.

5. RECTAL SPHINCTER AND PRESSURE

The rectal sphincter contracts at orgasm, especially in younger women [1], mirroring the contractions of the vagina [219, 227]. Older women do not always show such contractions [1]. More recently rectal pressure changes during orgasm have been analysed by calculating the spectral power in various frequency bands [228]. It was found that an objective rule (algorithm) based on the spectral power in the alpha band (8-13 Hz) identified 94% of the orgasms induced in normal women by clitoral masturbation undertaken by their partners. The alpha fluctuations only occurred during orgasm and were not seen in attempts to mimic orgasm or in failed attempts to induce orgasm (Figure 18). The authors proposed that the integrated spectral power in this 8-13 Hz band of rectal pressure was a specific and sensitive marker for attributing that an orgasm had taken place.

VIII. SUMMARY OF PERIPHERAL SIGNS OF ORGASM

While orgasm is a subjective experience it is normally accompanied by a number of physiological body changes. These changes can be classified as [229]:

i) Prospective – those changes that indicate an impending orgasm;

ii) Current – those changes taking place at orgasm;

iii) Retrospective- those changes that indicated that an orgasm had occurred

See Table 4 for more details

G. TRANSLATIONAL SCIENCE: WHAT IS THE ROLE OF SEXUAL AROUSAL AND ORGASM IN FEMALES?

Sexual arousal in women serves both procreation/reproduction and recreation/pleasure. The changes that occur in the female genitals and genital tract can be divided into those that serve procreation, those that serve recreation and those that serve both procreation and recreation. This section will describe briefly those changes induced by sexual arousal that have functional importance for reproduction (for greater details see [163, 230]).

II. DOES ORGASM HAVE ANY ESSENTIAL ROLE TO PLAY IN FEMALE REPRODUCTIVE MECHANISMS?

1. THE UTERINE UPSUCK HYPOTHESIS

The possible role(s) of orgasm and their importance in the female have always been disputed. A recent book by Lloyd [234], a philosopher, examined critically some 26 papers on the topic and she concluded that there was little or no real evidence to show that orgasm was important for reproduction. One school of thought argues that orgasm plays no essential role...

Figure 18: Rectal pressure (left), an index of perineal muscle activity and spectral analysis on the rectal pressure data (Right). The spectral power was calculated in the frequency bands delta (0.5-4 Hz), theta (4-8 Hz), alpha (8-13 Hz), and beta (13-25 Hz). The most significant and most important difference in spectral power between orgasm and both control motor tasks (imitation of orgasm and failed orgasm attempt) was found in the alpha band. With Permission from [228]
in the mechanism of reproduction promoting the facts that numerous women have become pregnant without an orgasm and that artificial insemination creates pregnancies without orgasm. Another arm of their argument is that as female orgasm created by penile thrusting alone is far from a universal feature among women [235] natural selection has clearly not favoured those who could orgasm easily from such stimulation indicating that it could not be an essential for the reproduction of our species. The other school of thought has proposed that the uterine contractions observed at orgasm (thought to be induced by the orgasmic release of oxytocin) create a uterine ‘upsuck’ and hasten the transport of the sperm. The initial basis for this scenario was the very early paper of Beck [236] who described a case of a patient with a pronounced vaginal prolapse of her uterus making the cervical os easily observed. She was also extremely sensitive to clitoral stimulation. Beck aroused her sexually by stimulating her clitoris digitally and observed that at orgasm the os made 5 or 6 ‘gasps’. He suggested that such activity would suck sperm up into the uterus when immersed in the vaginal seminal pool. Dickinson [237], in fact, using a glass test tube as a surrogate penis and arousing women by clitoral vibration did not find any evidence of such cervical ‘gasping’.

The proposed second supporting study was that of Fox et al [226] who used radio-telemetric pressure pills to measured the intrauterine and intravaginal pressures in a couple during coitus in the face-to-face position. They interpreted their recordings to indicate that the intrauterine pressure fell below that of the vagina during intromission and male ejaculation and after female orgasm suggesting that uterine upsuck of semen could occur. The size of the pressure pill placed inside the uterus, however, was such that it would have expanded the intrauterine virtual cavity abnormally introducing the influence of an unphysiological intrauterine stimulus. As has been pointed out, single-based case studies can be illustrative of a mechanism but they do not necessarily verify it [238]. Thus, the foundations of the upsuck hypothesis appear to rest on results from a 134 year old ‘single patho-physiological uterus and measurements in an over-distended normal one, hardly the firmest of experimental foundations for the putative importance to reproduction of this mechanism’ [163].

Since these early reports other studies [239] on enhanced genital particle transport in women (patients suffering from primary or secondary infertility) injected i.v. with oxytocin have been interpreted to indicate that the oxytocin released at orgasm by, enhancing uterine contractions, will cause the ‘upsuck’ of sperm and facilitate their rapid transport into the uterus and then fallopian tube (see section below for details).

III. SPERM TRANSPORT IN THE UNARoused AND AROUSed FEMALE GENITAL TRACT

Most, if not all, authors describing the influence of sexual arousal and orgasmic uterine contractions on sperm transport in the female reproductive tract have described it as facilitating and speeding up their movement through the cervix into the uterus and fallopian tube (see [163] for references). All have overlooked the crucial influence of vaginal tenting on this putative facilitation. Moreover, it has been shown that there is indeed a fast transport of spermatozoa in the female tract even in the sexually unstimulated woman. Spermatozoa present in liquified semen, when placed on the cervical os in women who are anaesthetised, are found in the fallopian tubes within 5 minutes of their application [240]. In another study, sperm-sized spheres of albumin labelled with 99mTechnetium (surrogates for spermatozoa) when placed in the posterior vaginal fornix in conscious women are found in the fallopian tube on the side of the ovulating ovary within 1- 2 minute of their application [239]. Note that the cervix in these women would be resting on the vaginal posterior wall unlike that in the aroused woman. The mechanism for this remarkably rapid transfer even in the basal state is surprisingly not contractions of the main uterine myometrium (stratum supravasculare and stratum vasculare) but that of the archimyometrium (stratum subvasculare), a thin layer of mainly circular smooth muscle that lies beneath the endometrial cell lining of the uterus and extends from the lower part of the cervix into the uterus and at its upper part dividing into two and continuing into the muscular layer of the fallopian tubes [241]. These cervico-fundal archimyometrial contractions create the rapid, passive uptake of the spermatozoa and direct them into the fallopian tube on the side of the ovulating ovary rather than into the contralateral tube. They are at a maximum intensity and frequency prior to ovulation, are not blocked by high doses of an oxytocin inhibitor (atosiban) and are not enhanced by injected oxytocin [241]. The authors concluded that the contractions were independent of systemic oxytocin but probably sensitive to local endometrial-synthesized oxytocin [242]. Unfortunately there appears to be a conflict with the possible role of systemic released oxytocin and its effect on sperm transport in the studies. According to the findings of these authors, on the one hand they state systemic oxytocin has no effect on the archimyometrial contractions thought to power the spermatozoal transport yet on the other hand, as they themselves report, ‘Surprisingly, oxytocin stimulated directed sperm transport, although given systemically’ [241]. They conclude that ‘oxytocin may not play a critical role in the control of the continuous wave-like activity.
of the archimyometrium, but appears to be a very potent and fast stimulator of uterine contractions! However, comparing the actions of bolus injections of oxytocin with that released at orgasm may be a flawed procedure because the injections were in women who were not sexually aroused, their genital tracts are in a different receptive state and also may have different responses and the dose of intravenous synthetic oxytocin used appears far greater than that released at orgasm making it pharmacological rather than physiological. The physiological role of oxytocin in spermatozoal transport in natural coitus is thus far from clear.

### IV. THE ‘TENTING’ OF THE CERVICOUTERINE COMPLEX – A MECHANISM TO DELAY SPERM TRANSPORT

As described previously, in the basal unaroused state the vagina is a potential space with the cervix close to or touching its posterior wall. Sexual arousal causes the release of VIP from vipergic nerves innervating the vagina which relaxes its smooth muscle during the initiation of coital thrusting. High sexual arousal then causes the contraction of the pelvic levator ani muscle followed by the smooth muscle in the connective tissue septa attached to the uterus. The former, being a striated muscle, fatigues quickly within seconds [209] but the latter can maintain contraction for long periods without fatigue [230]. The contractions lift the cervicouterine complex away from the posterior wall and up into the false pelvis. The back cul-de-sac of the vagina (fornix) becomes ballooned out creating a receptacle for the ejaculate to come. This lifting of the cervix and ballooning of the vagina was named ‘vaginal tenting’ by Masters & Johnson [1]. It has been confirmed by MRI [190,211] and by direct filming [243]. While Masters & Johnson [1] realised that this tenting would remove the os cervix from the path of the ejaculate thus greatly reducing the possibility of rapid sperm entry into the uterus they did not fully appreciate the importance of the mechanism to the reproductive process. This may be to impart a delay in the transport of spermatozoa into the cervical canal and hence through the uterus to the fallopian tube to fertilise the ovum. To understand why delaying sperm transport is of importance it is first necessary to describe the status of semen and sperm at insemination.

Freshly ejaculated spermatozoa in semen in the vagina are barely motile, are trapped in a gel formed by coagulation of semen protein and are incompetent to fertilise the ovum. They have to be reprogrammed into a fertilising state (called capacitation) and liberated from the trapping gel. According to Eisenbach [244-245], once capacitated they remain in this state for only 4 hours, they then become post-capa-
cicitated and irreversibly nonfunctional. Fortunately, not all the spermatozoa are capacitated at the same time and there is a continuous replacement of capa-
cicitated spermatozoa [245,246] from the semen pool. Sperm guidance in the female oviduct to the ovum is probably by thermotaxis (responding to a thermal gradient) and chemotaxis (responding to a chemo-attractant gradient). Only capacitated sper-
matozoaoa are capable of sensing a temperature dif-
ference of 0.5°C and responding to it by swimming from a cooler to a warmer temperature, possibly that of the oviduct and only a fraction of the sperm that are capacitated are chemotactically responsive, be-
ing attracted by chemo-attractants secreted by the ovum [245]. As the experiments to study these func-
tions are undertaken in vitro we have no knowledge whether, or how, sexual arousal influences such guidance in vivo.

It is now known, however, that the process of activating sperm to become capable of fertilisation is far more complex than previously thought [247,248]. The delay imposed on sperm transport by vaginal tenting is essential to allow a variety of mechanisms to operate that are involved in this activation. These currently include:

i) the activation of sperm motility by the enhanced vaginal oxygen pressure and enzymic breakdown of sperm motility inhibitors in the semen [163],

ii) enzymic decoagulation of the gelated semen [249].

iii) mixing and contact of the spermatozoa with activators and inhibitors present in the various component fluids of semen especially the prostate (prostasomes) and seminal vesicle secretions [163],

iv) activation of capacitation and then its suspen-
sion by first messengers in the semen which prevents spontaneous acrosome exocytosis reaction occurring before fertilisation thus preserving fertilising functionality [247].

All these processes are needed to create sperma-
toza that are competent to fertilise an ovum when they are transported from the vagina to the fallopian tube. Rapid transport without the spermatozoa under-
going these changes would deliver incompetent spermatozoa unable to fertilise.

One possible criticism of the importance of vaginal tenting to reproductive fitness is that it will only be most effective when coitus is performed in the face-
to-face or missionary position. Coitus with ejaculation in the rear entry would allow a greater likelihood of semen falling onto the cervix thus negating the delay. This may well, however, mean that fertilisation
in this position becomes more difficult. However, the missionary position is regarded by many, if not the most, as the basic one for achieving pregnancy. The answer to the critics is that ‘no evolved biological mechanism can be effective and can ensure reproductive fitness in every contingency. Biological adaptation can serve only one particular set of conditions there are always selective compromises’ [163].

Finally, while the elevation of the cervix by vaginal tenting is the major mechanism by which spermatozoal transport is delayed other mechanisms may also be involved. There is evidence, admittedly in a single case, that uterine motility is inhibited after orgasm [250] and that genital muscular reflexes are suppressed [163,205].

V. TIMING OF THE FEMALE ORGASM AND REPRODUCTIVE CONSEQUENCES?

The female orgasm can occur at three particular time points during coitus, these are:

i) before ejaculation occurs,

ii) during ejaculation,

iii) after ejaculation.

Clearly the first scenario will not influence the immediate transport of spermatozoa as there are none to transport. Baker & Bellis [251] proposed, however, without any experimental measurements, that such an orgasm would upsuck the acidic vaginal fluid making the cervical fluid hostile to sperm and could thus influence subsequent sperm uptake. This scenario obviously overlooked the fact that vaginal tenting in the fully sexually aroused state would have removed the cervical os from any contact with the vaginal posterior floor. Sexual arousal per se has no effect on the pH of cervical fluid it being unchanged from the basal values [233].

While orgasm can occur simultaneously with male ejaculation, scenario ii), its likelihood is low as most males ejaculate before women have their coital orgasms. Moreover, as the semen coagulates at ejaculation the relative immobile spermatozoa are trapped and uncapacitated so little effective transport into the cervix/uterus would occur. By far the most prevalent coital scenario will be that of iii), female orgasm after ejaculation. Not surprisingly, a study of women who were desirous of becoming pregnant indicated that they had their coital orgasms after their partner’s ejaculation [252].

A highly contentious proposal was that women could consciously reduce the amount of semen leaking from their vagina (termed ‘flowback’) thus controlling the amount of semen retained which would aid fertilisation from a chosen partner by the timing of their orgasm during coitus [251,253]. Low sperm retention was claimed to be associated with female orgasms earlier than 1 minute before the ejaculation whereas maximum retention was said to occur with orgasms from greater than 0 to 1 minute after ejaculation. The effect only lasted for 1 minute before ejaculation to 45 minutes after. These studies and the statistics used have been heavily criticised by Lloyd [234] who does not think that they can be relied on.

VI. OTHER PROPOSED REPRODUCTIVE FUNCTIONS OF THE FEMALE ORGASM

Various postulated functions for the female orgasm were collected by Levin [178]. Those that could have a bearing on reproduction were a) to create lassitude in order to keep the female horizontal thus delaying the occurrence of gravity-created ‘flowback’ of semen and the subsequent sperm loss, b) to release antidiuretic hormone (ADH or vasopressin) for the possible contraction of uterine and vaginal smooth muscle and to inhibit urination and thus any subsequent sperm loss from a need to urinate shortly after coitus with ejaculation, c) to release oxytocin for a possible bonding effect, d) because of the difficulty in creating orgasm through coitus per se, orgasm, when so induced, acts as a ‘Mr Right’

Box 4

- Sexual arousal increases vaginal lubrication which partially neutralises its basal acidity facilitating sperm survival and increases its oxygenation facilitating their function.

- Vaginal tenting – the elevation of the cervico-uterine complex from the posterior vaginal wall delays sperm transport.

- The delay is essential to allow seminal decoagulation which frees sperm allowing contact with semen pre-capacitation and capacitation factors to make the sperm functional for fertilisation.

- Proposed rapid uptake and transport of sperm by systemic oxytocin-induced uterine contractions at orgasm is unnecessary as sperm is effectively and rapidly transported by spontaneous contractions of the uterine archimyometrial smooth muscle layer.
indicator aiding in creating a strong pair-bond with the male, e) to create the loss of body boundaries and separateness allowing a unique merging or fusion with the chosen coital partner g) to resolve uncomfortable pelvic vasocongestion (fullness). Though these are mostly speculative.

**H. PATHOPHYSIOLOGY OF FEMALE SEXUAL DYSFUNCTION (FSD)**

It is evident from the physiological descriptions above that changes of the the female physiology and/or anatomy may play a role in pathophysiological processes of and in some cases lead to FSD. However, as most research in FSD has focused on psychological and relational aspects of risk factors for FSD there is limited evidence for into what extent pathophysiological changes predispose for and elicit sexual problems in women and often physiological, psychological and relational factors will interact.

As described above possible pathophysiological processes may interact on several levels of the female physiology and have an impact on different phases of the sexual response: desire, arousal, and orgasm. The pathophysiological changes can be at many levels: the central or the peripheral physiology of the female sexual response and may, amongst many factors, include pathophysiological changes in cell-to-cell communication, changes in endocrine milieu, disruption in homeostasis of neurotransmitters and signal molecules, tissue damage, organ damage, vascular changes and neurological changes central and peripheral. However it is important to keep in mind that women with impaired physiology may have no sexual problems as well as women with no physiological changes can experience sexual problems.

Consequently, endocrine, neurological, cardio-vascular, dermatological, neurological and psychiatric conditions as well as cancer, medication and surgical procedures all have the potential to induce pathophysiological processes influencing the sexual function in women.

Most of the pathophysiological aspects of FSD are covered in other chapters and the reader is referred to these chapters for more information.

However, Female genital mutilation/cutting (FGM/C) is not addressed in other chapters and a short section is therefore added to this chapter.

**I. FEMALE GENITAL MUTILATION/CUTTING (FGM/C)**

Female genital mutilation/cutting is an intervention with irreversible change of the female genital physiology. Different types of FGM/C refer to a spectrum of surgical excisions [254,255] of the female genitalia as outlined in table 5.

The complications to FGM/C are at different levels and can be immediate and delayed:

The trauma itself, as it is often done in infancy or just before puberty and often without anaesthesia[255]. The immediate complications at the time of the procedure can be, hemorrhage, infection, shock, septicemia and death. Delayed gynaecological complications as menstrual disorders, hematocolpos, vaginal stenosis, infertility and sterility, incontinence, urethral stenosis, urinary infections, obstetric complications and fistula formations [254,256,257]. Psychological/psychiatric problems may also be a longterm complication, as depression, phobia, anxiety, depression and somatization [258] secondary to the physical and psychological trauma.

All these complications may evidently have a possible affect on womens’s sexuality, though only few studies have addressed this and the reports are conflicting. Besides the sexual problems induced by side effects as mentioned above the damaged or missing structures and tissues can have a impairing effect on sexual desire, arousal, orgasm, satisfaction and pain during intercourse. Depending on which type of circumcision that is performed, genital sensitivity and orgasmic response may be affected. In the study by Thabet & Thabet [259] it was shown that desire, arousal and orgasm were significantly negatively affected in the more mutilated women and women with complications to the intervention. In the study of Elsashar [258] on 200 circumcised women, they showed a significantly lower libido, arousal and satisfaction with husband and higher level of dyspareunia in FGM/C women compared to non-circumcised women. Furthermore the FGM/C women experienced significantly more gynaecological problems. In the study by Catania et al. [260] it is reported that 86% of the FGM women experienced orgasm in almost all cases. They conclude that cultural factors in combination with the changed physiology is determining whether the

woman can reach an orgasm, but also underlines that one explanation may be that not all erectile tissue necessarily is removed during the FGM/C and that the vestibular bulbs are still preserved and functioning as erectile organs.

In conclusion FGM/C is a devastating intervention with serious risk for the women's general and sexual health and with a direct impact on the genital physiology.

I. INTERACTIONS BETWEEN PHYSIOLOGICAL AND PSYCHOLOGICAL STATES OF WOMEN'S SEXUAL RESPONSE

Until now the chapter has focused on physiology and pathophysiology of women's sexual response, but it is clear there is an interaction between physiology and psychology in the sexual response, and recently growing evidence has shown a gender difference in this interaction.

Among women, there is a lower degree of correspondence between the physiological and psychological states of sexual response, termed concordance, than is typically observed among men. Similarly, low agreement has also been observed between physiological responses and psychological traits, namely sexual orientation, particularly among heterosexual women, a phenomenon termed nonspecificity.

The potential for low concordance and nonspecificity of sexual response are examples of the relative independence between physiological, psychological, and behavioral aspects of women's sexuality. This section of the chapter examines current research on concordance and nonspecificity of women's sexual arousal within the broader context of implications for psychophysiological assessment of women's sexuality and sexual functioning, and for understanding the development and expression of female sexual orientation.

I. CONCORDANCE OF WOMEN'S SEXUAL AROUSAL

Psychological and physiological processes characterize human sexual response. Sexual arousal is an emotional state [261] and, similar to other emotions, sexual arousal possesses distinct antecedents (e.g., sexual stimuli) and patterns of expression (e.g., psychological, physiological, behavioral) serving to regulate behaviors fundamental to sexual reproduction [262].

The degree to which the individual's experience of sexual arousal corresponds with her physiological response (concordance) is a matter of interest to researchers and practitioners in sexual medicine, since subjective (or self-reported) experience and genital measures of sexual arousal do not always agree. Knowing the extent of concordance, and identifying factors that moderate subjective-genital agreement, informs our understanding of the best methods to assess each aspect of sexual response, and models of sexual response and sexual dysfunction.

The most frequently cited moderator of concordance is gender, such that men show significantly greater concordance than women. A recent meta-analysis of the sexual psychophysiological literature concluded that, across 134 studies assessing subjective and genital sexual responses, the gender difference in concordance was a robust phenomenon that was not accounted for by methodological or statistical factors [263].

First, agreement between actual genital arousal and self-reported arousal in women is not zero; the average correlation reported by Chivers and colleagues was +.31 for agreement between subjective state of sexual arousal and actual genital response, and +.20 for agreement between perception of genital arousal and actual genital response. Physiological sexual response is, therefore, positively related to subjective experience of and awareness of genital sexual arousal in women [263].

Second, it is notable that the relationships between subjective experience of sexual arousal and actual physiological response are significantly greater than the relationship between awareness of genital response and actual physiological response [263]. This suggests that women's experience of sexual arousal is not primarily related to experience of physiological responding and is mediated by additional cognitive and emotional mechanisms. It is not clear how much appraisal of subjective sexual arousal is influenced by perception of genital responding, or vice versa, but these measures are highly positively correlated in women [264]. That these two self-report measures differ in their relationship with psychophysiological measured genital sexual arousal suggests there is a difference between experiencing sexual arousal and perceiving physical changes.

Concordance between perception of genital response and actual genital sexual arousal is an index of interoceptive awareness, that is, the psychological capacity to perceive internal physiological changes. The tendency for women to demonstrate low sexual interoceptive awareness may result from the information women use to appraise their emotional state of sexual arousal; women attend more to external, situational cues when appraising their emotional states than men do [265]. The greater reliance on external information suggests that women's experience of sexual arousal is more influenced by their attitudes, beliefs, and values regarding sexuality, as well as immediate contextual factors such as sexual
stimulus properties and their appraisals of these properties [266].

Women’s concordance estimates can vary widely such that some women’s reports of sexual arousal are unrelated or even negatively related to genital responses, whereas other women show large and positive correlations between self-reported sexual arousal and genital vasocongestion [267]. This variability in women’s concordance estimates may reflect the multitude of psychological factors that influence women’s experience of sexual arousal more so than physiological factors, suggesting a role for individual differences in moderating concordance between self-reported and genital sexual arousal. This raises fascinating questions as to the origins of concordance among women and whether concordance is a desired state (see next section).

II. CONCORDANCE AND THE PATHOPHYSIOLOGY OF FEMALE SEXUAL RESPONSE

Cognitive models suggest that concordant sexual response is a desirable, or even necessary, state for satisfactory sexual functioning [268]. The potential for concordance to vary with sexual functioning has been demonstrated in studies of sexually dysfunctional women; women with sexual arousal problems report lower subjective sexual arousal to sexual stimuli in the laboratory, but typically do not show significantly lower genital responses when compared to women without sexual arousal problems [269,270]. Studies comparing the concordance of sexual responses of sexually functional and dysfunctional women have yielded mixed results: some report greater concordance among the functional women [269,271-275], some report negative concordance for the functional women [276-278], and one reported no group differences [279]. The strongest evidence in favor of lower concordance among women with sexual dysfunction comes from Chivers et al.’s [263] meta-analysis, which found lower concordance among women with sexual dysfunctions versus sexually-functional women.

Among sexually functional women, concordance may be related to better sexual functioning, such that women who show greater concordance also report greater frequency of orgasm during penile-vaginal intercourse, but not during other sexual behaviours [280,281]. Similarly, significantly positive concordance estimates have been obtained for frequently orgasmic women [282]. While orgasm frequency, particularly during heterosexual coitus, is an inadequate means of determining women’s sexual function, these studies do indicate an association between concordance and orgasmic frequency that suggests concordance may be a useful index of integration of physiological and psychology sexual information among women, and thus may prove to be a useful predictor of sexual functioning.

III. NONSPECIFICITY OF WOMEN’S SEXUAL AROUSAL

The relationship between the psychological and physiological sexual response, and psychological traits, like sexual orientation, also shows marked discordance in women. Gender differences have been observed in the relationship between self-reported sexual attractions (toward males or females) and patterns of genital and self-reported sexual arousal to female and male sexual stimuli; men’s sexual arousal patterns are very strongly associated with their self-reported sexual orientation, whereas women’s are not (see figure 19) [283-289]. Women’s genital arousal responses are less related to their sexual preferences; although a woman might report psychological (attraction, thoughts, self-reported sexual arousal) and behavioral preferences for women or men, her genital responses are not higher to sexual images of her preferred gender.

Women report increased sexual arousal to both preferred and non-preferred sexual stimuli [288,290-292], which suggests that their cognitive and affective responses to sexual stimuli are not dependent upon their sexual preferences, such as sexual orientation. Sexual desire, as evidenced by masturbation and partnered sexual behaviors, is also kindled by exposure to both preferred and non-preferred sexual stimuli [290] suggesting that, among heterosexual women, motivation for engaging in sexual behavior is also less dependent upon sexual preferences.

The nonspecificity of heterosexual female sexual responses measured using sexual psychophysiological methods is congruent with research in which other psychophysiological methodologies, such as electroencephalograms, fMRI imaging, and viewing time, were used to examine gender differences in the specificity of sexual responding [42,293-297]. For example, Wallen [298] reported that heterosexual women showed similar patterns of activation in brain areas associated with sexual arousal to both preferred and non-preferred sexual stimuli. Using still pictures of female and male nudes, Sylva et al. [42,294] have investigated the brain correlates of the specificity of women’s sexual response using fMRI to examine brain activity while processing still pictures of female and male nudes.

Contrary to data on peripheral genital responding, heterosexual and lesbian women’s brain responses showed specificity in areas associated with processing of visual stimuli and motivation, that is, greater response to stimuli matching a woman’s sexual orientation. Hypothalamic response, however, did not show category-specific response for either group.
Similar to the pattern of genital responses [288], specificity in amygdala function was found for lesbian women only; heterosexual women showed nonspecific amygdalar responses. The general pattern of results from these different lines of research demonstrates that specificity and nonspecificity of peripheral sexual responses are mirrored in central aspects of sexual functioning in women.

IV. NONSPECIFICITY OF SEXUAL AROUSAL AND WOMEN’S SEXUAL ORIENTATION

Research on the specificity of women’s sexual arousal converges with current models of female sexual orientation that emphasize flexibility in women’s sexual attractions and sexual identities. Flexibility refers to a pattern of intraindividual variability in sexual preferences, attitudes, and behaviors [266]. With respect to sexual orientation and identity, women are more likely than men to experience and express same-gender attractions and less likely to engage in exclusively heterosexual or homosexual sexual behaviors [217, 218, 266, 299-301], and women’s sexual identities show less temporal stability than men’s [302-307]. Diamond [308] has suggested that the processes underlying romantic and affectionate bonding are not intrinsically gendered toward females or males, and that romantic and affectionate feelings have the capacity to kindle sexual desire, particularly among women. Therefore, a woman’s sexual desire

Figure 19: Heterosexual women’s and men’s mean genital responses, in standardized z-scores (top panel), and self-reported sexual responses, in percentage increase from baseline (bottom panel), to various categories of stimuli.

Error bars represent the 95% confidence interval for the mean. E=exercise; M=masturbation; I=intercourse; C=control; NH=nonhuman; FM I=female–male intercourse. The stimulus category “Intercourse” in the male and female panels represents responses to depictions of two men and two women, respectively, engaged in intercourse. Figure adapted with permission from [288]
for another woman may emerge from a close emotional relationship instead of from sexual attraction to and arousal by women. Self-report data on the development of female sexual orientation support this proposition; women report that social and emotional factors are more salient than sexual arousal to the development of their sexual interests in either the same gender [305, 306] or opposite gender [309]. Nonspecific sexual responding may increase the potential for flexibility in women’s sexuality because patterns of sexual arousal do not constrain women’s sexual behavior, feelings, or identity.

V. NONSPECIFIC SEXUAL RESPONSE AND INFERENCES ABOUT WOMEN’S SEXUAL INTERESTS AND DESIRES

The potency of stimuli depicting any sexual activity to evoke genital response, regardless of the actors portrayed or context of the sexual activity [288] (Figure 19) is also highlighted in studies where women show physiological sexual responses to other clearly nonpreferred sexual stimuli, such as films of nonhuman sexual activity [287, 288] and sexual threat stimuli [285, 291, 310-312] In these studies, although women demonstrated significant increases in vaginal vasocongestion to nonpreferred sexual stimuli, they did not also report significantly greater self-reported sexual arousal to these stimuli compared to their preferred sexual stimuli.

Overall, current research suggests that little can be inferred about a woman’s sexual orientation or motivation from her genital responses alone. Some have proposed that physiological sexual response in women is an automatic reflex that is elicited by sexual stimuli before conscious appraisal of a sexual stimulus as being sexually arousing or preferred [313-315]. Genital response precedes subjective sexual arousal [316], is evident within seconds of the onset of a sexual stimulus [317], and can occur in the absence of subjective experience of sexual arousal [287].

Primary sexual cues, such as sexual activity [288], may initiate reflexive vasocongestion, leading to vaginal lubrication, and preparing the genitals for possibly sexual activity. Reports of women’s genital response and orgasm during sexual assault [182] and research showing that women experience genital responses to sexual threat stimuli suggests that genital response under conditions of nonpreferred sexual stimuli may be typical in women. For this reason, inferences regarding a woman’s sexual desire and relative sexual attractions based solely on her genital responding would very likely be inaccurate.

VI. CONCLUSION/SUMMARY

Gender differences exist in the relationships among psychological, behavioral, and psychophysiological aspects of sexuality, with greater flexibility observed in women. Low concordance between genital and psychological measures of sexual arousal is typical for women and not necessarily indicative of problematic sexual functioning. Nonetheless, there is some evidence that higher concordance may be associated with better sexual function (in terms of orgasm frequency during sexual intercourse). Concordance may, therefore, be a useful measure of the integration of physiological and psychological sexual response in research on sexual functioning. Women show nonspecific sexual responses, with respect to their sexual orientation; this effect is most pronounced in heterosexual women, and under certain stimulus conditions. The potential for discordance between physiological sexual response, psychological states of sexual arousal, and psychological traits, such as sexual orientation, strongly suggests that objective measures of sexual response should not be used in isolation to draw conclusions about women’s sexuality.

Box 5

- Gender difference in concordance; women show lower agreement between physiological and psychological aspects of sexual response than men.
- Concordance is variable in women, suggesting that individual differences, such as sexual functioning, moderate agreement between physiological and psychological aspects of sexual response.
- Gender difference in specificity of sexual response; men’s responses are category-specific and women’s are nonspecific, with respect to sexual orientation.
- Nonspecific sexual responding may underly flexibility in women’s sexual attractions.
- Female genital response is a reflexive response to exposure to any sexual stimulus depicting sexual activity, whether preferred or not.
- Nonspecific genital vasocongestion suggests that genital response is not a valid indicator of sexual desire or sexual orientation.
Recommendations for future research in physiology and pathophysiology of women's sexual function and dysfunction. It is recommended that future research focus on

- Sexual brain development and how extrinsic factors can alter it
- Neuroimaging of sexual function and dysfunction
- Central and peripheral neuromodulators and their interactions
- Integration of central and peripheral mechanisms
- Interaction between physiological and psychological mechanism

In recent years there is considerable and growing interest in using neuroimaging techniques to explore and understand the cerebral correlates underlying the sexual response. These techniques are powerful tools that are capable of providing a great deal of information on brain activity in response to sexual stimuli as has been summarized in this chapter. However, there are many limitations and potential pitfalls that one should be aware of when planning a study using these tools or even when reading a literature report describing results of a functional brain imaging study.

Use the appropriate technique

- [15O]-H2O PET is less sensitive to head motion than other techniques, but has relatively poor spatial and temporal resolution.
- BOLD fMRI offers good spatial and temporal resolution with exquisite sensitivity for detecting areas of brain activation, but is not sensitive to mental and emotional states that develop over minutes (like sexual arousal?). BOLD scanning loses sensitivity with stimuli > 1 minute.
- PET-signal is not stable over time because of radioactive decay and a single bolus infusion of isotope.
- BOLD signal is unreliable in air-tissue transition zones like the medial temporal lobe and the ventral prefrontal cortex adjacent to air-filled paranasal sinuses, because of magnetic susceptibility effects that cause rapid decay of T2*.

Multi-subject experiments are the rule

- In a single subject the level of activation is small and there are many sites of brain activation. Multi-subject studies will show which sites have high reproducibility and are likely to be connected to the (sexual) task, thus enhancing the power of the study. A typical multi-subject (BOLD) fMRI study comprises 10-20 subjects. For multi-group studies, 15 subjects per group are usually necessary. The number of subjects needed to yield an expected effect size may be calculated using the freely available tool G-power (http://www.psycho.uni-duesseldorf.de/aap/projects/gpower/).

Carefully attention to experiment design is essential

VSS

- Have good arguments for choosing videos versus still pictures. If video is used with BOLD fMRI, the duration of each video block should be as short as possible, ideally < 1 minute. Mode and duration of the stimuli will bias the activation pattern.
- Validate the effectiveness of the chosen stimuli (and the paradigm) outside the scanner in a separate group of subjects.
- Appropriate control stimuli should be chosen for a selected (sexual) activation task. Inappropriate, neutral or mildly pleasant control stimuli may result in considerable non-specific activation due to differences in emotionality produced by disparate stimuli.
- Check to determine whether subjects were attentive to the stimuli, e.g. by instructing them to pay attention to certain features in the stimuli and then to either respond to these during scan or answer a questionnaire at end. Number of correct responses can be used to validate attentiveness.

Sexual consummation

- Decide the type of genital stimulation to
use. The selected stimulus should induce as little head motion as possible.

Sexual arousal assessment

- Many tools are available to assess perceived level of sexual arousal that may be used during scanning or at end of scan (i.e., perceived level of arousal questionnaire). Note that rating process itself if performed during scan may cause distraction. For fMRI and objective sexual arousal (e.g., vaginal photopletysmography), make sure that devices you want to use are MR-compatible (are not paramagnetic).

Subject cohort(s)

- Subjects should be matched as closely as possible on gender, sexual orientation, menstrual cycle phase, age, handedness, etc. to reduce statistical noise in the data. If not possible remember to collect information on heterogeneity.

Limit head motion

- MAJOR LIMITATION of fMRI technique. A priori limits for head motion should be set and images that exceed these limits should be removed from data set. Translational and rotational head motion can be easily measured and can be used to remove motion-related noise in the data. Motion correction software should be used to align remaining images within data set. If task-induced head motion correlates with the model (such as for sexual consummation study), these procedures can become problematic since such correlated motion may remove ‘true’ task-related activity or introduce “false activations”.

Analysis strategies

- Parametric: Most widely used. Assumes brain activity correlates with pre-defined model and/or behavioral parameters.

- Non parametric: may be used to find brain activation patterns uncorrelated with a model or behavioral parameters that were nevertheless important during the experiment. Is particular to find sites where activation sites/patterns are correlated with each other (network) rather than with the model.

Analysis software

- There are many available software packages commonly used to assess functional neuroimaging data sets.

  - SPM: free download at http://www.fil.ion.ucl.ac.uk/spm/. Uses Matlab for calculations (version 6.5 or higher).
  - FSL: free dowload at http://www.fmrib.ox.ac.uk/fsl/. Requires Linux or Linux virtual machine (Vmware).

Non parametric

  - SnPM: free download at http://www.sph.umich.edu/ni-stat/SnPM/. Requires SPM to be installed.
  - GIFT: independent component analysis, plug in for SPM
  - MELODIC: independent component analysis, part of FSL toolbox

ACKNOWLEDGEMENTS

We are grateful to Dr. Helen O’Connell, Prof Norm Eizenberg and Anatomeedia for the permission to use their anatomical pictures. Furthermore we are thankful to Dr. Helen O’Connell for her comments to the chapter.

INTRODUCTION

Although our understanding of the physiology of sexual function in women is limited, there has been a renewed interest in the role of estrogens and testosterone in normal sexual functioning in women. Endocrine changes during aging as well as endocrine disorders may either directly or indirectly modulate sexual function by altering sex hormones, or by impacting on vascular, neurogenic and/or psychologic factors. This review will outline our current state of knowledge concerning the impact of the hormonal changes across the lifespan or those due to endocrine disorders on female sexual function and information on the risks and benefits of hormonal treatment.

I. REVIEW OF THE LIMITATIONS OF PAST AND CURRENT SEX STEROID MEASUREMENTS AND REFERENCE RANGES FOR WOMEN

1. PROBLEMS OF QUALITY CONTROL, ACCURACY, AND SENSITIVITY FOR TESTOSTERONE ASSAYS (LEVEL 1 EVIDENCE)

Like those in the physical sciences, we should insist that there be a fixed traceable standard for all measurements. The International Organization for Standardization (ISO) defines “traceability” as the property of the result of a measurement or the value of a standard whereby it can be related to stated references….through an unbroken chain of comparisons all having stated certainties.” [1] This definition forms the basis for accuracy-based proficiency testing. Although this is easier said than done, it can and has been done for a number of important analytes [1]. For testosterone and estradiol proficiency testing in the United States, however, the principle of traceability is not followed. Rather, analytes embedded in a synthetic matrix are sent to client laboratories for assay; the laboratories’ competences are not evaluated by the accuracy of their results but rather by a comparing their results to others using the same method. If a clinical laboratory changes instruments, new assays on the same patient cannot be compared to previous ones with confidence. Epidemiologic studies dealing with these hormones cannot be compared to another in which a different instrument/method was used. Nor can a new study by the same investigator be compared to a previous one if the original methods have become obsolete.

a) Total Testosterone (T)

In 2005, The College of American Pathology (CAP) sent multiple unknown samples to over 1,000 participating laboratories to measure total testosterone[2]. The mean levels of total T ranged from 33 to 772 ng/dL in the tested specimens and revealed a 2-fold difference in peer group means across all levels of total testosterone. More strikingly, for samples in the mid-normal range for women, the spectrum of results obtained (mean=32.7 ng/dl), was 7-100 ng/dl! Alternatively a single laboratory can compare the accuracy, sensitivity and reproducibility of immunoassays for testosterone with one another, and with a mass spectroscopy-based method. This approach has been the basis of a number of excellent studies [2-9]. The profound lack of accuracy, sensitivity and reproducibility of most immunoassays for testosterone is graphically illustrated by comparing 10 immunoassays [8] to a method based on mass spectroscopy (MS). For the higher values of T, e.g. in the male range, there was at least a relationship between the MS-based method and the immunoassays. However, this was not true for values below about 8 nM, i.e. levels seen in the plasma of women and children. The disagreements are severe enough to render current immunoassay results, in women and children, are virtually useless. Since normal women, both pre- and postmenopausal, have a plasma testoster-
one concentrations less than about 2.5 nM[10], it is clear that methods better than current automated immunoassays are needed to establish normal ranges. Together, these data suggest that prior studies attempting to correlate T levels with sexual function may not have been sensitive or specific enough to detect changes in women across the lifespan.

**b) Free Testosterone (FT)**

Testosterone binds SHBG and albumin. In men, albumin binds 50%, SHBG binds 48% and 2% is free; in women the respective percentages are 66%, 33% and 1%.[10]. The unbound portion, free testosteron (FT) and/or that bound to albumin, is often considered the moiety that gets into the cell and results in androgenic effects. The situation is more complicated than that [11, 12] but, as a practical matter, FT often correlates better with the hyperandrogenic state of the patient than does total testosterone [13]. The optimal method to measure FT is disputed and the advantages and disadvantages of each method have been recently reviewed. Importantly, all measurements of FT depend, among other things, on an accurate determination of total T (see discussion above). The measure of FT using a direct immunoassay has been soundly rejected in the literature [2, 14-17] and ought not to be used.

In the US, the Centers for Disease Control and The Endocrine Society have partnered to develop traceability in the measurement of testosterone and to invite the clinical laboratory community to join in the effort [18].

A number of laboratories are focusing on the use of mass spectroscopy-based methods to assay testosterone in biologic fluids [9, 19]. The various methods differ somewhat, particularly in how the sample is treated before entering the mass spectrometer. Although the agreement among MS-based methods is much better than among immunoassays, compared either to each other or to MS-based methods, there is as yet no universally accepted method. However, compared to immunoassays, the agreement above 5 nM is excellent and below this concentration, is significantly better than any of the immunoassays.

**2. RECOMMENDATIONS ON TESTOSTERONE ASSAYS**

As the methods for the measurement of testosterone gain the accuracy, sensitivity, and reproducibility that are necessary, normal ranges for women will have to be ascertained across the life span, across the menstrual cycle and among various ethnicities. The study of testosterone in women then will be able to proceed on a firm and rational basis. We therefore recommend the use of new assays to reassess changes in testosterone levels across the lifespan and their relation to sexual function and dysfunction (Grade A).

We recommend the use of total T, in an assay of optimum sensitivity and specificity, and SHBG to calculate FT to assess plasma androgens (Grade A).

**3. THE PROBLEMS OF QUALITY CONTROL, ACCURACY, AND SENSITIVITY FOR ESTRADIOL ASSAYS (LEVEL 1 EVIDENCE)**

**a) Total Estradiol (E2)**

The state of affairs with respect to estradiol is similar to that for testosterone. In postmenopausal women, where E2 levels are routinely <15 pg/ml, the risk of breast cancer and vertebral and/or hip fracture, may vary with E2 concentrations that are below the sensitivities of current commercial assays [20]. Other circumstances requiring more sensitive assays include: pubertal disorders; estrogens in men; monitoring of E2 in the context of antiestrogen therapy (e.g. aromatase inhibition), and research in Alzheimer’s disease and cardiovascular disorders [21]. Immunoassays for E2 lack the sensitivity, and hence the accuracy, to quantitate E2 in plasma at the concentrations present in the circumstances described above[22]. The CAP does “peer group” proficiency testing for estradiol[23]. The lowest sample distributed, 70 pg/ml, is substantially greater than the values seen in men and postmenopausal women. Even so, the overall coefficient of variation of 66.4%, and the overall ratio of highest to lowest value of 70 on the same sample suggests the need to improve these assays at low concentrations.

**b) Free estradiol**

Like T, E2 is bound to SHBG and albumin in plasma. A major difference in binding constants results in a quite different distribution of the steroid in its major three physical states. In men, about 78% of E2 is bound to albumin, 20% to SHBG and 2% is free whereas in women the respective percentages are 61%, 37% and 2%[10]. There has been substantially less investigation of physiology/disease with free E2 as an endpoint. Like T, its estimate depends upon an accurate assay for total E2, leading to the same major difficulties seen with FT assays. LCMS based methods for E2 have been cumbersome [22, 23], and until recently were not optimized for routine clinical use or for large epidemiologic studies. Of late there has been a substantial effort to modify the methods to increase both their sensitivity and throughput [19, 24-28]. Little data are available for estrone (E1) or other estrogens.

**4. RECOMMENDATIONS FOR ESTRADIOL ASSAYS**

We recommend that E2 levels across the lifespan be assessed with the newer assays to test whether levels correlate with female sexual function or dysfunction (Grade A).
5. THE POTENTIAL IMPACT OF INTRACRINOLOGY AND FEMALE SEXUAL DYSFUNCTION (LEVEL 1-2 EVIDENCE)

a) Overview

Primates have adrenals that secrete large amounts of the inactive precursor steroid DHEA which is converted into active androgens and/or estrogens in specific peripheral tissues [29, 30]. Since estrogen secretion by the ovaries stops at menopause, a major source of androgen and estrogenic precursors in women after menopause is DHEA of adrenal origin. There is also a significant decrease of androstenedione (a proximate precursor of both estrogens and testosterone) secretion by postmenopausal ovaries. This change, coupled with a marked reduction in the formation of DHEA by the adrenals with age [31], results in a parallel fall in the formation of androgens and estrogens in peripheral target tissues for want of appropriate precursors and/or reduced activity of converting enzymes.

Classically, the effects of sex hormones were assumed to be secondary to the ovarian secretion into the plasma, followed by their uptake by an appropriate target tissue. Thus, one could assess their activity by measurement in peripheral plasma. Local biosynthesis and action of prohormones that can be converted into androgens and estrogens in target tissues termed “intracrinology” may bypass the exposure of other tissues to the hormones [29]. This process may be important in normal physiology, i.e. aromatization of prohormones to estrogens in the brain or androgenic precursors in the vagina. Alternatively, risks may be increased by local biosynthesis of sex hormones, e.g. increased aromatization of androgens to estrogens in breast tissue. Data on the conversion of DHEA to active sex hormones in target tissues have raised the possibility of its use as a prohormone replacement therapy[32].

II. ROLE OF ESTROGENS IN FEMALE SEXUAL FUNCTION AND DYSFUNCTION: EVIDENCE FROM LOW ESTROGEN STATES AND EFFECTS OF ESTROGEN TREATMENT

1. WHAT IS THE EVIDENCE THAT ESTROGENS PLAY AN IMPORTANT ROLE IN FEMALE SEXUAL DYSFUNCTION?

With the menopausal transition, women often experience cognitive changes, mood instability, night sweats and disrupted sleep [33]. Urogenital atrophy results in dyspareunia which may adversely impact on sexual function. Although vasomotor symptoms generally improve with time, in the absence of treatment urogenital atrophy may worsen with time since cessation of menses[34]. Vasomotor symptoms are more severe with surgical than with naturally occurring menopause, likely due to the abrupt decline in estrogens at the time of bilateral oophorectomy (BSO) [35-39]. One difficulty of using menopause as a model for studying the effects of estrogen deficiency and treatment on sexual function is that T levels also change, in some but not all studies [40-42]. Naturally menopausal women have gradual changes in their T levels with aging; surgically menopausal women experience an approximate 50% decrease in circulating concentrations at the time of bilateral salpingo-oophorectomy (BSO)[37, 38, 43-46]. Surgical menopause also is an imperfect model for studying the effects of estrogen on sexuality, as most women undergoing hysterectomy and BSO have underlying uterine pathology, e.g., fibroids, pelvic pain or dysfunctional uterine bleeding; thus, sexual function may improve with treatment of the underlying gynecologic problem, independent of hormonal status [35, 47]. Alternatively, BSO may be unwelcome, imposing premature infertility and negatively affecting sexual self image and function.

Most evidence supports an important role for estrogens in healthy sexual functioning, principally by treating bothersome vasomotor symptoms and maintaining vaginal health. Estrogen deficiency results in sexual dysfunction if vaginal atrophy and dyspareunia occur, often leading secondarily to decreased sexual interest, arousal and response [34, 48, 49]. Sexual sensitivity of genital and non-genital skin is also linked to estrogen status. Vasomotor symptoms with associated sleep disruption, fatigue and impaired quality of life also will have a negative effect on sexual function [34, 50] Estrogen therapy may improve sexual function by treating vaginal atrophy and bothersome hot flashes and night sweats [51-53]. To summarize, a significant direct effect of estrogen on sexual interest, arousal and orgasmic response, independent of its role in treating the foregoing menopausal symptoms, is not supported by current evidence.

2. EVIDENCE FROM OBSERVATIONAL STUDIES IN SURGICALLY MENOPAUSAL WOMEN (LEVEL 2 & 3 EVIDENCE)

Women who undergo BSO prior to natural menopause experience an abrupt decline in plasma estrogens [36-38, 44, 54, 55]. The remaining estrogens present after BSO results from peripheral aromatization of adrenal prohormones. Optimally, oophorectomized women should be compared to hysterectomized women who retain their ovaries. Studies are imperfect, however, as the indications for surgery, the surgical procedures, and the accompanying testosterone deficiency following oophorectomy may impact sexual function post-operatively.
In the Maryland Women's Health Study, over 1,000 women were interviewed before and after hysterectomy. Although 44% of the women had concurrent BSO, improvements in sexual functioning post-operatively were observed. The majority of women (88%), however, were taking hormone therapy (HT) post-operatively. Thus, the independent impact of estrogen deficiency on impaired sexual function could not be assessed. Predictors of post-hysterectomy low libido were pre-hysterectomy low libido and depression [36]. In a retrospective study that controlled for post-operative estrogen therapy, approximately 100 women ages of 47-55 years were evaluated 2-6 years after hysterectomy. Comparisons were made between oophorectomized women not using estrogen therapy (ET), those using ET, and non-oophorectomized women. There were no differences in frequency of intercourse or orgasm, dyspareunia, arousal, or partner satisfaction between groups [44]. Non-estrogen-treated oophorectomized women had significantly worse scores for depression, anxiety, and psychological well-being compared to intact women, but these problems were not apparent in oophorectomized women receiving estrogen. Since this study was not randomized, however, symptoms may have influenced the prescription of ET to the women and thus affected the outcomes. In summary, the ability to draw conclusions about the effects of estrogen on sexuality from studies of oophorectomized women is limited; women with higher sexual function preoperatively are less likely to elect BSO at the time of hysterectomy [54], and women with problems are more likely to elect post-operative ET.

3. EVIDENCE FROM CLINICAL TRIALS OF ESTROGEN THERAPY IN SURGICALLY MENOPAUSAL WOMEN (LEVEL 1 EVIDENCE)

To assess the effects of estrogen and progestin therapy on sexual behavior, 49 women who had undergone hysterectomy with BSO were randomized in a double-blind, placebo (PL)-controlled cross-over study to 3 months each of ethinyl estradiol (EE), levonorgestrel (LNG), EE + LNG or PL [56]. Comparing estrogen-containing regimens to PL, estrogen treatment was associated with significantly greater sexual desire, enjoyment, orgasmic frequency and lubrication. Of note, hot flashes occurred without HT use, and a significant effect of hot flashes on orgasmic frequency was observed. These data support a detrimental effect of menopausal symptoms on sexual function, which may be treated effectively with HT.

4. EVIDENCE FROM OBSERVATIONAL COHORT STUDIES IN NATURALLY MENOPAUSAL WOMEN (LEVEL 2 EVIDENCE)

There are conflicting results on the role of estrogens in sexual functioning as women undergo natural menopause. Most of the studies are cross-sectional, although several cohort studies examine the association between change in E2 levels and change in sexual functioning over the menopausal transition. The Penn Ovarian Aging Study was a longitudinal population-based cohort designed to examine the associations between variability and changes in reproductive hormones and symptoms associated with ovarian aging [57]. Women were aged 35-47 at baseline, had normal menstrual cycles, with yearly hormonal measurements and various measures of sexual functioning assessed. At 4 years in 326 women, there were no significant differences in E2 levels between women with and without self-reported deceased in libido[57]. However, depression, vaginal dryness and children living at home were associated with decreased libido. A major limitation of this study is that only 7.7% were classified as late menopausal and 4.3% as post menopausal.

Followup analysis [58] using the Female Sexual Function Index assessed desire, arousal, lubrication, orgasm, satisfaction, and pain. Sexual dysfunction was defined as a total Index score of 20 or below. Although sexual dysfunction increased over the transition, there was no association between sexual dysfunction and any of the domain scores and estrogen level or variability. Predictors of sexual dysfunction were absence of a sexual partner, high anxiety, and children under the age of 18 living at home. A limitation of this study is the small number of women classified with dysfunction (N=102, 33% of sample). Freeman and coworkers [59] examined the association between hormones and reports of decreased libido or interest in sex over 9 years of follow-up of this cohort. A moderate association between lower mean levels of E2 and reports of decreased libido or interest in sex 9 years of follow-up. Freeman and coworkers also found a significant association between E2 and E2 variability and change in libido.

In the Melbourne Women’s Health Project (MWHP), a population-based longitudinal study of Australian-born white women aged 45-55 at baseline, annual assessments included hormone levels, the Short Personal Experiences Questionnaire and collection of a wide range of covariates. Among 336 women followed for 8 years, there was a significant association between decreasing E2 levels and sexual responsiveness (interest, arousal, enjoyment, orgasm) and dyspareunia, but not frequency of sexual activity [60]. Sexual responsiveness was adversely affected by aging and menopause transition[33]. Those women who had lower baseline scores on the Short Personal Experiences Questionnaire (SPEQ) had lower E2 levels, and lower scores over time.
correlated with lower E2. Further studies examining relationship factors [61], showed that while E2 was related to libido, sexual responsiveness and dyspareunia, prior function and relationship factors were more important than hormones.

More recently, Modelska et al.[62] examined the association between E2 and changes in sexual function over 3 years in postmenopausal women who participated in the raloxifene evaluation trial. All women were sexually active and at least 2 years post menopause with a mean age of 65 years. E2 was assessed at baseline and dichotomized at 20 pmol/l. The sexual history questionnaire was administered at baseline and at 3 years. At baseline, women with E2 levels <20 pmol/l reported significantly greater discomfort during sex and inability to relax, but there was no difference between groups in reported enjoyment, satisfaction, orgasm, interest, arousal, or difficulty during intercourse. After 3 years, women with E2 > 20 pmol/l had significantly less decline in sexual enjoyment, satisfaction and sexual feelings. There was no difference from women with low E2 in orgasm, lack of interest, inability to relax, arousal difficulty, or discomfort during intercourse, while pain was more evident. Limitations of the study included that only 121 women showed a decline in sexual functioning and E2 was measured only at baseline.

Thus, some evidence supports the hypothesis that decreases in estrogens may be associated with changes in sexual functioning after menopause. Relationship factors and physical or mental health contributed to sexual functioning to a greater degree than either menopausal status or hormonal levels. Limitations of sex hormone assay sensitivity at lower levels used in all of these studies may have influenced the lack of clear correlation with hormonal levels (discussed in section I).

5. EVIDENCE FROM OBSERVATIONAL CROSS SECTIONAL STUDIES IN NATURALLY MENOPAUSAL WOMEN (LEVEL 2 EVIDENCE)

A cross-sectional study of 141 women aged 40-60 with natural menopause with a current partner showed that no hormonal measure (including E2 and estrone (E1)) correlated with various measures of sexuality [63]. Predictors of sexual functioning were the quality of the relationship and measures of wellbeing. Similarly, Gallicchio et al.[64] evaluated 265 perimenopausal sexually active women aged 45-54 and found no association between overall sexual satisfaction and plasma E2, E1 or the free estrogen index (FEI). However, depressive symptoms and poor overall health were related to lower satisfaction.

More recently, Avis and coworkers [48] reported cross-sectional analyses from the Massachusetts Women’s Health Study of the association between log E2 and various domains of sexual functioning among 200 women aged 51-61. Log E2 was negatively related to reporting pain during or after sexual intercourse in both univariate and multivariate analyses. Plasma E2 was not significantly related to a decline in sexual interest with age or satisfaction with current sexual relationship, desire, frequency of sex, arousal, or difficulty reaching orgasm. Factors predictive of better sexual functioning were physical and mental health, marital status (or new partner), and not smoking. Similarly, in the Study of Women’s Health Across the Nation (SWAN), no association between sexual desire or arousal and E2 levels was detected among 2981 pre and perimenopausal women [40].

Thus, the literature in natural menopausal women provides conflicting data concerning the correlation of plasma E2 levels and sexual function. Issues related to sensitivity of sex hormone assays in postmenopausal woman must be considered (discussed in section I). Observational studies show that factors relating to mental and physical health and the partner relationship are more consistently related to sexual function than levels of estrogens.

6. EVIDENCE FROM CLINICAL TRIALS OF ESTROGEN THERAPY IN NATURALLY MENOPAUSAL WOMEN (LEVEL 1&2 EVIDENCE)

The effects of a transdermal patch containing 0.014 mg/day of transdermal E2 on sexual function in 417 postmenopausal women was studied in a randomized, double-blind, placebo-controlled 2-year trial [65]. Participants were aged 60-80 (mean age 66.8) with an intact uterus, and not recruited on a basis of sexual dysfunction. Outcome measures included frequency of sexual activity and the Medical Outcomes Study Sexual Problems Index, which includes items on loss of sexual interest, inability to relax and enjoy sex, difficulty becoming aroused, and difficulty in having an orgasm. Women assigned to E2 had significantly greater improvement in vaginal pain/dryness, but did not significantly differ in frequency of sexual activity or other sexual function domains. A study of 223 postmenopausal women aged 45-65 “requiring hormone replacement therapy for climacteric symptoms” randomly assigned to 0.05 mg/day of transdermal estrogen reported greater sexual satisfaction and fewer sexual problems than those in the placebo group[66]. Women in the E2 group reported greater satisfaction with frequency of sexual activity, greater sexual enjoyment and decreased dyspareunia, but no difference in sexual arousal or orgasm [44]. A double-blind, randomized, placebo-controlled study was performed in 285 sexually active postmenopausal women aged 45-65 (mean age 54 years) of daily oral low dose conjugated estrogens (0.45 mg) plus progesterone (1.5 mg) combined with 1g conjugated estrogen vaginal cream (0.625 mg) [67]. Treated women showed a significant decrease
in frequency of dyspareunia and an improvement in sexual interest, frequency and pleasure of orgasm compared both to baseline and placebo group, but no effect on frequency of sexual intercourse. Because this trial used a combination of oral estrogen/progestin therapy and vaginal estrogen cream, it is not possible to determine the relative impact of systemic vs. local estrogen treatment.

Thus, numerous studies of ET, whether oral, transdermal, or vaginal have demonstrated positive effects on vaginal pain and dryness. However, results on other aspects of sexual functioning are more mixed, with stronger results found for younger women. It is not surprising that results are less consistent for other aspects of sexual functioning, as observational studies show that sexuality in women is particularly complex and influenced by multiple hormonal and non-hormonal factors.

7. SUMMARY OF DATA ON NATURAL MENOPAUSE AND ESTROGEN

a) Estradiol levels and Sexual Function (Level 2 evidence)

Limitations of current research include: use of single hormone levels compared to fluctuations, variability in sexual functioning questionnaires with analysis of changes in individual items or a composite index, and also variability in the covariates included in analyses. Despite these differences, several patterns can be discerned. Studies of older women show consistent benefit. This would suggest that postmenopausal E2 levels may be more critical to sexual functioning than those during the transition. Studies including relationship factors and physical or mental health observe that these factors contribute more to sexual functioning than either menopausal status or hormonal levels.

b) Risks of systemic HT and ET (Level 1 and 2 evidence):

Daily estrogen/progestin therapy is associated with an increase in cardiovascular events in older postmenopausal women [68, 69]. Recent guidelines support the limited use of Estrogen alone in hysterectomized women and estrogen-progestin in women with intact uterus for women reporting menopausal symptoms (mainly hot flushes) across menopausal transition and beyond. The benefit-risk ratio for menopausal HT is favorable during the years close to menopause (the so-called "window of opportunity") but decreases with aging and with time since menopause in previously untreated women [68, 70, 71]. Estrogen or estrogen/progestin therapy should be used at the lowest dose for the shortest duration that meets treatment goals. Any woman treated with ET or HT requires ongoing monitoring, which should include annual breast and pelvic examinations, mammography, and evaluation of abnormal bleeding.

c) Benefits and risks of low dose vaginal ET (Level 2 evidence):

Vaginal estrogen preparations are effective and generally safe for treating urogenital atrophy and can improve vaginal lubrication and reduce dyspareunia [72, 73]. Vaginal ET products include Conjugated Estrogens, estriol (E3) (not available in the US market), and E2 at doses to avoid systemic absorption [74]. Vaginal E2 is contraindicated in women with a history of breast cancer because of the risk of increases in circulating estrogens [75, 76]. All of the low-dose vaginal estrogen products are equally effective at the recommended doses. The choice of therapy should be guided by clinical experience and patient preference. Local ET should be continued for women as long as bothersome symptoms remain.

8. EVIDENCE FROM STUDIES OF WOMEN WITH PREMATURE OVARIAN FAILURE (POF) (LEVEL 2 & 3 EVIDENCE)

Evaluating the effects of estrogens on sexual function using models other than natural or surgical menopause is difficult. Premature ovarian failure, menopause prior to the age of 40 years results in estrogen deficiency symptoms, but with the added psychological burden of unanticipated menopause and infertility. Testosterone levels also are lower, further complicating the assessment of the role of estrogens in sexuality in women with POF. In addition, POF may be associated with other autoimmune diseases, or be due to chemotherapy, pelvic surgery or radiation. The associated psychological burden and the underlying disease may independently alter sexual function.

Sexual well-being was compared in 81 women with POF and 68 age-matched control women with regular menstrual cycles [77]. Forty-eight of the women with POF (59%) were using HT. As expected, women with POF not using HT had significantly lower levels of E2 than HT-users, while those using HT had lower bioavailable T levels than HT non-users, likely due to the effects of oral ET on SHBG. Overall, women with POF were less satisfied with their sexual life. They had fewer sexual fantasies, masturbated less frequently, and reported less arousal, lubrication and increased genital pain during sexual activity. Sexual desire and frequency were similar to control women, although sexual satisfaction was lower [77]. Women with POF reported more anxiety, depression, somatization, sensitivity, hostility and psychological distress. HT users had higher scores for anxiety, depression and psychological distress than non-HT users, without differences for sexual activities, problems and satisfaction. A limitation of the study is that women with problems may be more likely to elect HT use.
9. EVIDENCE FROM WOMEN WITH HYPOTHALAMIC AMENORRHEA (LEVEL 4 EVIDENCE)

Women with hypothalamic amenorrhea experience estrogen deficiency due to lack of hypothalamic-pituitary function and anovulation [78-81]. There may be urogenital atrophy, but vasomotor symptoms do not usually occur. Hypothalamic amenorrhea typically is caused by excess stress, intensive exercise, eating disorders, or other physiologic or psychologic conditions. Sexual function has been poorly investigated in these conditions. Since HT typically is given to young women with hypothalamic amenorrhea to preserve bone mineral density, maintenance of vaginal health would be an expected benefit. No intervention studies, however, have been performed on the effects of HT on sexual function in women with hypothalamic amenorrhea.

10. EVIDENCE FROM STUDIES OF WOMEN USING, SELECTIVE ESTROGEN RECEPTOR MODULATOR (SERMS) AND USE OF AROMATASE-INHIBITORS (AIS), ORAL CONTRACEPTIVES AND TIBOLONE

a) SERMs and sexual dysfunction (Level 2 and 3 evidence):

Tamoxifen and raloxifene are selective estrogen receptor modulator with estrogen agonistic activities on bone and antagonistic activities on breast [82]. Tamoxifen is used in the treatment of patients with breast cancer and for chemoprophylaxis in high risk women. Tamoxifen causes estrogenic changes in the vaginal epithelium [83, 84] increased vaginal discharge, [85] but can also cause pain, burning, or discomfort with intercourse [86]. Tamoxifen increases SHBG [87]. In breast cancer survivors older than age 50, tamoxifen did not worsen sexual function [88]. Major confounding influences related to sexual dysfunction in breast cancer survivors include concerns about relationships, depression and increasing age[84].

Raloxifene is a newer SERM currently approved for the prevention and treatment of postmenopausal osteoporosis, and the prevention of breast cancer in high-risk women [82]. Raloxifene also increases SHBG levels. In healthy postmenopausal women, raloxifene lowered neither total nor free T, or DHEAS levels (Shifren et al unpublished observations). Others however found modest changes in prohormones and adrenal steroids after one year of raloxifene 89. The effects on sexual function was assessed in a study of a large, multicenter, RCT of the effects of 3-years of raloxifene on 600 postmenopausal women with osteoporosis compared to 300 receiving placebo [90]. No differences between groups were observed in sexual desire, frequency, enjoyment, satisfaction, orgasm or sexual problems. The effects of local vaginal ET with and without concurrent raloxifene were examined in two RCTs. In women treated with either conjugated estrogen cream [91], or an estradiol vaginal ring [92], raloxifene vs. placebo treatment resulted in similar improvements in signs and symptoms of vaginal atrophy, suggesting raloxifene did not block local E effects.

b) Aromatase-inhibitors (AIs) and sexual dysfunction (Level 4 evidence)

Examining the effects of aromatase inhibitors is an interesting way to try to understand the impact of estrogen deficiency on female sexuality. Inhibiting the conversion of androgens to estrogens in postmenopausal women results in profound hypoestrogenemia by eliminating peripheral estrogen synthesis [93]. Limitations of this model are that these subjects are being treated for breast cancer. This diagnosis and the effects of chemotherapy, radiation and mastectomy also have independent effects on sexual function. Women using AIs commonly experience urogenital atrophy, dyspareunia and bothersome vasomotor symptoms and arthralgias. As estrogen therapy is contraindicated, treatment of hot flashes with non-hormonal alternatives and regular use of non-hormonal vaginal moisturizers and lubricants is advised to improve sexual function in these women. Until such time as additional safety data are available on the effects of vaginal estrogen in women on AI therapy, routine use of local estrogen in women on AIs cannot be recommended.

c) Oral contraceptive use and sexual function (Level 2 evidence)

Oral contraceptives used by premenopausal women comprise supraphysiologic levels of estrogens in combination with supraphysiologic progestins of variable androgenic activity to block ovulation [94]. The estrogenic components increase SHBG. Some have argued that the nonandrogenic progestins increase SHBG further and some suggest that these compounds may in turn decrease free T levels and impact on female sexual function[95]. Comparison studies across OCPs are limited with few prospective randomized controlled studies [96-98] Over the years changes in dose and types of both estrogens and progestins confuse the issue. Clinically, practitioners may choose to change the type of OCP administered in a premenopausal woman with sexual dysfunction.

d) Tibolone as postmenopausal therapy and sexual function (Level 1&2 evidence)

Tibolone is a synthetic steroid not available in the US which is metabolized to two estrogeneric metabolites, 3α and β, which then circulate predominantly in their sulfated inactive forms [99, 100]. These metabolites
become estrogentially active when desulfated by the sulfatase enzyme in target tissues. Tibolone itself and its 3β metabolite is also converted to a Δ4-isomer which can activate both the progesterone and androgen receptor. Tibolone lowers SHBG and increases circulating free testosterone, adding to its androgenicity [101]. Tibolone alleviated postmenopausal vasomotor symptoms and improves urogenital atrophy by increasing the vaginal maturation index [102, 103] and was effective in postmenopausal women with symptoms of sexual dysfunction. [99, 104-106]. In a recent multicenter, double-blind, randomized, clinical trial tibolone improved sexual wellbeing in postmenopausal women with low libido with improvements in desire arousal, satisfaction and receptiveness compared to those receiving transdermal estrogen-progestin therapy [107]. Some concerns have been raised regarding the use of tibolone and risk of ischaemic stroke in women over 60 years [100].

11. RECOMMENDATIONS

a. Based on a systematic review of the clinical trials evidence of estrogen therapies for treating sexual problems in women, we conclude the following:

The decision to institute any hormonal therapy must be individualized and the patient adequately informed about risks and benefits (Grade A).

Estrogen therapy (ET) may improve sexual function in those postmenopausal women with vaginal atrophy (Grade A).

A significant effect of estrogens on sexual interest, arousal and orgasmic response, independent of its role in treating menopausal symptoms, is not supported by the majority of current evidence (Grade B).

Tibolone is effective for the treatment of menopausal symptoms and vaginal atrophy, and in many women results in improved sexual function (Grade A). Potential risks of treatment, including a possible increased risk of ischaemic stroke, must be balanced against potential benefits.

Women with premature menopause should use hormone therapy until the age of natural menopause, unless medically contraindicated (Grade C) [70, 108].

b. Based on expert opinion, findings from various studies and understanding of hormone physiology and pathophysiology, we conclude the following:

Due to the known potential risks, systemic ET may be recommended for the treatment of bothersome vasomotor symptoms in healthy menopausal women, while local vaginal estrogen therapy may be preferred for the treatment of isolated vaginal symptoms (Grade A).

As oral estrogen therapy results in increased levels of SHBG and resulting low free testosterone levels [109], transdermal ET may be considered when ET is elected and sexual function is a concern, although no RCTs to date have compared sexuality with oral vs. transdermal ET (Grade C).

III. ROLE OF TESTOSTERONE IN FEMALE SEXUAL FUNCTION AND DYSFUNCTION: EVIDENCE FROM LOW TESTOSTERONE STATES AND EFFECTS OF TESTOSTERONE TREATMENT

1. EVIDENCE FROM POPULATION-BASED, EPIDEMIOLOGIC STUDIES (LEVEL 3 EVIDENCE)

If androgens serve an important role in female sexual function, then clinical states associated with decreased androgens should be associated with sexual problems including low desire, arousal, and orgasmic response. Low androgen states include aging, surgical menopause, premature ovarian failure, hypopituitarism and adrenal insufficiency. Although natural menopause is not associated with an abrupt decline in androgen concentrations, menopausal women have decreased T levels compared to younger women due to aging [41].

Observational studies assessed the effects of age and menopausal status on sexual function. A population-based study estimated the prevalence of self-reported sexual problems accompanied by personal distress in approximately 31,000 U.S. women aged 18 years and older. Although low desire, arousal and orgasm difficulties increased with age, distressing sexual problems peaked in women aged 45-64 and actually were lowest in the elderly women [50]. A community-based, cross-sectional study of approximately 3,500 European and U. S. women showed that the prevalence of low desire increased with age, while the proportion of women distressed about their low desire decreased with age [110]. A survey of 2207 US women, using the same validated questionnaire confirmed an increased prevalence of low sexual desire with increasing age, and among surgically and naturally menopausal women compared to premenopausal women. Distress about low desire in older and younger women with relatively recent BSO was similar to age matched women with intact ovaries. Women older than 45 years who underwent oophorectomy prior to menopause had fewer complaints of low desire as compared to women of similar age but with intact ovaries [111].

Several population based studies have assessed the direct relationship between T levels and sexual function. In a population-based, longitudinal study, 438 Australian women were studied for eight years across the menopausal transition [60]. Sexual re-
responsiveness was adversely affected by both aging and the menopausal transition, but all other aspects of sexual function, including frequency and libido, were adversely affected by becoming postmenopausal. In a cross-sectional analysis of data from 201 women aged 48-58 years in this same cohort, sexual responsiveness again declined with age, but T levels were not associated with any aspects of female sexual functioning [112]. A limitation of this study is that T was measured by a kit that lacked the sensitivity to measure T levels <20ng/dl, commonly seen in women over the age of 45. A study of androgen concentrations and self-reported sexual function in a community-based, cross-sectional study of 1423 Australian women ages of 18 to 75 years [45] found no clinically significant relationships between a low score on any domain of sexual function and a low total T, FT or androstenedione level. There were associations between a plasma DHEAS level below the 10th percentile and low scores on several sexual function domains; however, the majority of women with low DHEAS levels did not have low sexual function [45].

2. EVIDENCE FROM OBSERVATIONAL STUDIES IN OOPHORECTOMIZED WOMEN (LEVEL 2 & 3 EVIDENCE)

To evaluate the isolated effects of T loss, oophorectomized/hysterectomized women should receive ET and be compared to hysterectomized women who retain their ovaries. However, the indications for surgery, the surgical procedures, the decision to keep or remove the ovaries and the accompanying estrogen deficiency or ET all may impact sexual function post-operatively. In the Maryland Women’s Health Study, over 1,000 women were interviewed before and after hysterectomy [36]. Despite the fact that approximately 44% had concurrent BSO, significant improvements in sexual functioning post-operatively were noted. Oophorectomy, however, was associated with a 2.7-fold increase in the likelihood of not experiencing orgasms 12 months post-operatively [36]. Similar results were found in a retrospective Swedish study of approximately 700 women under age 55 who underwent hysterectomy for benign disease. Although the majority of women reported an improved sexual life following hysterectomy, oophorectomized women receiving ET were significantly less likely to report improvement and more likely to report a worsening than non-oophorectomized women [37].

In a retrospective study that controlled for post-operative estrogen therapy use, approximately 100 women between the ages of 47-55 years were evaluated 2-6 years following hysterectomy [44]. No differences in frequency of intercourse or orgasm, dyspareunia, arousal, or partner satisfaction was observed between groups. The only difference noted was decreased pleasure from intercourse in the oophorectomized women. No correlations were found between sexual function variables and androgens, including total T, free T, A or DHEAS. A prospective, observational study of the effects of oophorectomy on sexual function in 362 perimenopausal women scheduled for elective hysterectomy for benign diseases also identified lower post-operative sexual function scores in women who underwent concurrent BSO compared to women with intact ovaries [54]. Interestingly, sexuality scores were unchanged by surgery in the hysterectomy plus BSO group, so these differences were all due to lower pre-operative sexuality scores in women electing BSO. In addition, there were no correlations between changes in androgen levels post-operatively and changes in sexuality measures. Two further prospective studies failed to show a worsening of sexual function after elective hysterectomy in women followed for 3 years [113, 114].

In a national sample of approximately 952 US women with sexual partners, the prevalence of HSDD was compared between premenopausal, naturally postmenopausal and surgically postmenopausal women [115]. Although the prevalence of HSDD was significantly greater in young surgically postmenopausal women (aged 20-49 years) than in age-matched premenopausal women, there was no significant difference in HSDD prevalence between surgically and naturally postmenopausal women, aged 50-70 years. Observational studies of oophorectomized women, therefore, are not generally consistent with the hypothesis that decreased T levels affect sexual function in women.

3. EVIDENCE FROM CLINICAL TRIALS OF T THERAPY IN POSTMENOPAUSAL WOMEN (LEVEL 1 EVIDENCE)

Two Cochrane reviews have examined the benefits and risks of testosterone plus HT versus HT alone for peri- and postmenopausal women. The most recent analysis included 35 studies with 4768 participants [116, 117]. Most trials included only postmenopausal women, both naturally and surgically menopausal. Many different testosterone regimens were examined, both pharmacologic and physiologic dosing regimens. The median study duration was 6 months (range 1.5-24 months). The major methodological limitations described were differences in diagnostic criteria for study entry, a lack of a washout period in the cross-over studies and attrition bias. The pooled estimate from the clinical trials suggested that the addition of testosterone to HT regimens improved sexual function scores and number of total satisfying sexual episodes in postmenopausal women who were able to have some (2-3 / month) satisfying sexual episodes at baseline [117]. Beneficial effects were seen for the composite sexual function score and domains of sexual activity, coital frequency, responsiveness, and libido. Adverse effects included
decreases in high-density lipoprotein (HDL) cholesterol levels with oral therapy that was not observed with transdermal treatment and increased incidence of excess hair growth and acne. Discontinuation from treatment was similar between groups. There was insufficient evidence of a treatment effect for perimenopausal/premenopausal women or for other outcomes examined, including wellbeing, fatigue, menopausal symptoms, cognition, body composition and bone health. Another large review of safety data also concluded that except for hirsutism and acne, the therapeutic administration of testosterone in physiologic doses was safe for up to several years [118].

Several recent clinical trials add clarification of the role for T therapy in improving female sexual function. A series of double-blind, randomized, placebo-controlled studies examined the efficacy and safety of a transdermal T patch (300 mcg) in postmenopausal women with HSDD [119, 120]. Two multicenter trials evaluated 24 weeks of testosterone patch treatment in over 1,000 surgically menopausal women with HSDD receiving concomitant ET. At baseline, women reported approximately 3 satisfying sexual episodes in 4 weeks, with a mean increase of approximately 2 events in testosterone-treated women, compared with an increase of 1 satisfying event with placebo. A 450 mcg patch, however, did not confer benefit beyond placebo [121] suggesting the lack of a dose response effect of the T patch.

In addition to increased sexual activity, significant improvements were seen in all domains of sexual function in T-treated women compared with placebo, including desire, arousal, orgasm, pleasure, concerns, responsiveness, sexual self-image and distress. More women receiving testosterone reported a "meaningful overall benefit" compared with placebo-treated women. Despite the low absolute change in satisfying sexual events, the degree of benefit seen with T therapy in these studies was "clinically meaningful" to women [122].

Adverse event profiles were similar except for a higher incidence of unwanted hair growth in T-treated women. Other androgenic adverse events such as acne, alopecia or voice deepening were more common in T-treated women, though not statistically significant. The safety and efficacy of transdermal T (300 mcg) for 24 weeks was also studied in a double-blind, placebo-controlled, randomized trial of 549 naturally menopausal women with HSDD on concomitant estrogen therapy. Total satisfying sexual episodes increased significantly from baseline in testosterone-treated women compared with placebo (2.1 episodes vs. 0.5) [123]. Small but statistically significant improvements also were seen in all domains of sexual function assessed, including sexual desire and personal distress.

As almost all studies of T therapy were performed in the setting of concurrent ET, a double-blind, placebo-controlled trial examined the safety and efficacy of testosterone treatment for HSDD in 814 postmenopausal women not receiving ET [124]. Women were randomized to 150 or 300 mcg of transdermal T per day or placebo; efficacy was measured to week 24 and safety to week 52. The increase in the 4-week frequency of satisfying sexual episodes was significantly greater in the women receiving 300 mcg T per day compared with placebo (2.1 episodes vs. 0.7), although not in the group receiving the lower T dose (150 mcg per day) [124]. Both doses resulted in significant increases in desire and decreases in distress compared with placebo. Androgenic adverse events, principally unwanted hair growth, was higher in the women receiving 300 mcg T compared with placebo, although rates of acne, alopecia and voice deepening were similar among the three groups [124]. Vaginal bleeding was more common in the 300 mcg T group, though no cases of endometrial hyperplasia or carcinoma were diagnosed. There were no differences between groups in vital signs or weight, serum lipid or lipoprotein profiles, measures of carbohydrate metabolism, liver function, or other laboratory tests. Breast cancer was diagnosed in four women who received testosterone, as compared with none who received placebo (p=NS).

Transdermal T has been studied in only limited populations of premenopausal women with HSDD [125]. Premenopausal women ages 30-45 with HSDD were randomized to treatment with a testosterone cream (10 mg/d) versus placebo in a double-blind crossover study for 12 weeks with a 4-week washout. Thirty one women completed the study. Testosterone treatment resulted in statistically significant improvements in the composite scores and many subscale scores of both the Psychological General Well-Being Index and the Sabbatsberg Sexual Self-Rating Scale. Resulting T levels were in the high normal to high range. In a larger randomized controlled trial, 261 women age 35 to 46 years were randomized to placebo or 3 different doses of a transdermal T spray [126]. Over the 16 week treatment period, the two higher doses were associated with a significant increase in satisfying sexual events compared with placebo.

Variable recommendations by international medical societies concerning T therapy in women have been published. In 2005, The North American Menopause Society concluded that postmenopausal women with decreased sexual desire associated with distress and with no other identifiable cause may be candidates for T therapy [127]. Transdermal formulations were preferred over oral products due to the absence of first-pass hepatic effects. Treatment was contraindicated in women with breast or uterine cancer, or in those with cardiovascular or liver disease. Women should be informed of all potential risks and that data on long term use were lacking.
Several epidemiologic studies have raised the concern with different conclusions [129-131]. The potential effects of T therapy on breast cancer science research and observational studies address cancer. Several thorough reviews of relevant basic women, including cardiovascular disease and breast are as yet unknown long term risks of T treatment in resolve with cessation of therapy. of greatest concern problems, which are easily recognized, treated, and but unwanted hair growth and acne are cosmetic adverse events appear to be increased with T use, however, showed a relationship with SHBG and cardiovascular event free survival [134]. Bell et al, current biochemical hyperandrogenemia was associated with more angiographic CAD and worsening cardiovascular event free survival [134]. Bell et al, These epidemiologic data may reflect the detection of an aging cohort of women with prior premenopausal hyperandrogenism and its associated insulin resistance. However, further studies are needed to balance the potential benefits and risks of long term T therapy in postmenopausal women.

5. RECOMMENDATIONS

a. Based on a systematic review of the clinical trials evidence of androgen therapies for treating sexual problems in women, we conclude the following:

The decision to institute any T therapy must be individualized and the patient adequately informed about known and potential risks and benefits (Grade A).

Testosterone patch therapy increases satisfying sexual activity, libido, arousal and orgasmic response in postmenopausal women with HSDD (Grade A).

Long term safety data for testosterone therapy are lacking, so additional safety data are required before long term use of T therapy in women can be recommended (Grade A).

Current data are not adequate to support the use of T therapy in premenopausal and perimenopausal women (Grade A).

Achieving physiological free T levels by transdermal delivery appears to be the best approach for minimizing the adverse effects of androgens (Grade C).

Relative contraindications to T therapy include androgenic alopecia, seborrhea or acne, and hirsutism (Grade C).

T therapy is relatively contraindicated in women with hyperlipidemia or liver dysfunction (Grade C).

T therapy is contraindicated in women with, or at high risk for, breast cancer, endometrial cancer or cardiovascular disease, pending additional safety data. The safety of T therapy in women with or at high

5. RECOMMENDATIONS

a. Based on a systematic review of the clinical trials evidence of androgen therapies for treating sexual problems in women, we conclude the following:

T therapy is relatively contraindicated in women with hyperlipidemia or liver dysfunction (Grade C).

T therapy is contraindicated in women with, or at high risk for, breast cancer, endometrial cancer or cardiovascular disease, pending additional safety data. The safety of T therapy in women with or at high
risk for cardiovascular disease, venous thrombotic event or breast cancer is unknown (Grade C).

b Based on expert opinion, findings from various studies and understanding of hormone physiology and pathophysiology, we conclude the following:

Any woman treated with androgen therapy requires ongoing monitoring, which should include annual breast and pelvic examinations, annual mammography, and evaluation for any abnormal bleeding. When T therapy is given, continuation for longer than 6 months should be contingent on a clear improvement in sexual function and satisfaction and absence of any adverse effects, considering the substantial placebo effects found in all studies to date. Women must be informed that data on long term safety are lacking. Physical examination at follow-up visits should include inspection of skin and hair for seborrhea, acne, hirsutism and androgenic alopecia which may appear very gradually. Laboratory monitoring should include total T and SHBG levels, and a calculated value for FT, with the goal of keeping these values within the normal range for premenopausal women. Whether a lower target level for older women should be advised remains unknown. Although no adverse effects on lipids have been found with androgen therapy, a lipid profile and metabolic screening should be considered.

IV. ENDOCRINE DISORDERS: EFFECTS ON FEMALE SEXUAL FUNCTION

1. HYPOPITUITARISM (LEVEL 2 EVIDENCE)

a) Evidence that supports the influence of pituitary hormone deficiencies on female sexual dysfunction.

Hypopituitarism is defined as multiple pituitary hormone deficiencies, either genetic or commonly after removal of a pituitary and/or hypothalamic tumor or radiation [136]. Combination of sex hormone, thyroid hormone, glucocorticoid and /or growth hormone deficiency may occur and require physiologic replacement. There are limited studies concerning sexual function in these patients. A 12 month randomized study in 51 women with hypopituitarism demonstrated improvements in mood and sexual function in addition to increased bone density, fat-free mass, quality of life but not cognitive function in women randomized to T patch [136]. These women had variable forms of estrogen replacement with either oral contraceptives or low dose ET. Side effects included 1/3 with hirsutism and 65% with skin irritation due to the patch. 38 women with hypopituitarism on standard hormonal replacement were randomized to DHEA (30mg/d if <45 and 20mg/d if >45) or placebo for 6 months [137]. Women on DHEA had improved alertness, stamina and initiative as perceived by their partners and a trend toward improved sexual relations (p=0.06). Increased interest in sex or activity at 6 months was noted in 50% of women receiving DHEA 30mg/d but none receiving 20mg/d. These data support a modest effect of aromatizable androgens or androgen and estrogen precursors (ie DHEA) on sexual function in women with hypopituitarism after optimization of standard hormonal therapies. Whether the effects are due to androgenic, estrogenic actions or both is unknown.

b) Recommendations

Women with hypopituitarism have profound estrogen and androgen deficiency and should be considered for therapy with ET and T therapy at least until the age of natural menopause, unless medically contraindicated (Grade B).

2. HYPERPROLACTINEMIA (LEVEL 2&3 EVIDENCE)

a) Evidence that supports the influence of elevated levels of prolactin on female sexual dysfunction.

Hyperprolactinemia may be due to physiologic, pharmacologic or organic causes [138]. Elevated levels of PRL inhibit gonadotropin releasing hormone (GnRH) pulsatility and thus ultimately decrease ovarian hormone secretion (estrogens, androgens). Hyperprolactinemia is observed in primary hypothyroidism and commonly with medications that inhibit dopamine tone such as the antidepressants and serotonin reuptake inhibitors [138, 139]. Elevated prolactin may alter libido via direct neuroendocrine effects (impaired negative dopaminergic and positive serotoninergic control of PRL release) and indirect endocrine mechanisms (i.e. secondary effects of hypoestrogenism) [140]. Although menstrual disturbances are a more common symptom than sexual dysfunction, hyperprolactinemic women without depression or other hormonal disorders reported lower scores for sexual desire, arousal, lubrication, orgasm and satisfaction in comparison with controls [141]. Hulter et al observed that 79% of 48 women with pituitary disease had a decrease in sexual desire, while problems with lubrication and orgasm were reported in 65% and 69%, respectively [142]. However, neither prolactin or T levels, but instead a normal pattern of menses, young age and intra-sellar tumor correlated with normal sexual desire and sexual function. In 109 women with hypothalamo-pituitary disorders, 63% had decreased sexual desire [142]. Altered sexuality was reported in 84% of the hyperprolactinemic women, but only in 33% of women with normal serum prolactin. Despite these ob-
servations, PRL-normalizing agents (bromocriptine, cabergoline) have not been evaluated as to potential beneficial effect on female sexual dysfunction [143].

Antipsychotic and neuroleptic drugs reduce sexual drive and may cause anorgasmia, in part related to drug-induced hyperprolactinemia, as demonstrated by less sexual dysfunction in patients treated with the so-called PRL-sparing drugs in comparison with those with a higher incidence of PRL elevation [144, 145]. Antidepressant agents such as SSRI>s may induce hyperprolactinemia and therefore impact negatively on sexual function [146, 147]. Decreased sexual drive and orgasmic disorder [148, 149] have been reported. These studies are limited by few containing proper control groups, variable dosages of agents and variability in underlying mood disorder.

b. Recommendations

Women with hyperprolactinemia may develop sexual dysfunction, especially loss of sexual drive and impaired orgasm, but it is unclear if these symptoms are independent of associated estrogen deficiency (Grade B). Studies are lacking to prove that lowering circulating prolactin levels improve sexual function in women.

3. THYROID DYSFUNCTION AND FEMALE SEXUAL DYSFUNCTION

Although the literature is replete on the effects of both hypothyroidism on menstrual cyclicity and fertility [150-152], there are no clinical studies on the effect of thyroid disorders on female sexual function. This is an area for future research.

4. EFFECTS OF ADRENAL DISEASE ON SEXUAL FUNCTION

a) Adrenal prohormones

Dehydroepiandrosterone (DHEA) is produced by the ovaries and adrenal glands whereas its sulphate ester, DHEAS, is produced primarily by the zona reticularis of the adrenal cortex [29, 153]. Together DHEA and DHEAS are the most abundant steroids in plasma, providing a large precursor reservoir for the intracellular production of androgens and estrogens in non-reproductive tissues. Thus DHEA and DHEAS are not androgens (ie bind to the androgen receptor to activate transcription) but are precursor hormones that are metabolized to androgens and estrogens in the brain, bone, breast and adipose tissue [154]. Serum levels of both DHEA and DHEAS decline with age in women independent of menopausal age [55].

b) Adrenal insufficiency and sexual dysfunction (Level 4 evidence)

Primary adrenal insufficiency is characterized by abnormally low, serum concentrations of DHEA and DHEAS. Secondary adrenal insufficiency is due to loss of pituitary ACTH production and may be isolated or with low T levels because hypopituitarism results in combined ovarian and adrenal insufficiency [155]. Adrenal insufficiency, irrespective of cause, has been associated with impaired quality of life, low libido and lack of wellbeing. However, there are no data comparing sexual function in women with adrenal insufficiency with normal age-matched controls using validated questionnaires.

c) Clinical trials of DHEA therapy in adrenal insufficiency (Level 1 evidence)

There are few, small studies of DHEA treatment to improve sexual wellbeing in women with adrenal insufficiency. In Addison’s Disease [156, 157], a randomized controlled trial (RCT) of DHEA 50mg/day versus placebo in 24 women demonstrated no improvement in sexual function [156]. Arlt et al. randomized 24 women with primary (n=14) and secondary (n=10) adrenal insufficiency to treatment with either 50 mg oral DHEA daily for 4 months or placebo in a double-blind, crossover trial [158]. Improvements in sexual function (thoughts, interest and satisfaction measured by a visual analogue scale) and mood were reported. However, more recent randomized studies have not shown benefit.

A randomized controlled trial of DHEA 50mg/day versus placebo for 12 months in 62 women showed no improvement in sexual function measured by a visual analogue scale [157]. Similarly, other groups reported no benefit of DHEA, 25mg/day for 9 months, on sexual function using the Norwegian version of the McCoy’s Sex Scale Questionnaire in a placebo-controlled, parallel group trial involving 39 women with primary and secondary adrenal insufficiency [159]. A placebo controlled trial for 6 months followed by 6-month open label phase of 38 women with hypopituitarism and secondary adrenal insufficiency [159]. A placebo controlled trial for 6 months followed by 6-month open label phase of 38 women with hypopituitarism and secondary adrenal insufficiency suggested that 20-30 mg of DHEA/day increased sexual interest and activity only during the open label phase with no significant change in quality of life in either phase of the trial [137]. No effect of DHEA 50mg/day on sexual function was found in a double blind crossover study of 15 patients with secondary adrenal insufficiency [160].

d) Recommendations

DHEA therapy is not currently recommended for women with primary or secondary adrenal insufficiency: the majority of clinical trials of DHEA replacement in women with primary or secondary adrenal insufficiency do not show any benefits on sexual function (Grade A).
5. EVIDENCE FROM WOMEN WITH ANDROGEN INSENSITIVITY SYNDROME (AIS) (LEVEL 4 EVIDENCE)

There are limited data concerning the sexual function of XY males with androgen insensitivity due to mutations in the androgen receptor [161, 162]. These subjects are phenotypically female with normal breast development, but variable shallow vaginal development which may impair sexual performance. Limited retrospective case series suggest these subjects have a heterosexual orientation and normal libido and orgasmic response under the influence of high estrogens with complete or partial absence of androgen action at all target tissues. This model suggests that androgens are not necessary for normal sexual function.

V. HORMONAL EXCESS STATES

1. POLYCYSTIC OVARIAN SYNDROME (LEVEL 3 EVIDENCE)

a) Current state of the field

Polycystic ovarian syndrome (PCOS) is the most common cause of female hyperandrogenism, occurring in 5-10% of premenopausal women [163]. Clinical manifestations of androgen excess (e.g. hirsutism, acne, seborrhea, alopecia etc) together with obesity and infertility may cause emotional distress, but data are limited concerning psychosocial and sexual functioning in PCOS. [164]. An increased risk for depressive disorders, particularly in women with higher body mass index (BMI) and evidence of insulin resistance, has been recently outlined. Anxiety, vulnerability to distress, abnormal eating attitudes coupled to body dissatisfaction and low self-esteem and quality of life have been also reported. In addition, PCOS women seemed to be less satisfied with their sex life and found themselves less attractive, presumably because of being frequently overweight and suffering from cosmetic androgen-related symptoms [165, 166]. The relationship between androgen excess in PCOS and sexual function has been difficult to study, probably as a consequence of the comorbid conditions which confound outcome measures. Indeed, PCOS women display a similar partner status and frequency of sexual intercourse in comparison with controls [167].

A recent study by Battaglia et al [168] failed to demonstrate any significant difference in clitoral circulation between women with PCOS and controls. Moderate hirsutism and hyperandrogenism in these women did not induce a sense of loss of feminine identity and had no impact on sexual self-worth and sexual satisfaction. Treatment of women with androgen excess using antiandrogens has produced mixed results in a small case series of women presenting with hirsutism (increased desire in 6 women and decreased desire in 13 women) [169], while the use of the insulin-sensitizer, metformin, improved the psychosocial, emotional and psychosexual situation of PCOS women [170], presumably because of the reduction in other clinical symptoms.

b) Recommendations

Overweight women with PCOS may have an increased incidence of sexual dysfunction mainly due to emotional difficulties related to clinical manifestations of androgen excess and obesity. (Grade C/D) These data have not been confirmed in lean PCOS women, suggesting that moderate hyperandrogenism alone may not significantly modulate sexual function. Further research is needed to understand if normalizing androgen excess and/or insulin resistance would improve sexual function in PCOS women.

2. SEX HORMONE PRODUCING TUMORS (LEVEL 3&4 EVIDENCE)

Many kinds of ovarian tumors produce estrogens or androgens. Sertoli-Leydig cell tumors is an example of an androgen-producing tumors that cause virilization [171]. Conversely, granulosa cell tumors and thecomas are well-known estrogen-producing tumors. Pediatric or postmenopausal women with estrogen-producing tumors present with postmenopausal bleeding or isosexual precocity. Other forms of sex hormone producing tumors are extremely rare [172]. Androgen excess from these tumors might be expected to result in a state of hypersexuality in women, but no studies on sexual function are available in women with sex hormone producing tumors [173]. Thus, this is an area for further research.

3. CONGENITAL ADRENAL HYPERPLASIA (LEVEL 2&3 EVIDENCE)

Congenital adrenal hyperplasia (CAH) refers to a family of inherited disorders in which defects occur in one of the enzymatic steps required to synthesize cortisol from cholesterol in the adrenal gland [174]. In 21-hydroxylase deficiency (21OHD), responsible for 90–95% of CAH cases, accumulation of precursors immediately proximal to the 21-hydroxylation step in the pathway of cortisol biosynthesis are shunted into androgen precursor pathway. Three forms of 21OHD CAH can be distinguished by clinical, hormonal, and molecular criteria: the classical salt-wasting, classical simple-virilizing, and nonclassical forms. Postnatal androgen excess leads to various hyperandrogenic signs that manifest from childhood to adulthood, depending on the severity of the 21OH enzyme deficiency [174]. Meyer-Bahlburg and coworkers [175] reviewed the sexual orientation in women with classical or non-classical CAH and reported that most women were heterosexual. The
rates of bisexual and homosexual orientation in their subjects were increased above controls in women with classical and nonclassical CAH, and correlated with the degree of prenatal androgenization. Limitations of this report include that this patient cohort was derived from a specialized referral base and may represent a biased group of subjects and lack appropriate controls. Importantly, the sexual functioning of women with non classical 21OHD did not differ from that of controls, unlike women with classical CAH who showed impaired sexual functioning, presumably as a consequence of disturbed body image, repeated genital examination and surgery [176, 177]. Retrospective qualitative data revealed a history of discomfort and social stress related to their extent of masculinization prior to treatment.

4. Recommendations

Caring for women with CAH requires careful individualized management, including appropriate therapy for their signs and symptoms of androgen excess as well as psychosexual counseling when needed (Grade C).

VI. CHRONIC ENDOCRINE DISORDERS

1. DIABETES (LEVEL 3 EVIDENCE)

a) Current state of the field

Women with diabetes have many factors potentially contributing to their risk of sexual dysfunction, including vascular, neurogenic, metabolic, sex hormone and psychologic abnormalities. Data on the incidence of female sexual dysfunction in diabetic women was recently reviewed by Bhasin and Basson [143]. The literature is limited by few studies with control groups, the poorly validated types of tools used to diagnose female sexual dysfunction, and the changing definitions of female sexual dysfunction from older to newer studies. The authors noted rates of decreased desire ranged from 9-60% in controls to 17-85% in female diabetics, and of decreased arousal from 41% in controls to 76%. Reduced lubrication was about 2-fold more common in diabetic all in but one study; pain and orgasmic difficulties were more prevalent in diabetics than nondiabetics. Overall dissatisfaction with sexual function ranged from 7-37% in controls to 42-52% in diabetics. A careful dissection of any differences in the incidence of or etiologies of sexual dysfunction in Type 1 compared to Type 2 diabetics was not examined in most studies. Importantly most studies did not separate pre- versus postmenopausal women and estrogen status was not controlled. Sexual dysfunction was consistently linked to comorbid depression.[143].

Several other studies have been published showing similar increased risks of sexual dysfunction in various populations [178 179], suggesting the incidence is independent of cultural norms. Studies have postulated altered reactive oxygen species activity in the mechanism underlying both male and female sexual dysfunction in diabetes [180]. A recent review of the literature of 400 citations concluded that research on sexual function in women with diabetes is limited, but multiple reports suggest that abnormalities in sex hormone levels contribute [181]. In contrast to men with diabetes and erectile dysfunction where the diabetic control and length of the disease correlate with incidence of impotence, no such correlation has been observed in women diabetics with sexual dysfunction. No intervention studies are available concerning changes in sexual function with aggressive treatment of vascular or metabolic derangements in women with diabetes. The impact on sexuality of living with a chronic, serious medical illness, and the confounding effects of obesity in many Type 2 diabetics should not be underestimated.

b) Recommendations

Women with Type 1 and Type 2 diabetes have an increased incidence of sexual dysfunction which may be due to metabolic, vascular, neurogenic, hormonal as well as psychological etiologies (Grade C). No studies are available concerning the impact of improved glucose lipid or hypertensive control or hormonal therapies on the sexual dysfunction in these patients. Thus, these women should be screened for sexual dysfunction. Further research is needed.

2. OBESITY AND METABOLIC SYNDROME (LEVEL 2-3 EVIDENCE)

a) Evidence that obesity influences sexual function

The metabolic syndrome (MetS) is a constellation of findings including central adiposity, insulin resistance, hypertension and various other clinical features. The International Diabetes Federation consensus definition for MetS includes a waist circumference >80cm in addition to 2 of the following factors: triglyceride >150mg/dl (1.7mmol/l), decreased high density lipoprotein cholesterol <50mg/dl (0.9mmol/l) or treatment for lipids, elevated blood pressure or treatment for hypertension, and/or elevated fasting serum glucose >=100mg/dl (5.6mmol/l) or known Type 2 diabetes [182]. Esposito initially described an independent effect of the MetS on the incidence of FSD in 100 premenopausal women with MetS compared to controls matched for age and BMI [183]. Sexual function was measured by the Female Sexual Function Index (FSFI). Ponholzer and coworkers recently performed a modified German Female Sexual Dysfunction (FSD) questionnaire

1139
on 538 women (mean age 44, 61% pre- and 39% postmenopausal women). Of the group, 18% had MetS[184]. FSD prevalence was 4.8% for disorders of low satisfaction and 39% for HSDD. The rate of these disorders increased with transition to menopause. There was no increased risk of disorders of arousal, pain or orgasm in this cohort. Impaired desire was present in 59% in premenopausal women with MetS compared to 32% of controls. In postmenopausal women, however, there was no effect of MetS on the incidence of FSD. Thus, although age increases the risk of FSD overall, the concomitant presence of MetS had a more profound effect on premenopausal women. No data are available concerning interventions to reverse MetS and incidence of FSD.

b) Recommendations:

Women with MetS may have an increased incidence of sexual dysfunction, which may be due to vascular, metabolic, neurogenic, hormonal, or psychosocial causes (Grade C). We recommend screening women with MetS for sexual dysfunction and study of treatment interventions; none are currently available in these patients.

Summary and Conclusions

This review has summarized the scientific evidence supporting the mechanisms by which hormonal changes associated with aging and endocrine disorders contribute to sexual dysfunction in women. Data on the impact of hormonal therapies in female sexual disorders has been discussed. Many studies suggest that plasma T and/or E2 concentrations do not correlate with female sexual function or dysfunction. However, the limitations of past and current sex steroid hormone assays and normal reference ranges for women suggest additional studies are needed. The potential importance of intracrinology, i.e. local production and action of hormones, on sexual function and the well documented age related decline in substrate precursor hormones remains unclear. Natural and surgical menopause and endocrine disorders that alter estrogens and androgen precursors may impact female sexual function. The consequences of hormone therapies in these states including, hypothalamic amenorrhea, premature ovarian failure, surgical and natural menopause and chemically induced estrogen deficiency with selective estrogen receptor modulators (SERMs) and aromatase inhibitors is variable but is indicative of benefits of low dose HT in individuals. Hypopituitarism, hyperprolactinemia, thyroid disorders and adrenal insufficiency alter a variety of hormones, each to a variable extent. Data are limited on the effects of therapies with estrogens, testosterone and DHEA in each of these disorders, but they may provide additional model systems for future interventional trials. Studies on the effects of hormonal excess observed in PCOS, hormonally active ovarian or adrenal tumors, congenital adrenal hyperplasia and obesity induced hyperandrogenism do not suggest that excess androgens and/or estrogens per se promote normal or hypersexuality, suggesting an optimal balance of hormonal milieu is critical to normal sexual functioning. Information on the effects of diabetes and metabolic syndrome on female sexual dysfunction suggest that the disorder is common in these populations, but no interventional trials have been performed show that improved metabolic control alters female sexual function.

Most importantly, the available literature emphasizes that hormones are only one component of the many factors that contribute to normal sexual function in women. It is hoped that this review of the state of the field will spur new research into the impact of hormones and endocrine disorders on female sexual dysfunction and additional research into the benefits and risks of hormonal therapies for these patients.

I. DEFINITIONS, EXPRESSIONS, AND PREVALENCE OF SEXUAL COMPLAINTS

1. DEFINITIONS OF SEXUAL DYSFUNCTION

Women’s sexual desire, arousal, and orgasm disorders have traditionally been conceptualized, studied, assessed, and often treated from a perspective which compartmentalizes them. This is reflected in the Diagnostic and Statistical Manual of Mental Disorders, 4th edition text-revised [1] whereby Hypoactive Sexual Desire Disorder (HSDD), Female Sexual Arousal Disorder (FSAD), and Female Orgasmic Disorder (FOD) are discrete disorders with criteria and descriptions in the text that do not overlap and the explicit statement that diagnosis of another Axis I Sexual Dysfunction is permissible.

However, despite the common finding in recent population-based epidemiological studies in which low sexual desire is the most prevalent of concerns relating to women’s sexual functioning, women’s sexual complaints are rarely experienced as discreet entities and there is often comorbidity with impaired sexual arousal and orgasmic dysfunction. Due to these overlapping symptom criteria, it may be difficult to determine which sexual dysfunction is primary for a woman. The four DSM-IV categories pertaining to lack of desire, arousal, to orgasm problems or to sexual pain, are not independent. In clinical practice, classification is often based on the way in which complaints are presented [2]. For example, a recent study on Malaysian women found a high degree of overlap in the desire and arousal domains of the Female Sexual Function Index (FSFI) with both domains loading significantly onto one factor [3] (Level 3). A number of both qualitative and quantitative studies find comorbidity between desire and arousal [4-6] (Levels 2 and 3). In a qualitative study of women with and without sexual arousal disorder, both groups of women articulated great difficulty in differentiating sexual desire from arousal, and there was increasing confusion about this distinction as the interviews progressed [7] (Level 2). In reality, the distinction between subjective arousal and desire may be unclear at best. In part, this may be because women express difficulties differentiating desire from subjective arousal [7-9]. Also, some women report their experience of desire to precede arousal (mimicking the Human Sexual Response Cycle as conceptualized by Masters and Johnson [10]), whereas for other women, desire appears to follow arousal [8], as women do not seem to follow one universal sexual response cycle [11]. Treatment outcome research also highlights the overlap between phases of the sexual response cycle in that a psychological intervention for low desire also significantly improved subjective sexual arousal [12].

In research, the overlap between sexual desire and arousal is also evident. For example, some conceptualize sexual desire entirely as the cognitive component of sexual arousal [13]. Others prefer the term “arousability” in place of sexual desire as it reflects the notion that sexual desire is considered to be an early arousal process [14].

Over the years, many have criticized the DSM-IV-TR classification of sexual dysfunctions in women. Hartmann and colleagues [9] proposed that a new classification system for women’s sexual function be considered in light of this significant comorbidity. They suggested that sexual problems were not the result of a single phase of a “virtual response cycle,” but, rather, sexual problems may be due to a global lack of interest, arousability, and arousal. Thus, they suggested that sexual desire disorder be classified as (i) in combination with sexual arousal disorder, (ii) in combination with orgasmic disorder, (iii) associated with depressive symptoms, (iv) associated with low self-esteem, and/or (v) associated with partner conflict (Level 4). Although their idea was compelling
and supported by much of the literature and clinical findings, this is not the currently adopted system.

To illustrate the overlap between phases of the sexual response cycle, consider the following case example. Julie is a 44-year-old chartered accountant who was married for the past 15 years. Her children are 12, 10, and 7. She reported a decrease in her sexual desire and arousal shortly after the birth of her first child. Whereas in the past Julie would often initiate sexual contact, she increasingly found herself rejecting her husband’s invitations for sex, and avoiding sexual contact altogether. When she did engage in sexual activity (once/month compared to twice/week previously), she experienced only a minimal increase in subjective excitement, minimal genital sensations, and great difficulty in attaining orgasms. Intercourse was occasionally painful if she was inadequately aroused, though provoked vestibulodynia was ruled out. Her loss of sexual response was highly distressing and negatively impacted her mood and self-esteem.

2. CRITICISMS OF EXISTING DEFINITION OF HSDD

Criticisms of the DSM-IV-TR definitions of women’s sexual dysfunctions are considered here because the definitions of sexual dysfunction which are adopted by this classification system have a direct and profound impact on instrument development, epidemiological studies, treatment protocols, etc. Using DSM-IV-TR criteria (See Table 1), Julie would meet criteria for HSDD, FSAD, FOD, and possibly even Dyspareunia. The DSM-IV-TR [1] diagnosis of HSDD focuses on “persistently or recurrently deficient (or absent) sexual fantasies and desire for sexual activity” which causes marked distress or interpersonal difficulty. This definition has been criticized as overpathologizing women on the basis that women themselves may not necessarily consider sexual fantasies and desire for sexual activity to be an index of their sexual desire. In a qualitative study of mid-aged women with and without sexual dysfunction, the majority of women did not mention fantasies in their narratives of desire, although, interestingly, the vast majority did endorse having fantasies when asked on a questionnaire [7]. It was suggested that rather than fantasy being an expression of desire, some women may deliberately evoke fantasy as a way to boost their sexual arousal. Another problem relates to the fact that although HSDD is defined as the lack of desire for sexual activity, when 3,262 multi-ethnic perimenopausal women were assessed, 70% reported desiring sex less than once a week; however, the majority (86 - 89%) were at least moderately to extremely emotionally sexually satisfied and reported moderate to intense physical pleasure [15]. Others have also found desynchrony between reported sexual satisfaction and frequency of sexual activity [16] (Level 2). With such a high proportion of sexually satisfied women, it is curious that their low frequency of desiring or engaging in sex would be considered dysfunctional. Similarly, among 5,892 partnered women with low desire, the majority (71.2%) were happy with the relationship [17] (Level 2). Collectively these studies suggest that women may experience a satisfying sexual life with a partner without the outright desire for sexual activity.

Complicating this issue of the validity of fantasy and desire for sex as a hallmark sign of sexual desire is the finding that clinicians and researchers may differ from patients in how they define sexual desire. For example, 401 women attending a British general practice clinic were asked if they thought they had any kind of sexual problem and how distressing it was for them. Based on responses to the Brief Index of Sexual Functioning for Women [18], 38% of women were diagnosed with at least one ICD-10 sexual dysfunction [19]. Among women with an ICD-10 diagnosis who also self-reported having a sexual problem, the prevalence dropped to 18%. The prevalence dropped further to 6% if women received the diagnosis, acknowledged it, and reported distress. There was more agreement between the diagnosis and self-report of problems for dyspareunia (74%) and vaginismus (77%) than for FSAD (38%) and HSDD (39%). A mere 48% of women given an ICD-10 diagnosis agreed that there was a sexual problem but 69% of women with no diagnosis agreed on the absence of a problem. Age, ethnicity, employment, and recent sexual activity were unrelated to these associations [19] (Level 3).

Another criticism of the DSM-IV-TR definition of HSDD relates to the implication that women experience a “spontaneous” sexual desire for sex. A large body of research [20-24] has supported an incentive-motivation model of sexual response which argues that all sexual desire is triggered (Level 2 and 3); therefore the notion of spontaneous sexual desire is nonsensical. Rather, several recent studies have illustrated the large number of cues that provoke sexual desire (125) and sexual activity (237) in women [25-26] (Level 2). Engaging in sexual activity in the absence of an identifiable external trigger (e.g., “because the opportunity presented itself”, “because I was in the mood”) was an unlikely reason women provided for having sex.

These empirical findings combined with the clinical observation that women (at least women in long-term relationships) report sexual desire as emerging during a sexual interaction after sexual arousal, led to the conceptualization of a new sexual response cycle [57-59] (Level 4). This model (Figure 1) proposes that women initiate sexual activity for any number of reasons or incentives, and that “feeling” sexual desire is not a usual trigger. Moreover, this clinical model emphasizes that sexual desire is responsive (i.e., it emerges after sexual arousal).
**Table 1: Diagnostic criteria for women’s sexual dysfunctions according to the Diagnostic and Statistical Manual of Mental Disorders, 4th Edition, Text-Revised (DSM-IV-TR) [1] and American Urological Association Foundation (AUAF) [41]**

<table>

<tbody>
<tr>
<td><strong>Desire</strong></td>
<td><strong>Sexual Interest/Desire Disorder:</strong> Absent or diminished feelings of sexual interest or desire, absent sexual thoughts or fantasies and a lack of responsive desire. Motivations [here defined as reasons/incentives] for attempting to become sexually aroused are scarce or absent. The lack of interest is considered to be beyond a normative lessening with life cycle and relationship duration.</td>
</tr>
<tr>
<td><strong>Arousal</strong></td>
<td><strong>Subjective sexual arousal disorder:</strong></td>
</tr>
<tr>
<td><strong>Female Sexual Arousal Disorder:</strong></td>
<td>Persistent or recurrent inability to attain, or maintain until completion of the sexual activity, an adequate lubrication-swelling response of sexual excitement. The disturbance causes marked distress or interpersonal difficulty. The sexual dysfunction in not better accounted for by another Axis I disorder (except another Sexual Dysfunction) and is not due exclusively to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition.</td>
</tr>
<tr>
<td><strong>Orgasm</strong></td>
<td><strong>Female Orgasmic Disorder:</strong> Persistent or recurrent delay in, or absence of, orgasm following a normal sexual excitement phase. Women exhibit wide variability in the type or intensity of stimulation that triggers orgasm. The diagnosis of Female Orgasmic Disorder should be based on the clinician’s judgment that the woman’s orgasmic capacity is less than would be reasonable for her age, sexual experience, and the adequacy of sexual stimulation she receives. The disturbance causes marked distress or interpersonal difficulty. The orgasmic dysfunction in not better accounted for by another Axis I disorder (except another Sexual Dysfunction) and is not due exclusively to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition.</td>
</tr>
<tr>
<td><strong>Women’s Orgasmic Disorder:</strong></td>
<td>Despite the self-report of high sexual arousal/excitement, there is either a lack of orgasm, markedly diminished intensity of orgasmic sensations or marked delay of orgasm from any kind of stimulation.</td>
</tr>
</tbody>
</table>
In such a model, the woman who lacks feelings of sexual desire at the outset but who is able to become sexually excited during the interaction would not be deemed to have a sexual desire disorder.

When 580 women from “The Nurses Sexuality Study” were presented brief descriptions of different models of sexual function, only a third endorsed the Masters and Johnson linear model of sexual function [11]. The findings from this study suggest that there might be great heterogeneity in women’s perceptions of the source of their sexual responses and the models they can most relate to. Most recently, a large random sample of Australian women responding to an online survey showed that women with and without sexual dysfunction were equally likely to endorse the circular model which emphasizes responsive desire [27].

With the upcoming publication of DSM-V in 2013, there have been proposed criteria for low desire in women which incorporate the overlap between sexual responses, attempt to fit the wide heterogeneity of women’s responses, and depathologize normative declines in “spontaneous” desire [28].

**Recommendation:**

The current accepted definition of HSDD in women is highly problematic and the emphasis on sexual fantasies and desire for sexual activity is not applicable to all women. We recommend that desire be regarded as the result of an incentive (sexually competent stimulus) which activates the sexual system, of which the subjectively perceived desire is one of many components. **GRADE C**

### 3. CRITICISMS OF DSM DEFINITIONS OF FSAD AND FOD

In the most recent edition of the DSM [1], FSAD is defined as the pervasive or recurrent inability to attain, or to maintain until completion of the sexual activity, an adequate lubrication-swelling response of sexual excitement, coupled with marked distress or interpersonal difficulty. In contrast to the 3rd edition of the DSM, subjective sexual experience is no longer part of the definition of arousal disorder, possibly in an attempt to match norms and criteria for men’s and women’s sexual dysfunctions [29].

There are a number of problems with the current DSM-IV criteria for FSAD, defined according to a deficient “lubrication-swelling response” ([Table 1](#)). Lubrication problems are not necessarily distressing for women. For example, although 11% of women were classified as having “manifest” lubrication problems, none of them reported distress about their symptoms [30]. In another study of 31,581 American women [31] with distress measured by the Female Sexual Distress Scale [32], whereas the age-adjusted prevalence of current “low arousal” was 25.3%, the prevalence of arousal problems with associated distress was far lower (3.3% - 6.0%, depending on age) (Level 2). In a closer exploration of personal versus interpersonal distress associated with lubrication problems, Bancroft and colleagues [33] found that among the women who complained of lubrication difficulties (31.2% of their sample), 7.3% reported “marked distress” about the relationship and 6.5% personal distress (Level 2). In the total sample, lubrication problems was a poor predictor of relationship distress and the best predictors of distress were indicators of emotional and relationship well-being and the quality of the emotional relationship with the partner. Lack of lubrication is often a poor predictor of distress, except among postmenopausal women. In the clinical setting, complaints of “genital deadness” or absent/impaired subjective sexual arousal are far more common.

Secondly, although the DSM-IV explicitly requires the clinician to assess the adequacy of sexual stimulation only when considering the diagnosis of Female Orgasmic Disorder (FOD), adequacy of sexual stimulation is a critical factor in the evaluation of the other female sexual dysfunctions, and FSAD in particular. Exactly what is adequate sexual stimulation? Some sort of physical (genital) stimulation is usually a necessary, but not necessarily sufficient, prerequisite for arousal. For many women, adequate sexual arousal involves physical as well as ‘psychological’ and ‘situational’ stimulation, such as intimacy with a partner, the exchange of confidences, the sharing of hopes and dreams and fears, and not only directly prior to the sexual event [34] (Level 3). What if certain types of sexual stimulation have been adequate in the past, but not anymore? Is it evidence of FSAD, or could it be explained in terms of habituation or an adaptation to changing life circumstances [33] (Level 4)? And what is meant by “completion of the sexual activity”? Is it masturbation to orgasm, sexual contact with a partner, sexual contact including coitus? These are very different activities that are known to differ in their sexually arousing qualities [35] (Level 2).

Thirdly, the description of the first problem demonstrates that clinical judgements are required about sexual stimulation and the severity of the problem, the validity of which is questionable. The clinician has to evaluate what is normal, based on age, life circumstances, and sexual experience. Research, on the basis of which clear criteria can be formulated, is lacking. There is a great variety in the ease with which women can become sexually aroused and which types of stimulation are required [2] (Level 4).

In general, women have difficulty perceiving genital changes associated with sexual arousal [23] (Level 2). However, women who report little or no desire for sexual activity, lack of orgasm, or sexual pain, may in fact be insufficiently sexually aroused during sexual activity. It is particularly difficult to differentiate
between FSAD and FOD. FOD is defined as the persistent or recurrent delay in, or absence of, orgasm following a normal sexual excitement phase [1]. In cases where the clinician does not have access to a psychophysiological test, it cannot be established that her deficient orgasmic response occurs despite a normal sexual excitement phase, unless she reports feelings of sexual arousal. Ironically, this subjective criterion has been removed from the DSM-IV.

Studies investigating the efficacy of psychological treatments for sexual dysfunction have demonstrated that directed masturbation training combined with sensate focus techniques is very effective for women with lifelong anorgasmia to become orgasmic. In fact, this is the only psychological treatment of sexual dysfunctions that deserves the label 'well-established', and is probably efficacious in acquired orgasmic disorder [36] (Level 2). The success of directed masturbation suggests that lack of adequate sexual stimulation is an important etiological factor underlying lifelong, and probably also acquired, FOD. Consequently, if the clinician would strictly adhere to the DSM-IV criteria, neither the diagnosis of FSAD, nor FOD, would be appropriate, because the problem can be reversed by adequate sexual stimulation. Perhaps the diagnosis FOD should be restricted to those women who are strongly sexually aroused, but have difficulty surrendering to orgasm [37] (Level 4).

There are no clinical or epidemiological studies that differentiate between women with lifelong or acquired FOD. Whereas Segraves posited that FSAD hardly exists as a distinct entity [38], it can be argued that in a classification system based on etiology, FSAD (meaning lack of subjective arousal) should be considered to be the most important female sexual dysfunction, with complaints of lack of desire and orgasm, and pain, frequently being consequences of FSAD (Level 4).

Finally, there is a good deal of evidence that, especially for women, genital response does not coincide with subjective experience [23] (Level 2). Instead, women's subjective experience of sexual arousal appears to be based more on their appraisal of the situation [39] (Level 3). This gender difference in concordance between subjective experience of sexual arousal and genital response was confirmed in a large meta-analysis with total sample sizes of 2,505 women and 1,918 men, and therefore not likely to be a methodological artefact [40] (Level 1). Thus, it is highly problematic that the current definition of FSAD neglects the most important aspect; namely that of subjective sexual arousal.

**Recommendations:**

The focus on “lubrication/swelling response” in the DSM-IV-TR definition of FSAD is highly problematic...
given that this is rarely a complaint motivating treatment seeking. Moreover, there is minimal, if any, correlation between subjective and genital sexual arousal. Given the importance of “adequate sexual stimuli” for sexual arousal and desire, this should be assessed clinically when evaluating whether an arousal or orgasm disorder is present.

GRADE C

4. ALTERNATIVE CLASSIFICATIONS FOR SEXUAL DYSFUNCTION IN WOMEN

Because of these criticisms of the DSM, an international classification committee sponsored by the American Urological Association Foundation (AUAF) met to deliberate and propose alternative criteria to sexual dysfunctions experienced by women [41]. The resulting classification system maintained the same four categories of the DSM-IV (i.e., desire, arousal, orgasm and pain disorders), however the definitions characterizing these changed (Table 1). Sexual Interest/Desire Disorder emphasized that lack of sexual desire prior to engaging in sexual activity was not symptomatic of a sexual dysfunction if the woman was able to become sexually excited and experience desire during the sexual encounter. Instead, the diagnosis of Sexual Interest/Desire Disorder was given if there was also a lack of responsive sexual desire during the sexual interaction or following sexual arousal.

Changes in the diagnostic criteria for FSAD were also proposed. Three separate sexual arousal disorders were proposed based upon the self-reported difficulty of subjective versus genital arousal impairment (Table 1). With the evidence to date that genital vasocongestion demonstrated by the majority of women with loss of subjective arousal, is comparable to that of healthy women, and given that women differ in their awareness of these genital changes, recognition of a Subjective arousal disorder was advocated (Table 1).

Women may be subjectively aroused by, for instance, viewing an erotic film, or pleasuring her partner, being kissed or receiving breast stimulation, but complain of a marked loss of intensity of any genital response, including orgasm. Awareness of throbbing/swelling/lubrication is absent or markedly diminished. This clinical picture has been described by the following groups of women: Women with autonomic nerve damage [42], some postmenopausal estrogen replete women with demonstrable lack of vasocongestive response and some for whom there is no evidence of physically impaired vasocongestion but a lack of sexual sensitivity is still present [43]. Therefore, a category of Genital sexual arousal disorder was proposed (Table 1). However, this is a clinical diagnosis based on the woman’s report for which there may or may not be demonstrable physical pathology or evidence of psychophysiological impairment when tested in a laboratory [44]. Despite many women disclaiming genital swelling, pleasurable sensations from direct stimulation of their genitalia or awareness of lubrication, it is highly possible that there may be reflexive genital vasocongestion [14,45].

The most common clinical presentation, however, was thought to be Combined genital and subjective arousal disorder (Table 1). Again, research suggests that many women with this presentation may still be genitally vasocongesting in a healthy manner [14,44] (Level 2). It is the lack of report of subjective excitement from any type of sexual stimulation that distinguishes these women from those with genital arousal disorder.

These definitions (Table 1) were adopted by the last International Consultation on Sexual Medicine: Men and Women’s Sexual Dysfunction, in Paris in July 2003 [46]. Some work was done on the validity of these new definitions. Basson and Brotto aimed to assess genital response using vaginal photoplethysmography in 34 estrogenized, postmenopausal women diagnosed clinically (using a detailed semi-structured interview) with acquired Genital Sexual Arousal Disorder and orgasmic impairment [43] (Level 2). They found this group of women to be heterogeneous, with psychophysiological arousal responses varying from absent to robust. In another study, Brotto and colleagues found that women with Genital Sexual Arousal Disorder exhibited lower levels of sexual psychophysiological arousal than women with Subjective Sexual Arousal Disorder and women with Combined genital and subjective sexual arousal disorder [47] (Level 2). Clearly, validation of this differentiation based on clinical presentation awaits further replication.

Recommendation:

The available evidence suggests that there are problems in existing definitions of sexual desire, arousal, and orgasmic disorders in women. Given the upcoming publication of the DSM-V in 2012, it is likely that the current diagnostic criteria for these disorders may change. The proposed definitions that were sponsored by the AUAF in 2003 present alternative criteria for these disorders that are currently recommended for the clinical setting.

GRADE B

5. PREVALENCE OF SEXUAL DESIRE AND AROUSAL DYSFUNCTION IN WOMEN

There has been a recent surge in epidemiological studies estimating the prevalence of sexual desire, arousal, and orgasm complaints in women. These studies have been conducted on pre and postmenopausal women, naturally and surgically menopausal women, women of varying ages up to 105, and
of sexual arousal beyond lubrication. Bancroft and colleagues [33] looked at a composite measure of arousal labelled “Impaired physical response”, which included feeling arousal during sexual activity, pleasant genital tingling, and enjoying genital touch. The presence of impaired physical response increased the probability of marked relative to no distress about the relationship by 51% but was unrelated to personal distress, and it was overall less problematic for older women (Level 2). A British study by Dunn and colleagues asked more generally about “problems becoming sexually aroused” and found that 17% reported this problem in the previous three months [53]. Similar to the issue with prevalence on low desire, the prevalence of low arousal plus distress drops markedly (Witting and colleagues [56] found the prevalence of impaired lubrication plus distress to be only 7%). When considering the association between duration of complaints and prevalence, lubrication difficulties lasting 6 months or longer were found to be much more common than those lasting one month (2.6% vs 9.2%, respectively) [49].

6. SEXUAL SATISFACTION AND THE ASSOCIATION WITH DESIRE AND AROUSAL

Sexual satisfaction is an important component of contemporary models of women’s sexual response [57-59], but across studies, the precise definition either varies or is not provided. It is recognized, however, to have personal and relational domains [60]. Hartmann and colleagues defined satisfaction with sexual intercourse as being both relational (e.g., feeling safe, not lonely, not distant from partner) as well as individual (e.g., not feeling unsettled inside, feeling content, free of sexual tension, pleasantly indulged, relaxed, happy) [61]. Byers [62] pointed out that one’s level of sexual satisfaction depends on one’s frame of reference (e.g., expectations and past experiences). Therefore, a woman who does not expect to experience orgasm during sexual encounters with her partner may be more sexually satisfied than a woman who occasionally doesn’t experience orgasm. Among several recent population-based studies of sexual difficulties in women, a proportion of women will report being sexually satisfied despite the presence of sexual symptoms. In a study of 290 British women aged 18-75, 79% indicated being very satisfied with their current sex life despite the fact that 24% had not engaged in any sexual activity in the past 3 months [16]. Similarly, in the Study of Women’s Health Across the Nation (SWAN), 70% of women reported thinking about sex less than once/week but 86% remained sexually satisfied [15]. Sexual fantasies and sexual satisfaction are also not correlated in women [15,33]. The interesting counterpart to this finding is that a number of studies have found that a proportion of women without sexual symptoms will report dissatisfaction [19,30,33,50,63]. Moreover, sexual satisfaction is associated with, but is not the

---

Across different countries and cultures. Three of the most widely cited epidemiological studies in the sexological literature are discussed and several others are presented in Table 2. The National Health and Social Life Survey (NHSLS) [48] found that between 27-32% of women aged 18-59 who had been sexually active over the past year reported a lack of interest in sex (Level 2). However, the investigators did not stipulate the duration of time the symptom had to be experienced, which likely resulted in an inflation of dysfunction rates. In the National Survey of Sexual Attitudes and Lifestyles (NATSAL) conducted on 11,161 British men and women aged 16-44 who participated in a computer-assisted self-interview, low sexual desire was the most common complaint in women, at 40.6% over the past month and 10.2% for the past 6 months [49] (Level 2). In the Global Study of Sexual Attitudes and Behaviors (GSSAB), 13,882 women across 29 countries took part either in a computer-assisted telephone interview or a face-to-face interview [50] (Level 2). Lack of interest in sex was the most common problem in women, ranging from 26-43%. Of course the very low response rate from this survey (19%) renders the external validity of the findings questionable.

Although different assessment tools have been employed and in differing formats (e.g., face to face interview versus questionnaire versus computer assisted interviewing), in general these studies find convergence on the frequency of reported low desire in women to be approximately 20-30% (Table 2). However, when the complaint of sexual distress is also included, the prevalence of desire difficulties drops usually by half. In addition, the age-associated decline in sexual desire that is found somewhat consistently is not found when low desire plus distress are taken into account. Hayes (2008) found that low desire and age were positively correlated (i.e., complaints of low desire become more prevalent as women age); however, low desire, together with its associated distress, was not significantly associated with age [51]. In analyses of both European and American women participating in the Women’s International Study of Health and Sexuality (WISHeS) study, Hayes et al [52] found low desire to significantly increase with age but the proportion of women with low desire who were distressed by it decreased with age (Level 3) [52]. Table 3 lists the specific predictors of sexual distress across a number of recent epidemiological studies.

Among these epidemiological studies, most have also assessed the prevalence of sexual arousal complaints. However, these studies have tended to use the DSM-IV-TR definition of FSAD with a focus on the “lubrication-swelling response” [1]. The prevalence of FSAD is listed in Table 2, with an overall range between 10.9% and 31.2% [30,33,48,49,53-56]. Few studies have attempted to explore other aspects

same as, lack of sexual distress and deserves further study in population-based studies. For women, sexual satisfaction does not equal sexual function. In using the NHSLS data to explore individual, relational, and cultural sexual satisfaction in 1,035 mid-life women in a sexual relationship, women’s health positively influenced her emotional satisfaction [64] (Level 2). Interestingly, relationship duration was not a predictor of sexual satisfaction in this study. Both studies focusing on sexual satisfaction found an important role for orgasm consistency [61, 64].

**Conclusions and Recommendations:**

Overall, the prevalence of desire complaints ranges from 10-40% and for arousal difficulties from 10-30%, depending on the study methodology, participants, and geographic location. Moreover, when the assessment of distress is included, the prevalence of these complaints drops to approximately half. Given these disparate rates, we recommend that distress or some other measure of severity always be included in future epidemiological trials and that clear operational definitions of the sexual domain be given, along with a duration of complaints of at least 3-6 months for denoting difficulty. Sexual satisfaction is rarely correlated with sexual frequency and is not consistently associated with sexual symptoms; thus, sexual satisfaction must be assessed clinically. Future research is needed on the definition of sexual satisfaction, on the correlates of sexual satisfaction in women, and how these correlates may differ for men. *GRADE C*

### II. ASSESSMENT

#### 1. THE BIOPSYCHOSOCIAL INTERVIEW

Assessment of sexual desire/arousal problems is critical in planning meaningful and sensible treatment interventions. Assessment is important not only for diagnosis but for determining the incidence and prevalence of various disorders and for evaluation of treatment outcome [65]. The most common approach to diagnosing sexual difficulties is via a comprehensive clinical interview of both the identified patient and her partner when possible. Such an interview includes discussion of the presenting problem and the predisposing, precipitating and maintaining factors that govern its appearance and

</table>
intensity [66]. Table 4 provides an overview of the contributory factors that may be etiologically relevant in such a biopsychosocial interview (adapted from Table 1 in Graziottin and Leiblum, 2005 [66]).

In addition to the various considerations described in Table 4, there are a wide array of precipitating factors that may “tip the balance” from satisfactory sexual function to dysfunction. Among these factors are life stage stressors such as childbirth, infertility, divorce or partner loss, unemployment, extra-relationship affairs, humiliating or traumatic sexual experiences, partner sexual inadequacy or clumsiness, and most significantly, relationship discord.

Often, there is not a clear distinction between either predisposing and precipitating factors or precipitating and maintaining factors. As a predisposing factor, for example, anxiety can increase an individual’s vulnerability to sexual dysfunction. It can also serve as a maintaining factor leading to sexual avoidance or arousal inhibition. Nevertheless, it is helpful to attempt to determine what the immediate triggers or precipitating factors are for the appearance of a recent sexual complaint since these are likely to be important areas to address in the early stages of treatment.

As far as the perpetuating or maintaining factors to consider, the clinician also should assess the current contextual factors that affect sexual expression and interest such as relationship satisfaction, privacy issues, current health of self and partner, medical or psychiatric issues, use of medications or recreational drugs/alcohol that may affect sexual expression and current stressors.

### 2. SELF-REPORT ASSESSMENT TOOLS

Many practitioners find that the use of standardized self-report questionnaires can be helpful in terms of saving time, identifying problems, and providing direction or greater focus for follow-up interview and evaluation. The assessment tools listed in Table 5 have demonstrated good reliability and validity and

can identify problems with the various components of female sexual response, many of which overlap. Often, it is difficult to determine which is the primary and which is the secondary diagnosis. Consequently, the scales listed in Table 5 can provide a helpful overview of problematic areas to be assessed further in a clinical interview, and should not be used to form a diagnosis on their own. Caution in using these self-report questionnaires and the tradition of focusing on (sexual event) quantity as opposed to these self-report questionnaires and the tradition of forming a diagnosis on their own. Caution in using these self-report questionnaires and the tradition of focusing on (sexual event) quantity as opposed to quality are real criticisms of existing measures that must be taken into account [67].

In addition to these more general scales that focus on all or several aspects of female sexual response, there are some scales that focus on a particular population. For example, for the assessment of HSDD in post-menopausal women, there is a brief assessment tool called the HSDD Screener [68] which consists of four self-report questions with an interpretable cut-off score. Depending on the responses the woman provides, the screener is followed by a more detailed face to face interview. The newest self-report assessment instrument for identifying HSDD is the Decreased Sexual Desire Screener (DSHD) [69]. It consists of four yes/no questions concerning both past and present sexual interest, whether or not the woman is bothered by her lack of, or diminished interest in sex, whether she wants her interest to increase, and a fifth seven-part question covering various factors that may be relevant to the differential diagnosis of HSDD such as medical procedures, medications, or partner’s sexual problems.

Finally, there are several instruments that are available which may be used to guide or direct a diagnostic interview in order to obtain a more comprehensive picture of the various contributions to desire or arousal problems. These include the Sexual Interest and Desire Inventory–Female Version [70] and the Women’s Sexual Interest Diagnostic Interview (WSID) [71] for assessment of sexual functioning in postmenopausal women. The latter instrument consists of 39 questions which allow for the identification of HSDD, FSAD, FOD, sexual pain, and personal distress associated with these complaints. In addition, the WSID provides a structured format for the identification of partner relationship problems, partner sexual dysfunction, and symptoms of depression.

**Recommendation:**

Although instruments may be helpful in guiding diagnosis or treatment, none is a substitute for a thoughtful and sympathetic clinical interview that includes the woman and her partner (if possible). **GRADE C**

### 3. THE PHYSICAL EXAMINATION

A physical examination is recommended for reasons of good medical care and for education and reassurance. The examination is also a setting to explore perceptions, beliefs, and attitudes about a woman’s own anatomy and encourage a patient’s positive approach to her genitals and body.

The examination is particularly important for ruling out or identifying medical factors when concomitant complaints such as loss of sensitivity or sexual pain exist. A gynecological examination should include an evaluation of the level of voluntary control of the pelvic floor muscles, pelvic floor muscle tonus, presence of vaginal wall prolapse, signs of vaginal atrophy, size of introitus, presence of discharge, or evidence of infection (acute or chronic), epithelial disorders and/or pain.

In Multiple Sclerosis [72,73] and other neurological diseases there may be sensory loss in the genitalia. In renal disease, there may be anemia, hyperprolactinemia and other disturbances of the hypothalamic-pituitary-gonadal axis (with reduction in androgens and estrogen levels) and subsequent vulvovaginal atrophy [74,75]. Vulvovaginal hypotrophy or atrophy is a common finding after natural or iatrogenic menopause, in hypothalamic or pituitary disease, breast-feeding women, and in women using low-dose estrogen or progesterone only contraceptives.

**Recommendation:**

A gynaecological examination is recommended in the assessment of women with desire and arousal complaints to assess and rule out medical/physical contributors. **GRADE C**

### 4. PSYCHOPHYSIOLOGICAL TOOLS

Over three decades, several techniques have been developed to assess genital physiological changes in response to sexual stimuli. In 1975, Sintchak and Geer introduced a method for the laboratory measurement of vaginal vasocongestion, using vaginal photoplethysmography (Level 3) [76]. The most widely used type of vaginal photoplethysmograph is a menstrual tampon-sized device, easy to insert and sterilize, containing an infrared light-emitting diode as a light source and a photo transistor as a light detector. The light source illuminates the vaginal tissues, and the photo transistor responds to the incident light that is backscattered from the vaginal wall and the blood circulating within it. Because of the opacity of the tissue, the amount of light backscattered is largely dependent upon the volume of blood within it; thus, the vaginal photoplethysmograph provides a measure of vaginal vasocongestion.

Two components are obtained from the same output signal of the photo transistor. When the signal is DC

<tr>
<th>Scale</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Golombok-Rust Inventory of Sexual Satisfaction (GRISS) [382]</td>
<td>A 28-item questionnaire designed to assess the existence and severity of sexual problems across five domains relevant to women: anorgasmia, vaginismus, avoidance, nonsensuality and dissatisfaction. Items are presented with a five point response format ranging from never to always. Interpretation of the data is based on patterns across the different subscales and Rust and Golombok note that “this leads to indications for therapy, rather than to a diagnosis”. The GRISS was standardized on couples receiving sex therapy. Split half reliability is 0.94 and test-retest reliability is 0.65 for women. It was validated in those with a known sexual dysfunction versus a control group and found to have good discriminant validity.</td>
</tr>
<tr>
<td>Brief Index of Sexual Functioning for Women (BISF-W) [18]</td>
<td>A 22-item questionnaire that provides domain and total scores on the following aspects of sexual function: desire, arousal, frequency of sexual activity, receptivity/initiation, pleasure/orgasm, relationship satisfaction and problems affecting sexual function. A principal components analysis resulted in three discrete factors: sexual interest/desire, sexual satisfaction, and sexual activity. BISF-W was also shown to possess a high degree of concurrent validity with the DSFI, displaying a Pearson correlation of 0.69. BISF-W, however, is much easier to administer than the DSFI and results in a more detailed evaluation of current sexual functioning.</td>
</tr>
<tr>
<td>Sexual Desire Inventory (SDI) [383]</td>
<td>A 14-item questionnaire that measures dyadic and solitary sexual desire on the basis of factor analysis. Using Cronbach’s alpha, SDI exhibited high internal consistency estimates with coefficients of 0.86 for dyadic sexual desire and 0.96 for solitary sexual desire, suggesting excellent reliability.</td>
</tr>
<tr>
<td>Derogatis Interview for Sexual Functioning (DISF) [384]</td>
<td>A 25-item questionnaire that includes five domains: cognition, arousal, behavior, orgasm and drive/relationship as well as a total score. The DISF/DISF-SR appears to fulfill fundamental psychometric criteria. High reliability scores and a nearly ideal subtest-total score relationship have been found. The hypothesized internal structure as well as the discriminative capacity of the scale have also been firmly established.</td>
</tr>
<tr>
<td>Female Sexual Function Index (FSFI) [203]</td>
<td>A 19-item questionnaire specific to women that assesses six domains (desire, subjective arousal, lubrication, orgasm, satisfaction and pain). FSFI was shown to possess excellent test-retest reliability for each domain with a range of reliability coefficients from 0.79 to 0.96. High internal consistency was also determined using Cronbach’s alpha which yielded values of 0.82 and higher. More importantly, greatly significant mean difference scores between women with Female Sexual Arousal Disorder and controls attest to the scale’s construct validity (p &lt; 0.001). Suggestions for improved scoring of the FSFI so it does not penalize women who are not currently sexually active have been offered. [385,386]</td>
</tr>
<tr>
<td>Sexual Function Questionnaire (SFQ) [387]</td>
<td>A 31-item relatively new instrument designed to assess eight domains of women’s sexuality: desire, physical arousal/sensation, physical arousal/lubrication, enjoyment, orgasm, pain, partner relationship and cognition. This scale features exceptional internal consistency, respectable reliability, excellent discriminant validity and sensitivity. Specifically, internal consistency of the domains was found to range from 0.65 and 0.91, and test-retest reliability was noted to be between 0.21 and 0.71 for Cohen’s weighted kappa and 0.42 and 0.78 for Pearson’s correlation coefficient. In terms of validity, there was a significant difference between the baseline mean SFQ domain scores of female patients with sexual dysfunctions and scores of controls. Additionally, SFQ scores at the end of the study also significantly diverged between patients who reported improvement in their sexual functioning and those who did not.</td>
</tr>
<tr>
<td>Female Sexual Distress Scale (FSDS) [32]</td>
<td>A 12-item instrument for determining the amount of current distress experienced by a woman who reports sexual difficulties. A cut-off score of 15 or greater is believed to indicate personal distress. Using Cronbach’s alpha, a high level of internal consistency was established for FSDS with a range from 0.86 in an early study to the low 0.90s in later clinical trials. Test-retest reliability has also been found to be respectable. In regards to discriminative ability, FSDS was found to successfully distinguish women with and without sexual dysfunctions.</td>
</tr>
</tbody>
</table>
coupled, slowly developing changes in vaginal blood volume (VBB) are observed, which are thought to reflect pooling of blood in the vaginal tissue [77] (Level 3). With AC coupling, a measure of vaginal pulse amplitude (VPA) is obtained, reflecting short-term changes in vaginal engorgement. Fluctuations in VPA reflect the phasic change in blood content or volume of the illuminated tissue at each heart beat, with larger amplitudes reflecting higher levels of vasoengorgement. Specificity and construct validity of VPA and VBB were investigated during sexual, neutral, as well as nonsexual emotional states, convincingly showing that changes in VPA are specific to sexual stimuli, while VBB appears to increase in response to both sexual and anxiety-inducing stimuli [20,78-80] (Levels 2 and 3). VPA is usually increased by sexual arousal up to, but not including, orgasm due to movement artifacts [81] (Level 3). To reduce interference with signal recording, they can be deleted using modern signal-processing and data reduction software [78,82]. Depth of the probe and orientation of the light source can be controlled by an acrylic plate that is usually attached to the cable within 5 cm of the optical sensor [78].

Although the use of vaginal photoplethysmography has been of great value for indicating the arousal status of the vagina per se, it is still unclear exactly what VPA actually represents [83]. This may, in part, be explained by its lack of an absolute scale. VPA is measured on an ordinal scale rather than an interval or ratio scale, hampering the development of this measure as an individual diagnostic method of genital responsiveness.

Despite this limitation, all studies that have compared genital responsiveness between women with and without sexual problem were done using VPA, and nearly all of these have failed to find group differences in VPA, whether between women with dyspareunia and controls [84-87], women with HSDD, FOD, and controls [88], women with FSAD seeking treatment and controls [89], women who improved on sexual arousal symptoms following sex therapy, placebo, or gingko biloba versus those who did not improve [90], women with broad sexual problems and controls [91], and medically healthy women with FSAD versus controls [44] (Level 2). When using the AUAF definition of genital sexual arousal disorder, one study found that VPA differed significantly from women with subjective sexual arousal disorder [47] (Level 2). These findings suggest that genital responsiveness in somatically healthy women, at least as it is defined by the DSM-IV, may not play an important role in women’s sexual problems. It is unlikely that these findings are the result of VPA not being a sensitive measure; there is abundant evidence that VPA is a sensitive measure, distinguishing baseline levels of premenopausal women from postmenopausal women [44,92-94], discriminating sexual stimuli varying in intensity [24,95], and differentiating responses from heterosexual and homosexual women when stimuli depicting solitary males and females are used [96] (Level 2). In women with medical conditions, VPA proved sensitive as well. In fact, one of the few psychophysiological studies to date that found a significant effect of sildenafil on VPA in women with FSAD was done in women with spinal cord injury [42] (Level 2). A study comparing genital response during visual sexual stimulation of women with diabetes mellitus and healthy women found VPA to be significantly lower in the former [97] (Level 2). A Dutch study measured VPA in medically healthy women who had undergone a simple hysterectomy, and women with a history of radical hysterectomy for cervical cancer [98] (Level 2). Only in the latter group was VPA during visual sexual stimuli impaired, despite the fact that the women with simple hysterectomies reported more sexual problems than the other two groups. Similar findings came from a later study from the same group, with VPA differentiating between women who had undergone nerve sparing radical hysterectomy from women who underwent conventional radical hysterectomy [99] (Level 2). The latter group had lower VPA increases than the former group, whose VPA levels were similar to those of a healthy control group. Summarizing these findings, Laan and colleagues concluded that not presence of sexual arousal problems but presence of a somatic condition that influences genital response may be the most important determinant of impaired genital responsiveness [44].

Several alternative, albeit to date less well researched, methods for measuring genital response in women have been developed. One of the earlier methods was a heated oxygen electrode fitted into a suction cup that could be applied to the vaginal wall and held there by a partial vacuum generated in the rim of the cup [100] (Level 3). The silver disc electrode is heated by an electric current to a set temperature (usually 43°C). The amount of electrical power needed to keep the disc at this temperature can be monitored. Heat is lost from the disc mainly by conduction through the tissue and tissue fluid to the blood. Increased blood perfusion under the electrode will increase its heat loss and thus a greater power output will be needed to maintain the electrode at the set temperature. The changes in power in milliwatts thus become an indirect measure of the changes in blood flow under the electrode, reflecting the pooling of blood in the vascular bed. The electrode also records the amount of oxygen that diffuses across the skin, reflecting transient changes in blood flow. The greater the blood flow beneath the disk the greater will be the apparent oxygenation of the flow as it gradually approaches that of the saturation of the arterial blood. A number of studies have documented that the heat dissipation measure
and the oxygen perfusion measure are sensitive to sexual arousal and orgasm [101-103] (Level 3). In those studies subjects usually applied clitoral self-stimulation as a means to induce sexual arousal. A great advantage of this device is that it combines two measures of blood flow. Also, it is relatively free of movement artifacts because it is attached to the surface of the vagina [104] (Level 3). This makes the device suitable for monitoring changes in blood flow from low levels of sexual arousal up to orgasm. In a similar vein, the reliability of the signal obtained does not seem to be compromised by masturbation and clitoral vibration. Finally, both measures can be calibrated in terms of absolute blood flow. Nevertheless, use of this method has been limited. Disadvantages are its expense, the fact that the electrode should not be applied for very long periods of recording to protect the vaginal mucosa from heat damage, and that the device needs to be attached by the experimenter. A general disadvantage of temperature methods seems to be that subjects require relatively long resting periods to show temperature stability, and after moderate to high sexual arousal the measures do not appear to return to baseline very easily [104,105] (Level 3).

Another commonly used physiological measure of female genital response is the labial thermistor. This device consists of a thermistor placed on a small clip that is attached to the labia minora [106-108] (Level 2-3). Unlike VPA, the units of change are measured on an interval scale (degrees Celsius), allowing direct comparisons across participants. Also, labial temperature is unaffected by orgasm [109] (Level 3). At the same time, menstrual cycle effects have been reported for labial temperature change recorded during the follicular and luteal phases of the menstrual cycle [5,107] (Level 2, 3). Onset of change in labial temperature is typically slower than VPA and temperature takes longer to return to a pretrial level of response. Payne and Binik have argued that labial temperature is a more consistent measure of genital response than VPA and is more strongly correlated with self-reported sexual arousal than VPA [110] (Level 3). Recently, Prause and Heiman directly compared the labial thermistor with VPA [111] (Level 3). Participants wore the labial thermistor simultaneously with the vaginal photoplethysmograph. The labial thermistor discriminated sexual from nonsexual arousing stimuli and was sensitive to different levels of sexual arousal. One woman reported that the labial thermistor was very uncomfortable, while others indicated no or mild discomfort from each instrument. In contrast to earlier findings [23,95] in this study VPA did not discriminate sexual stimuli of different intensity.

A new approach, the labial photoplethysmograph, relies on measurements of genital responses that are similar to the vaginal photoplethysmograph [112] (Level 2). The labial photoplethysmograph is a small plastic clip, which can be attached to the labia majora, originally designed to measure blood flow in the ear lobe. In a small study, the labial photoplethysmograph was compared with VPA while participants viewed neutral, sexual, sexually threatening and threatening film clips. Both instruments were specific to sexual content and correlated strongly with participants’ own ratings of their sexual arousal. Although participants reported that the labial photoplethysmograph was somewhat more difficult to place and less comfortable, the labial device exhibited fewer movement artefacts than the vaginal photoplethysmograph [82].

A very recent development is measurement of clitoral photoplethysmography in conjunction with vaginal photoplethysmography [113] (Level 2). A clitoral photoplethysmograph was attached to the silicon tube of the vaginal plethysmograph, along with a silicon placement device holding the clitoral photoplethysmograph in the correct anatomical position. Subjects are able to insert the probe and attach the clitoral device without supervision. The shape of the clitoral probe follows the anatomical curves of the area surrounding the urethral opening up to the clitoris, between the labia minora and just above the introitus. Thirty-two women, 20 of whom with mixed sexual problems, participated in the study. Clitoral photoplethysmography, but not VPA appeared sensitive to a sudden (planned but unannounced to the subject) interruption of the visual stimulus. No differences between women with and without sexual problems were found for either measure.

Devices have also been designed to measure vagina pH. On average, vaginal pH increases with increasing sexual arousal [114] (Level 3). Measurement of pH, however, requires potentially disruptive experimenter involvement, and pH seems to vary nonsystematically across different areas of the vagina [82] (Level 3).

Clitoral color Doppler assessment of clitoral blood flow was first attempted in 1995 [115] (Level 3). This non-invasive, reproducible, low-cost, and quantitative technique allows for ultrasonographic identification of the clitoris and for color Doppler assessment of clitoral blood flow. More than a decade later, Kukkonen and colleagues examined the convergent and discriminant validity of this measure by assessing its ability to discriminate between sexual and other forms of arousal. Results from 63 healthy premenopausal women indicate that ultrasonography was not successful in differentiating sexual arousal from a humor control condition [116] (Level 2). Caruso and colleagues studied 30 women with type 1 diabetes using clitoral color Doppler ultrasonography and found that they had a lower pulsatility index, peak systolic velocity, and end-diastolic velocity values compared with controls [117] (Level 2). Because the technique requires a
A new method that may prove to have better ecological validity is Laser Doppler perfusion imaging (LDPI). This is a method of measuring superficial skin microcirculatory blood flow (no deeper than 1.5 mm below skin surface) that doesn't require genital contact nor (presumably) the presence of a technician in the subject's room. The Laser Doppler perfusion imager allows measurement of tissue blood flow over a defined area. It is noninvasive, as the laser is placed between 15 and 40 cm from the vulva. It is based on the Doppler principle, i.e. the frequency change that light undergoes when interacting with objects in motion. Styles and colleagues [118] measured LDPI in two separate sessions coinciding with the follicular and luteal phase in 16 sexually functional women before and after sexual stimulation (reading a chapter of erotic fiction). The method requires women to undress from the waist down and to assume a lithotomy position allowing unimpeded access to the vulval area. In this study, the room was temperature controlled and scans were performed in a dark room to ensure consistency in flux (units of blood flow) readings. Styles and colleagues used a piece of black card, with an individualized hole cut out, taped so that it covered the subjects' genital skin apart from her vulva, to ensure that backscattered light was kept to a minimum. Percentage of change in blood flow after sexual stimulation was significantly different in all four areas that were measured: the clitoral area, right and left labium, and the fourchette. Flux change was greatest in the latter area. There were no differences between the first and second visits or follicular and luteal phases. Increases in blood flow did not correspond with subjective sexual arousal reports. In this study, scans could not be made continuously while the subjects were reading, as the scans had to be made in the dark. Other forms of stimulation or technical advances in stimulus delivery can be used to overcome this disadvantage. A second, very recent study [119] measured LDPI in 65 sexually functional women in their luteal phase while they viewed three 15-minute films (two nature films and one of four experimental films: erotic, humor, anxiety or neutral) through i-goggles. During each film, scans were produced every 163 seconds. The region of interest included parts of the labia majora, labia minora, and clitoral hood; one general vulvar blood flow score was generated from these data. Results showed that the erotic condition generated significantly more vulvar blood flow than the nonerotic conditions, which were not significantly different from each other. Genital blood flow during the erotic condition was significantly and positively associated with subjective ratings of sexual arousal. The authors presumed that when female genital response is measured externally, women are better able to accurately describe their level of sexual arousal. This hypothesis presupposes that women can differentiate between sexual feelings in their vagina and other genital areas; this has never been tested empirically. Alternatively, simultaneous measurement of an internal measure such as VPA and an external measure such as LDPI is another possible way to elucidate possible differences in genital-subjective arousal correlations associated with these measures. In all, this (expensive) technique shows promise in that in contrast to the current gold standard, data obtained are on an interval scale and therefore do allow comparison between individuals.

Recently, Kukkonen and colleagues investigated thermal imaging technology as a means to measure genital response. Infrared thermography detects natural thermal radiation from the body and is able to produce an image representing temperature distribution of body areas. During sexual arousal, there is increased blood flow to the genalia, resulting in vasocongestion and a rise in temperature. This measure discriminated between a sexually arousing, humorous, and neutral clip, in a student sample [120] and between a sexually arousing, humor, anxiety and neutral clip in an older sample [121], using between-subject designs (Level 2). In the latter study, within-subjects correlations between temperature change and subjective continuous arousal were variable with significantly positive correlations in 4 of 10 women who were measured in the sexual arousal condition. In principle, thermal imaging is a promising technology for the assessment of genital sexual arousal in both women as well as men, even though its high cost may prevent widespread use of this measure.

Magnetic resonance imaging of the pelvic area is another new method to evaluate genital response in women. Initially, this method required a contrast agent to observe dynamic changes in blood flow and engorgement, which yields the risk, albeit small, of an adverse reaction [122], but more recent techniques without contrast agent proved to be equally sensitive [123] (Level 3). A limitation of the noncontrast magnetic resonance technique is that it is not possible to obtain quantitative regional blood volume measurement, but since this is less robust than three-dimensional, anatomical clitoral volume measurements [124], this is not a significant limitation (Level 3). During sexual arousal, the crura and body of the clitoris as well as the vestibular bulbs, which according to O'Connell and colleagues should be considered part of the clitoris and therefore renamed as clitoral bulbs [125] demonstrate a very prominent increase in size and signal intensity [126] (Level 2). Measurement of other structures, including analysis of vaginal mucosa, vaginal wall thickness, or changes in the labia proved either unsuccessful or less reproducible than the clitoral volume measurement. Thus far, no differences were found between small groups of premenopausal and postmenopausal women when changes during sexual arousal of the vaginal wall, vaginal mucosa, clitoris, femoral vein...
signal intensity, relative regional blood volume, and clitoral volume were measured [127] (Level 2). Moreover, the mean unaroused clitoral volume (not including the vestibular, or clitoral, bulbs) of premenopausal women (2.8 cc) did not differ from that of postmenopausal women (3.1 cc), implying that even absolute changes in clitoral volume do not differ between groups [128] (Level 2). To date, none of the studies using this technique have compared women with and without sexual difficulties.

Most recently, Foldes and colleagues studied the clitoral anatomy in a sexually unstimulated state using functional 3D sonography [129,130] (Level 3). This technique requires a sonography probe placed on top of the vulva with a coronal, transversal, orientation to obtain coronal and transversal planes and the probe placed sagittally on the majora labia to obtain a sagittal scan. An echo-scan provides a fine anatomy of the clitoris and visualizes the displacement of structures during movement or perineal contractions in real-time. These images reveal the clitoris as a three planes (cross-section, sagittal section and coronal section) organ, with the clitoral bulbs reaching as far posteriorly as the perineal body, supporting the anatomical findings by O’Connell and colleagues [125]. The authors suggest that the special sensitivity of the lower anterior vaginal wall called the Grafenberg or G-spot could be explained by pressure and movement of the clitoral’ root during a vaginal penetration and subsequent perineal contraction.

Recommendations:

To date, psychophysiological techniques have been reserved largely for the research setting and are not a standard component of the clinical assessment or treatment in women, due in part to its invasive nature. Although vaginal photoplethysmography, the best researched measure to date, is a sensitive tool, it is not useful diagnostically because it cannot be calibrated. More research is needed using one of the newer psychophysiological techniques to explore whether these methods hold utility in discriminating clinical subgroups. Findings from psychophysiological studies to date suggest that in somatically healthy women, the potential to become genitally aroused is not disrupted. GRADE B

5. LABORATORY INVESTIGATIONS

The possibility that laboratory testing will identify causes of sexual dysfunction is low. Estrogen deficiency is best detected by taking a history and performing a physical examination [131]. Measurements of estradiol and follicle stimulating hormone (FSH) are indicated in amenorrheic young women or in women with irregular menstrual patterns or to evaluate menopausal status in hysterectomized women without a clear symptom history. Although some interpret the “hypo” in HSDD to infer a biological deficiency of testosterone [132], the majority of studies have failed to find a correlation between low sexual desire and serum testosterone levels in women [133-139]. In women with symptoms or signs of thyroid disease or hyperprolactinemia (galactorrhea, irregular menses and/or infertility), diagnostic assays should be taken.

Recommendation:

In women with symptoms or signs of thyroid disease or hyperprolactinemia (galactorrhea, irregular menses and/or infertility), diagnostic assays should be taken. GRADE C

6. HORMONES AND SEXUAL RESPONSE: ESTROGEN

The naturally occurring estrogens 17β-estradiol (17β-E2), estrone (E1), and estriol (E3) are C18 steroids derived from cholesterol. The most abundant and potent estrogen before menopause is 17β-estradiol (or estradiol). Estril and estrone are present at much lower levels and display less activity on estrogen receptors [140]. The primary source of estradiol in premenopausal women is the granulosa cells of the ovaries. After menopause, estrogen is produced in extradragonial intracellular sites from dehydroepiandrosterone (DHEA), dehydroepiandrosterone sulphate (DHEAS), and androstenedione (A4). This peripheral production of estrogens from adrenal and ovarian prohormones and their interconversion depends on several factors, such as local activity of aromatase, 17β-hydroxysteroid dehydrogenases, and estrogen sulfatases [141,142]. The major estrogen in serum of postmenopausal women is E1 which is not measured by clinically available assays.

There are two subtypes of estrogen receptors (ERα and ERβ) and several isoforms and splice variants of each subtype. The overall degree of homology of the receptors is low, causing binding of ligands to the two receptors with different affinities. Estrogens act on estrogen receptors found in the vagina, vulva, urethra, and neck of the bladder [143,144]. Estrogen has been demonstrated to stimulate maturation and proliferation of vaginal and skin epithelia, to enhance vascularity and blood flow and to stimulate glandular secretion. In animal models, estrogens have been found linked to the regulation of vaginal and clitoral nitric oxide synthase expression [145,146], the enzyme responsible for the production of nitric oxide, a primary mediator of the physiological vasocongestive sexual response.

Several clinical studies have shown that an adequate estradiol level is important for maintaining vaginal lubrication and avoiding dyspareunia [147-150]. However, this is not to say that low estrogen levels invariably cause dyspareunia. Several studies showed
that baseline vasocongestion levels are related to estrogen levels in postmenopausal women, but in-
crease in genital arousal during sexual stimulation is not [93,94]. Thinning of the vulvo-vaginal epithelium,
atrophy of vaginal wall smooth muscle, diminished blood flow and reduced activity of specialized glands
are known consequences of the lack of estrogen. Hypoestrogenism has also been found to cause a
decrease in the resistance of the intercellular tight junctions in ectocervical epithelial cells. This has
been suggested as the cellular mechanism responsible for the decreased permeability which leads to
decreased lubrication of the lower genital tract [151].

A weak correlation between lower levels of estradiol and decreased sexual desire has been found by some
[150,152,153], but not by others [154-156]. Of note, studies have significant methodological differences:
assessment of women at different menopausal transition stages, different study designs and the use
of different sexual function questionnaires. Table 6 summarizes recent population-based studies that
have explored the association between estrogens and women’s sexual response.

Vaginal shortening and narrowing and introital stenosis are known complications of severe
vulvovaginal atrophy. Severe pain and/or bleeding from attempted penetration may occur; inability to
penetrate or avoidance may follow. Fear of hurting his partner and/or physical difficulty from introital
or vaginal narrowing might deteriorate the erectile function of the male partner.

Effects of menopause and hypoestrogenism on genital sensitivity are not well known. The sensory
field of the pudendal nerve has been found to be significantly larger in estrogen treated ovariectomized
female rats than in untreated controls [157]. A study measuring vaginal and clitoral warm, cold,
and vibratory thresholds in 89 women aged 18-78 found increasing age to be a positive predictor of
increased thresholds and worsening neurological function, but the study did not control for menopausal
status [158]. Interestingly, they found a smaller age
effect for the clitoral measurement, attributed to the richer innervation of the clitoris. Another study randomized 39 postmenopausal women with mixed lower-genitourinary-tract complaints into four arms: one group received topical estradiol (E2) cream and pelvic muscle biofeedback training, the second received topical E2 cream and sham biofeedback, the third received placebo cream and pelvic muscle biofeedback training, and the fourth received placebo cream and sham biofeedback. They concluded that topical estradiol cream significantly improved mechanical sensitivity of the vulvar vestibule compared with placebo cream [159] (Level 1). Another study compared 17 premenopausal against 15 postmenopausal women for vulvar sensitivity to pressure/touch. A clear association was found between reduced vulvar sensitivity to pressure/touch and estrogen deficiency. Significantly further reduced sensitivity was found in postmenopausal women not using estrogen replacement therapy [160] (Level 2).

Non-genital symptoms characteristic of the menopausal transition are hot flushes, breast
tenderness (at early stages, ceasing at later stages of transition) and insomnia. These could affect
sexuality indirectly. Estrogen modulation of central α2-adrenergic receptors has been linked to an
elevated sympathetic activation with menopausal estrogen withdrawal, which plays a role in the
initiation of hot flushes. Plasma levels of 3-methoxy-4-hydroxyphenylglycol (MHPG), the main metabolite
of norepinephrine, have been found to be significantly higher in symptomatic than in asymptomatic
postmenopausal women and increased significantly more during hot flushes. However, there is no
correlation between hot flush occurrence and plasma, urinary, or vaginal levels of estrogen, nor
are there differences in plasma levels between symptomatic and asymptomatic women [161].

Atrophic changes of the urogenital tract cause urgency, frequency, dysuria and predispose for urinary
tract infections [162,163] which could indirectly affect sexual function, or become consistently precipitated by intercourse.

Recommendations:

Lack of estrogen has been found related to dyspareunia and vaginal dryness. However, many
hypoestrogenic women do not have dyspareunia. When sufficiently sexually stimulated, low estrogen
may be irrelevant. An association between reduced estrogen and decreased sexual desire has been
only described clinically. There is some limited evidence to affirm that there is an association
between reduced vulvar sensitivity to pressure/touch and estrogen deficiency. GRADE B.

7. HORMONES AND SEXUAL RESPONSE:

The term “androgen” is applied to the class of C19 steroids, which are produced by the gonads and the
adrenals in both sexes from circulating low-density lipoprotein (LDL) cholesterol (a C27 molecule), and
include Testosterone (T), dehydroepiandrosterone (DHEA), dehydroepiandrosterone sulphate (DHEAS),
androstenedione (A4), and 5 α-dihydrotestosterone (DHT) [164,165]. Of the androgenic steroids, T and
DHT have the most potent biological activity. DHEA, DHEAS, and A4 are adrenal and ovarian precursor
steroids that can be metabolized into T, DHT, and estrogen in peripheral tissues [166,167].

To date, no nuclear or membrane receptor for DHEA
has been identified. DHEA exerts its effects via the androgen receptor (AR) and/or estrogen receptor
(ER) after its conversion to androgen or estrogen, although direct effects of DHEA on the AR (exerting
both agonistic and antagonistic effects) and ER (as

</table>
agonist) have also been demonstrated. Moreover, DHEA can act via non-steroid-receptor nongenomic pathways [168,169]. Androgens circulate in the body bound by a variety of proteins, including albumin, cortisol-binding globulin, α2-glycoprotein, and most importantly, sex hormone-binding globulin (SHBG). The affinity of androgens for SHBG is several orders of magnitude higher than that of albumin, and thus SHBG binds the largest portion of circulating testosterone. Androgens bound to SHBG are essentially not bioavailable; in contrast, androgens complexed to albumin are rather available due to their lower affinity. The liver produces SHBG—production which is stimulated by estrogen, particularly oral forms, and inhibited by androgens, and more importantly, insulin.

Androgen levels peak when women are in their 20’s and drop gradually with age, so that women in their 40’s have approximately half the level of circulating total testosterone as women in their 20’s. Testosterone levels do not decline consistently during or after menopause [170,171]. Androgens are known to act on multiple tissue and receptor sites, including the central nervous system pathways in the hypothalamus and limbic system, and peripheral sites such as bone, breast, pilosebaceous unit, skeletal muscle, adipose, and genital tissues [165].

The role of androgens in maintaining overall health, mood and sexual function has been the subject of research for more than 50 years, and its potential use in treating sexual problems of women is still under debate. This is covered in much more detail in Chapter 23. In 2002, a Consensus Conference on androgens agreed that androgen insufficiency in women with adequate estrogen levels could lead to a diminished sense of well-being and energy, fatigue, and decreased sexual desire [165]. The conference noted, however, that these symptoms were non-specific, and that there is lack of epidemiological data as well as limitations in laboratory assays to link these psychological changes to androgens. More recent guidelines from the Endocrine Society recommended against making a diagnosis of "androgen insufficiency", because of the lack of a well-defined clinical syndrome and normative data on testosterone levels across the lifespan that can be used to define such a disorder [172]. However, a panel of sexual medicine clinicians challenged the conclusions from the Endocrine Society Guidelines as ignoring some of the available data in support of androgen therapy [173] (Level 4).

As reviewed in Table 7, population-based studies have shown minimal or no correlation between androgen levels and sexuality in women. In the Melbourne Women’s Midlife Health Project, a representative sample of women from the general population was recruited and followed yearly during the menopausal transition. Fasting morning samples of estradiol, serum testosterone, SHBG, and DHEAS were taken along with a number of physical measurements at 2 year intervals. At their 9 year review, findings showed minimal change in testosterone levels measured in 438 women. Also, androgen levels did not correlate with any aspect of sexual functioning [150]. In the Study of Women’s Health Across the Nation (SWAN) [139], 2,961 pre-menopausal women aged 42-52 were recruited to participate in a longitudinal study that aimed, among other things, to characterize the reproductive hormone patterns of women as they approached and traversed menopause. DHEAS, T, and SHBG concentrations measured at baseline showed T to be minimally associated with increased desire (odds ratio=1.09) and very weak or no correlation between androgens and sexual function or mood. Another Australian study which included 1,021 women aged 18 to 75 found no correlation between T or A4 levels and sexual function but higher odds of low sexual responsiveness if DHEAS was less than the 10th percentile. Nevertheless, most women with low DHEAS levels did not report low sexual function [134].

The lack of accuracy of current assays to measure testosterone is a well known limitation [174]. Most clinically available assays are designed to measure testosterone in the male range or to identify hyperandrogenic states in women [175]. Tandem mass spectrometry methods in combination with gas chromatography or liquid chromatography have been developed for testosterone and are the methods of choice for the precise measurement of the low levels [176]. Unfortunately, these assays are not widely available in clinical settings. Recently, the Centers for Disease Control and Prevention, National Center for Environmental Health, Division of Laboratory Sciences (CDC/NCEH/DLS) have initiated a project to standardize and to improve steroid hormone measurements [177].

An additional aspect to consider here is the intracrinology of sex hormones. Steroidogenic enzymes are widely distributed in peripheral cells to convert adrenal DHEA, DHEAS and A4 (and for pre-menopausal women, also ovarian DHEA and A4) to T, DHT, estrone (E1) and estradiol (E2). This intracellular production is a major source of T and DHT, and is known to reduce by 80% through adult life. Active androgens, whether produced in a peripheral cell or stemming from the ovaries, are inactivated to glucuronide derivatives before their diffusion from the intracellular compartment into the general circulation (plasma), where they can be measured as the androgen metabolites, androstenedione glucuronide (ADT-G), 3α-diol-G and 3β-diol-G [178]. Although glucuronide derivatives, appeared as reliable markers of the total androgen pool, since they are the obligatory route of elimination of all androgen [179], a recent study comparing glucuronide derivatives levels in 121 women with sexual dysfunction vs. 124 controls, did not show a significant difference between the groups [180].

</table>

Over the last two decades it has become clear that the brain is a steroidogenic organ.

The steroids synthesized de novo by the brain and nervous system, given the name neurosteroids, have a wide variety of diverse functions [181]. In general, they do not mediate their actions through classic steroid hormone nuclear receptors, but through stimulation of rapid changes in excitability and direct activation of membrane receptors in neurons [182]. Current evidence in animals points to important roles for neurosteroids in sexual and gender-typical behaviors, control of ovulation, and behaviors that strongly influence sexual interest and motivation [182]. Sex steroid production and action within the brain may be more relevant to women’s sexual desire and function than peripheral androgens.

The great variability in the responsiveness of women to treatment with androgens is another confounding factor. For example, there are contradictory findings on the effects of the oral contraceptive pill on sexual interest. The former increases the concentration of SHBG thereby lowering the bioavailable testosterone [183-185]. A possible explanation could be the polymorphic variations of the androgen receptor (AR) gene. The AR gene is located on chromosome Xq11–12. A polymorphic polyglutamine stretch in the amino-terminal domain of the AR, encoded by the nucleotides cysteine, adenine, and guanine (CAG), appears to influence the function of the receptor. Long CAG repeat fragments have been associated with a low level of receptor function [186]. The polyglutamine region is assumed to be involved in interactions between the AR and different coactivators; recent data suggest that long repeat regions are inhibitory to these interactions, which could explain the lower activity of the receptor [187]. Although androgen receptor CAG repeat length has not been studied in regard to sexual function, its relation to dermatological, oncological, fertility and behavioral conditions has been established. Further elucidation of the genetic determinants for serum androgen activity could explain why some women are more sensitive to androgens than others [188].

** Recommendations: **

Although controversial, the majority of evidence fails to find a significant correlation between sexual desire and response and testosterone levels in women. There are significant limitations in this research: (i) the lack of standardized assays which are suitable for detecting androgens in the female range; (ii) the inability to quantify neurosteroid production and action, (iii) the current lack of understanding of the role of the androgen receptor gene polymorphism in the extent of serum androgen activity and (iv) the current lack of a clear definition of sexual desire and consensus about what constitutes sexual desire problems, Testosterone level measurements in women cannot be recommended until more accurate measures of androgenic activity emerge **GRADE B**

8. **SEX HORMONES AND NEUROTRANSMITTERS**

Fluctuations in estradiol levels during perimenopause have been linked to irritability, tearfulness, anxiety, depressed/labile mood, lack of motivation/energy, poor concentration and interrupted sleep [189]. Neurotransmitters and steroid hormones appear to have a modulatory function on each other, and changes in one system may have a dramatic effect on the other [190]. For instance, recent longitudinal data suggest that the transition to menopause is strongly associated with new onset depressed mood among women with no history of depression [191]. Clinical and experimental data in addition to new imaging techniques such as PET, SPECT, spectroscopy and functional and structural MRI have confirmed a large part of earlier animal studies: the major neurochemical systems involved in sexual behavior consist of pathways involving neurotransmitters and hormones including dopamine, serotonin, norepinephrine, prolactin, oxytocin, melancortins and endogenous opioids. Some of these substances are substantially influenced by gonadal steroid hormones and/or interact among each other [190,192]. In rodents, estrogen receptor type beta (ERβ) has been found in populations of gonadotropin-releasing hormone, corticotropin-releasing hormone, vasopressin, oxytocin and prolactin containing neurons in the hypothalamus [193]. As noted earlier, steroids may also act through stimulation of rapid changes in the neuron membrane excitability.

9. **AGE VERSUS MENOPAUSE IN PREDICTING SEXUAL PROBLEMS**

When exploring the influence of menopause on sexual response, separating age-related effects from hormonal changes can be difficult though it is essential. In the Melbourne Women’s Midlife Health Project, comparison between age-matched premenopausal and postmenopausal women showed that sexual desire and lubrication are affected by both menopause and aging, independently [150,152]. In a longitudinal study of 1,525 British women aged 47-54, independent effects of menopause and aging on sexual functioning were also found [194]. Health factors related to aging are known to affect sexuality. A study assessing 1,384 women and men older than 45 found that high blood pressure was linked to low sexual desire whereas diabetes, arthritis, and depression were not [195]. Age was strongly associated with a decline in desire but not for all women. In 22% of women with higher levels of desire, an association was found with the
belief that sexual activity is important for quality of life, disagreeing with the belief that “sex is only for younger people”, and the presence of a partner. In a multiple regression analysis, psychological variables were more predictive of desire than any biological factor [195]. The Global Study of Sexual Attitudes and Behaviors (GSSAB) conducted in 27,500 men and women aged 40-80 across 29 countries, found low sexual desire was related to age in women, and was associated with the belief that aging reduces sexual desire [50]. Reduced lubrication was also age-related but curvilinear in that symptoms decreased in the oldest cohort of women.

A 2003 review of all population-based studies exploring sexuality after menopause found that sexual problems were more common in older women, but more distressing for the younger cohorts [196]. This phenomenon (sexual problems greatest, but least distressing in older women) has been replicated in larger, more recent studies [31,197]. The Prevalence of Female Sexual Problems Associated with Distress and Determinants of Treatment Seeking Study (PRESIDE) was conducted in 31,581 US women aged 18 and older. Desire, arousal, and orgasm problems were found in 27.2% of women aged 18–44 years, compared with 44.6% of women aged 45-64, and 80.1% of 65 years or older, although the prevalence of having a distressing sexual problem was far less (10.8%, 14.8% and 8.9% respectively) [31].

**Recommendations:**

Teasing apart age-associated versus menopause associated contributions can be difficult although practitioners should make and effort to do so. Age and menopause are both significantly associated with desire and arousal problems in women, however, the presence of distress appears not to be. Whereas sexual complaints increase with age, the associated distress appears to diminish. Psychosocial aspects of aging and menopause contribute more to difficulties than hormonal contributions and should therefore be the focus of assessment and treatment **GRADE B.**

**10. SURGICAL MENOPAUSE AND DESIRE/AROUSAL COMPLAINTS**

The contribution of surgical (via bilateral salpingo-oophorectomy; BSO), as opposed to natural menopause, has been extensively studied but with inconsistent findings. The WISHes study recruited 4,517 women from France, Germany, Italy, the United Kingdom, and the USA [197,198] (Level 3). In this study, a greater proportion of surgically menopausal women had low sexual desire compared with age-matched premenopausal or naturally menopausal women. Surgically menopausal women aged 20 to 49 years were significantly more likely to experience distress about their condition. Of note, no subgroup analysis comparing estrogen-replete to non-estrogen-replete women was done. Another recent cross-sectional study assessed prevalence of low sexual desire with and without distress in 2,207 US women aged 30-70 [199]. The highest prevalence of low sexual desire was found in naturally menopausal women (52.4%) rather than surgically menopausal women (39.7%) when compared to premenopausal women (26.7%). Low desire plus distress (HSDD) was found to be nearly twice as prevalent among surgically menopausal women (12.5%) than in premenopausal women (6.8%), especially if women were younger than 45. Women receiving exogenous hormones were less likely to complain about low desire but had slightly more distress than women not using hormones (Level 3).

Prospective studies have not confirmed sexual dysfunction subsequent to surgical menopause for benign disease. Aziz et al. found no correlation between ovarian removal and reduced sexual function in a study of 362 perimenopausal women undergoing elective hysterectomy with and without BSO [200] (Level 2). In this study the women were evaluated for sexual function within 2 months before the surgery and one year after. Importantly, women were the ones who chose either to undergo BSO or not, after receiving information on its potential advantages and disadvantages (e.g., change in hormonal milieu with possible negative effects on sexuality and psychological well-being vs. prevention of ovarian cancer and avoidance of future surgery for benign adnexal mass). Teplin et al. prospectively compared sexual function among 112 premenopausal women who underwent hysterectomy with and without BSO. BSO was performed at the patients' request or to treat intraoperative ovarian pathology. Assessment was carried out at 4 weeks, 6 months, and 2 years after the surgery. There were no statistically significant differences in measures of sexual functioning between the groups at any follow-up visit [201] (Level 2). A more recent study collected data prospectively for 3 years from 257 women undergoing hysterectomy and 57 women undergoing hysterectomy with BSO. The proportion of sexually active women in either group after the surgery and the prevalence of vaginal dryness did not differ [409] (Level 2). No data on sexual desire or interest were presented.

**Conclusion:**

Distress associated with low desire, but not low desire per se, is most prevalent among surgically as opposed to naturally menopausal women. Among prospective trials of elective BSO, sexual function did not appear to differ from a control group. Sexual distress should always be assessed when there are complaints of low desire. **GRADE B**
11. DIAGNOSIS AND FORMULATION

On the basis of a thorough biopsychosocial assessment of partners individually and together (when available and possible), and the relevant physical, physiological, or hormonal assessments, the clinician determines a diagnosis and formulation of a woman’s sexual problem(s). Assessment does not end when treatment begins; emerging information continues to inform treatment, and outcomes from interventions may in turn modify the diagnosis and formulation. Patient rapport is facilitated if a cogent formulation is presented and explained to the patient. Historical details, direct observation of the couple, couple interactions and attitudes, and response to initial treatment interventions modulates the formulation. The initial formulation may well change as patient visits continue. With the publication of DSM-V in 2013, it is likely that diagnostic criteria may evolve even further [28].

The type, frequency, and severity of sexual complaints must be determined as well. Using the DSM-IV-TR system, one might apply a diagnosis of HSDD and/or FSAD. The recommended diagnoses and criteria set out by the AUAF (Table 1) offer an improvement over the DSM-IV-TR with less pathologizing diagnostic criteria. Some find it useful to include both diagnostic schema. With the publication of DSM-V in 2013, it is likely that diagnostic criteria may evolve even further [28].

Part of the formulation also includes relevant information from self-report questionnaires, interviews, and relevant physical or physiological examinations and testing. Graham and Bancroft describe a “three windows” approach helpful for contextualizing factors influencing the sexual complaint [202] (Level 3) (Figure 2). The first window describes aspects of the woman’s current situation, e.g., are poor communication, relationship difficulties, fatigue, or lack of privacy responsible for the desire or arousal concerns? The woman plagued with fatigue might benefit from a course of sleep hygiene therapy prior to (or instead of) sex therapy. In the second window, Graham and Bancroft suggest looking at individual vulnerability factors influencing the presentation of complaints. Does the woman display persistently negative attitudes about herself and her body? Does she have a high need to maintain control in all life and sexual situations? Is there a past history of sexual abuse or trauma such that flashbacks to the prior abuse are frequent and intrusive when she is attempting to be sexual? If such individual vulnerability factors are present, she may benefit from a cognitive behavioral (CBT) treatment focused on that vulnerability factor (e.g., Cognitive Processing therapy for sexual assault, CBT for perfectionism, etc). The third window invites the clinician to consider health-related factors influencing the sexual response. One aspect of this domain would include mental health, such as depression or anxiety. This window also explores physical health related factors, such as problems in the neural control of desire and arousal, problems in vascular supply to the genitals, endocrine dysfunction, and metabolic problems. The presence of any of these physical health related factors significantly impacts the formulation of the sexual complaint (as being due to a general medical condition). An important aspect of this third window includes the influence of both over-the-counter and prescription medications on sexual response. These ‘windows’ echo the descriptors recommended by the AUAF committee [41] and are depicted in Figure 2.

Although objective duration and severity criteria are not features of either the DSM-IV-TR or the AUAF systems of classification, such information can be a very useful adjunct in the formulation. The DSM-IV-TR text for HSDD indicates that “occasional problems with sexual desire that are not persistent or recurrent or are not accompanied by marked distress or interpersonal difficulty are not considered to meet criteria for HSDD” [1]. Notably, data on the required frequency or intensity of low desire for designating desire disorder and the specific duration of complaints have not been reported on in the empirical literature. In the FSFI [203] --the most commonly used self-report measure of sexual response in women--the desire domain is assessed as a composite of one question assessing the frequency of sexual desire and another question about the level (degree) of sexual desire (from very low to very high). Whether a reduction in sexual desire is experienced more often in terms of reduced frequency or reduced intensity, however, has never been empirically tested. It has been recommended that only problems lasting for a minimum of 6 months duration be considered for diagnosis [28,29,204]. This time duration was chosen given the finding of the NATSAL survey [49] that lack of interest in sex for the past one month was significantly more common (40.6%) than lack of interest lasting for six months (10.2%). Short term complaints that might be attributable to transient changes in the woman’s health or relationship should not be diagnosed as a sexual dysfunction. Whether the problem is lifelong or acquired and generalized versus situational can be coded as specifiers if one uses the traditional DSM-IV-TR classification scheme. However, in clinical practice, a sexually distressing problem that is only situational is rarely diagnosed as a dysfunction, although treatment of that problem might still take place (Level 4).

Recommendations:

A formulation of the diagnoses is recommended. The formulation integrates all information obtained from (sometimes a series of) assessments of the woman with and without a partner, and any relevant physical examinations, blood analyses, and self-report questionnaires completed. On the basis of the formulation, a diagnosis is applied, possibly using
both the DSM-IV-TR as well as the AUAF systems. The clinician also continues to modify the formulation as information emerges during treatment. The “three windows” approach can be very helpful for considering the many biopsychosocial factors that influence the woman’s sexual complaints. An effort should be made to determine the duration and severity of symptoms. **GRADE C**

**12. TREATMENT INGREDIENTS RELEVANT TO ALL SEXUAL PROBLEMS IN WOMEN**

General issues related to improved well-being, such as diet, exercise, possible alcohol and chemical substance abuse, and sleep should be addressed in all women. Advising on all prescription and non-prescription medications, vitamins and herbal supplements, and recreational drugs is important as well. Providing women relevant information on improving general health related to each of these domains may also be a component of care, and referral to appropriate medical or specialty providers may be necessary. The early stage of treatment might also include providing information on basic genital anatomy and physiology, and a discussion of sexual stimulation and sexual activities other than intercourse. Women should be encouraged to use techniques that enhance arousal, including enhancing the context within which her sexuality is expressed and the stimuli she receives. **GRADE C**

**III. ISSUES SPECIFIC TO LOSS OF DESIRE**

**1. BIOLOGICAL ASPECTS OF LOW SEXUAL DESIRE AND LOW SUBJECTIVE AROUSAL**

The biology of desire and subjective arousal is not yet well known and understood. It seems that the instinctual part is rooted in thalamic, hypothalamic and limbic brain regions. Sexual desire may be conceived of as being connected to other basic emotional systems like fear-anxiety, in that it is a highly adaptive response to an emotionally competent stimulus [205] (Level 4). In this perspective, the subjective experience of desire may be the conscious awareness of the automatically generated bodily responses to the stimulus (i.e., arousal) which produces the sensation of “wanting” [206] (Level 4). The subjectively experienced state of desire may thus be the final result of a complex interplay of driving and inhibiting forces [207] (Level 4). The biological factors mentioned below may hamper responses to “sexually competent stimuli”. The most important neurotransmitters involved in desire and subjective arousal are norepinephrine, dopamine, melanocortins, oxytocin, serotonin acting via 5 HT_{1A} and 5 HT_{2C} receptors—being prosexual, and prolactin, GABA and serotonin acting via other receptors—being inhibitory or negative [46] (Level 4). The actions of
these substances are modified and influenced by the endocrine milieu provided by estrogen, progesterone and testosterone (Level 4). Here we briefly consider the influence of chronic disease, the postpartum, and oral contraceptives on sexual desire.

Chronic diseases may have an important negative impact especially on desire and arousal, and are covered more thoroughly in Chapter 9. The mechanisms involved can be separated into biological changes that interfere directly with the physiology of the central and peripheral sexual response on the one hand, and the psychological consequences of being ill (coping with the illness, depressive reaction etc.) on the other [208] (Level 2 and Level 3). The chronic conditions listed in Table 8 have been found to be positively correlated with the incidence of HSDD. Table 9 provides recommendations for assessment questions specific to the sexual complaints among women with chronic disease.

Research suggests that a woman’s interest in sexual relations changes after childbirth; 47-57% of women interviewed at three months postpartum noted a decreased sexual interest. Lower libido has been attributed to fatigue, pain, and concern over injury. Despite any potential changes in desire, more than 80% of women resume coitus by six weeks postpartum [209] highlighting the disconnect between sexual desire and sexual activity frequency.

Combined oral contraceptives containing ethinylestradiol increase SHBG and thus decrease available free testosterone. This has been purported to contribute to a lack of desire and subjective arousability [210] (Level 3). Due to the fact that oral contraceptives display manifold psychological and biological actions, some of which may have a positive impact on sexuality (reduce anxiety about unwanted pregnancy, diminish dysmenorrhea, attenuate acne etc.), it is very difficult to discern the clinical effect of the diminution of free testosterone in users of oral contraceptives [211] (Level 3).

2. PSYCHOLOGICAL ASPECTS OF LOW SEXUAL DESIRE AND SUBJECTIVE SEXUAL AROUSAL DISORDER

A woman’s sense of personal well-being is important to sexual desire. Low perceived levels of physical and emotional satisfaction and a sense of unhappiness correlate with low sexual desire [31,33,46,212] (Level 3).

Psychological factors may contribute to desire and subjective arousal in manifold ways, including motivational and cognitive pathways. The motivation to engage in sexual activity may be the wish to be emotionally close to the partner, to satisfy the partner, to feel feminine, to feel powerful and accepted [26]. Cognitive pathways refer to the meaning given to the sexual activity which implies previous experiences provided by episodic memory. There are many factors that may have a negative impact on motivation and cognition.

There is very little evidence-based research in this field. The observations about facilitating and impeding factors for the development of sexual health are mainly theoretical, clinical and anecdotal. The most frequent applied research methodologies in this field are correlational and ecological studies.

Some major groups of predisposing factors have been found to be clinically relevant for desire and arousal difficulties and these include:

a) Sexual abuse and emotional neglect in childhood:

Several studies have shown variable midterm and long-term effects on the female adult’s sexuality after childhood abuse and neglect. One of the possible sequelae is low desire and sexual aversion [213-219] (Level 2 and 3).

b) Traumatic experiences during puberty:

Research among adolescents has shown that first negative sexual experiences and especially humiliation and offense may have long-term consequences for the internal sexual script which determines positive and negative attributions to one’s sexual life [220] (Level 3).

Other psychological factors may act as predisposing and maintaining factors:

a) Perceived stress:

Some observational studies have shown that psychosocial stress in general may reduce the motivation to become sexually active. Apart from cognitive processes there may be an incremental effect of a stress induced cortisol secretion [31,221] (Level 3). There is one experimental study on the effect of (acute and chronic) psychological stressors on genital and subjective sexual arousal [222]. To investigate whether psychological stressors inhibit sexual responding, sexually functional women were randomly assigned to an experimental condition in which acute psychological stress was induced by a frustrating computer task or to a control condition. After the acute psychological stress or control induction women were exposed to an erotic stimulus. Genital sexual arousal was assessed with VPA. Women in the acute stress condition responded with lower levels of genital and subjective sexual arousal to an erotic stimulus than women in the control condition. Women were post hoc divided into a ‘low’ and a ‘high’ chronic stress group, based on their pre-assessment scores on a chronic daily stress questionnaire. Those with high levels of chronic stress responded with lower levels of genital sexual arousal to an erotic stimulus than women with low levels of chronic stress. Chronic stress did not affect the level of subjective sexual arousal (Level 3).

</table>
b) Distraction/Attention:
Distraction has been shown to be detrimental to female sexual arousal, especially subjective arousal and desire [91,223,224] (Level 3). Attention has been investigated as it relates to sexual arousal. In two subgroups, which were differentiated on the basis of their initial preconscious attentional bias for sexual cues, a different sexual response profile was found. In an initially low-attention group, preconscious attentional bias for sexual cues increased under a testosterone condition. In these women, the combination of supra physiological testosterone and vardenafil caused an improvement in genital response and subjective indices of sexual functioning. In the group that had initially a high attention for sexual cues, preconscious attentional bias for sexual cues decreased under the condition of testosterone. In these women, the combination of testosterone and vardenafil had no effect on any of the indices of their sexual functioning [225] (Level 3). An earlier pilot study found similar results [226] (Level 3).

c) Self-focused attention:
Self-focused attention may negatively impact genital and subjective sexual arousal. In a recent study, state self-focus was induced by switching on a TV camera that pointed at the participant’s face and upper torso in sexually functional women. Induction of state self-focus per se did not affect genital responses, but an interaction effect between self-focus and participants’ level of trait sexual self-focus was revealed. Compared with women with low scores on this trait, women with high scores exhibited smaller genital responses when state self-focus was induced. Both groups did not differ when no self-focus was induced. Increase of state self-focus did not affect subjective sexual arousal, but participants with a high level of trait sexual self-focus reported stronger subjective arousal, compared with those with low trait level [227] (Level 3).

d) Anxiety:
The model of performance anxiety was largely derived from male patients with erectile dysfunction. For women sexual performance concerns have a different focus because the signs of sexual arousal are less publicly evident. For women there is a large array of sexual concerns (worries about pleasing her partner, fear of partner rejection, fear of pregnancy and STI, unease related to the ability

Note: This information is covered more fully in Chapter 9.
to reach orgasm) that may interrupt her experience of sexual desire [228] (Level 3). Anxiety has been conceptualized as consisting of a chronic somatic component of overactivation, a cognitive component focusing on perceived lack of control, and a shift of attention to internal somatic cues. In terms of the subjective experience, anxiety can be characterized as a condition of anxious apprehension [229] (Level 3). Research examining the role of anxiety in sexual dysfunction has included both clinical studies and controlled laboratory investigations. Early psychodynamic theories placed a heavy emphasis on anxiety as an important etiological predictor of sexual dysfunction. In Kaplan’s influential model of etiology [230], performance anxiety was both a consequence of sexual activity, and a cause of sexual dysfunction, and reflected the failure of psychic defenses to prevent the emergence of anxiety (Level 4). Based completely on clinical experience, anxiety and sexual arousal were thought to be incompatible with each other. The empirical literature, however, suggests such conclusions to be overly simplistic.

The role of anxiety as a key etiological agent in the genesis of sexual disorders has been highlighted in a number of clinical research studies. One review found high levels of anxiety in sexually dysfunctional individuals [231] (Level 2) however, there was a high degree of variability in the amount and quality of anxiety across individuals with different sexual disorders [232,233] (Levels 2 and 3). Sexual aversion tends to correlate highly with acute anxiety [234] (Level 3). More recent studies on women with general sexual dysfunction [235], (Level 2) as well as those with low sexual desire [236], find higher rates of depression and anxiety compared to sexually healthy women (Level 3). Worry, on the other hand, while it is associated with many psychiatric disorders and especially anxiety, did not appear to be a risk factor for sexual desire [237] (Level 3).

Whereas most of the research examining the relationship between anxiety and sexuality has explored anxiety in women with sexual dysfunction, some research has looked at sexuality in men with anxiety disorders. The literature suggests a higher incidence of sexual difficulties in women with anxiety disorders compared to non-anxious women. For example, women with panic disorder [238,239] and obsessive compulsive disorder [239] show lower sexual desire than healthy controls (Level 2). Women with OCD are more likely to experience sexual difficulties, in particular avoidance of sexual activity, than women with generalized anxiety [240] (Level 2). Social anxiety has also received attention as it relates to sexual function. Compared to women with panic disorder, a small retrospective study found that those with social phobia have more difficulties with orgasm than sexual aversion [241] (Level 3). However, in a very large sample of college students [242], as well as in a clinical sample of 40 socially phobic women [243] social anxiety was very strongly related to sexual difficulties, fewer sexual partners, and greater unhappiness in sexual encounters (Level 2). Looking at the causal relationship of panic disorder and sexual dysfunction, data indicate that there is either a coincidence of panic syndrome and sexual phobia/aversion or, more often, a panic experience during sexual arousal. The results tend to confirm hypotheses claiming that sexual phobics with panic syndrome are not really afraid of sexuality, but rather of panicking and losing control [244]. Van den Hout and Barlow (2000) reviewed the empirical literature on sexual disorders and anxiety disorders. In general they found that anxious patients tend to selectively attend towards perceived threat whereas patients with sexual dysfunction focus their attention away from relevant cues [245] (Level 2).

The notion that anxiety is associated with sexual dysfunction has been challenged by a number of well-controlled laboratory investigations. Different techniques for manipulating and inducing anxiety have been explored, and sexual arousal has been assessed by both subjective (e.g., self-report questionnaire) and psychophysiological (e.g. vaginal photoplethysmograph) techniques. In sexually healthy women, anxiety-inducing techniques have been found to significantly increase psychophysiological sexual arousal [246-249] (Level 2). Anxiety’s mechanism of action may be via increased sympathetic nervous system (SNS) activity given that exercise [250] and other methods of SNS-facilitation [251] enhance physiological sexual arousal (Level 2). This explanation of the above findings was recently challenged by Bancroft [252] (Level 3), who argued that sexual arousal is the result of a complex interaction of sympathetic and parasympathetic processes, varying according to the response being controlled and the part of the body affected. The Meston et al. findings may be better explained by ‘excitation transfer’ [253]. Subjective sexual arousal, however, has been shown to be increased [246], decreased [248], and unaffected [92,250,251] by these techniques (Level 2). In women with heterogeneous sexual difficulties, anxiety significantly improved genital sexual congestion [248,249,254] (Level 2).

e) Depression:

DeRogatis and colleagues administered the Symptom Check-List Revised 90 (SCL-90R) to 325 male and female outpatients seeking treatment for sexual dysfunction [255] (Level 3). Of the 126 women, 50% were assigned a psychiatric diagnosis. Specifically, major depression was found to be a feature of women with FOD and sexual pain disorder. In an older study, women with impaired sexual de-
sire were compared to sexually healthy controls on current and lifetime affective symptoms [256] (Level 2). Although no patient met criteria for major depression at study entry, women with impaired desire were twice as likely as controls to have a history of major depressive disorder. Interestingly, the major depressive episode always either coincided with or preceded the sexual dysfunction onset.

Compared to the literature on anxiety and sexual function, a strong and clear relationship exists between depressed mood and sexual dysfunction in women. However, the literature on sexual function of depressed individuals is complicated by the influence of antidepressant medications. However, in a detailed review of the literature, it was concluded that loss of desire is a consistent consequence of major depression, regardless of antidepressant use [257] (Level 2). In older studies, sexual desire was found to be associated with depression in Finnish women in their 60s [258] and with Bipolar disorder [259] (Level 3). Most recently, Kennedy and colleagues examined a consecutive series of 79 women with Major Depression and found that half the sample experienced problems with sexual desire and arousal [260] (Level 3). Frohlich and Meston compared depressed to nondepressed college women using the Beck Depression Inventory. The depressed group showed higher rates of desire for sexual activity alone, despite more problematic sexual arousal, orgasm, pain, satisfaction, and pleasure. This novel finding was explained by the speculation that masturbation may reflect a reliable form of pleasure compared to partnered sexual activity [261] (Level 2).

Given the retrospective design in the studies reviewed, it is difficult to determine the order of causality, however, some have speculated that depression may play a causal role in the development of female sexual dysfunction. Even in the absence of a diagnosis of Major Depressive Disorder, women with HSDD are more likely to have a “vulnerable self-system” characterized by more depressed thoughts and lower self esteem compared to controls [262] (Level 3).

f) Personality variables:

Some authors have speculated that mood or affect-related difficulties are deep-rooted as opposed to acute reactions to the sexual difficulty. Women with histrionic personality disorder were compared to non-histrionic women and were found to have significantly lower sexual assertiveness, greater erotophobic attitudes toward sex, lower self-esteem, and greater marital dissatisfaction [263] (Level 2). Despite lower sexual desire, more sexual boredom, and greater orgasmic dysfunction, this group displayed higher sexual esteem and increased likelihood of entering into an extramarital affair compared to non-histrionic women. Women with borderline personality disorder show a similar pattern in that despite sexual depression and dissatisfaction, there were higher rates of sexual esteem and sexual assertiveness compared to non-borderline personality disorder women [264] (Level 2). Sensation seeking, a characteristic of individuals with narcissistic personality, has been found to be related to increased sexual desire and arousability, but is not associated with marital or sexual satisfaction [265] (Level 2). In an extensive review which included individual differences pertaining to women’s sexuality, Andersen and Cyranowski [266] report that developmental factors are important to consider when examining the relationship between personality and sexuality. Specifically, older women seeking treatment for mixed sexual dysfunctions had higher Neuroticism scores [267] whereas in younger women, the trait of Extraversion was more prominent [268] (Level 2).

From the available literature it is apparent that personality features of low/fragile self-regulation and self-esteem, as well as histrionic personality relate to impaired sexual desire. Cluster B traits of histrionic and borderline personality are associated with increased sexual esteem, despite impaired sexual desire and dissatisfaction. Additionally, developmental factors must be taken into account when considering the role of personality in women’s sexual function and dysfunction.

g) Body image self-consciousness:

Body image self-consciousness has negative effects on female sexual function, above and beyond actual body size or general body image dissatisfaction [269,270] (Level 3). In the laboratory setting, desire in response to viewing erotic stimuli was positively correlated with higher body esteem [271] (Level 2). Interestingly, inducing a state of increased body awareness while exposed to a sexual stimulus resulted in significant enhancement of physiological and subjective sexual arousal [272] (Level 2). Another recent study in 320 men and women found that body concerns negatively affect sexual pleasure and promote sexual problems [273] (Level 2). Women were significantly more likely to report appearance concerns than men across sexual and non-sexual contexts. The relationship between body shame and sexual pleasure and problems was mediated by sexual self-consciousness during physical intimacy, that is, body shame was related to greater sexual self-consciousness, which in turn predicted lower sexual pleasure and sexual arousability.

Recommendations:

Screening for and treatment of anxiety disorders is recommended. Overall, the empirical results provide evidence of a significant relationship between anxiety and sexual difficulties. Sexual disorders including impaired arousal, desire and satisfaction are common complications of various anxiety
disorders. A strong and clear relationship exists between depressed mood and sexual dysfunction in women, although it is difficult to determine the order of causality. Given that personality factors (i.e., trait of an individual) are much less amenable to change than psychological reactions (i.e., state of an individual), assessment of personality as it might influence sexual health is important but there may be limits to what the clinician can do in terms of improving these aspects of the woman’s personality disposition. Body concerns are found to have negative effects on sexual function in women and should be assessed. **GRADE C**

### h) Relationship factors

Evidence based research about relationship factors contributing to desire and arousal concerns is scant, but clinical experience and correlational studies show a close link between relationship and sexual satisfaction, although there is not a strict interdependence (both domains can operate independently meaning that couples with a good quality of their relationship may have severe sexual problems and couples with marital difficulties may function sexually in a positive way).

Another difficulty in the clinical evaluation of relationship factors is the question about cause and effect. Sexual dissatisfaction which leads to relationship problems or couple maladjustment then leads to sexual dysfunction. Additionally in some couples one problem may be unconsciously used to "resolve" or "disguise" another problem, which is experienced as even more threatening than the sexual dysfunction [274] (Level 4). There is a strong association between sexual function/satisfaction and feelings for a partner [33,275].

1. **Partner’s sexual dysfunction:**

A considerable number of studies have shown that sexual dysfunction of the male partner, especially erectile dysfunction and premature ejaculation have a negative impact on the female partner’s sexual desire [276] (Level 2 and 3) and successfully addressing the former restores the woman’s sexual quality of life [277] (Level 2). However, there are also qualitative data showing women’s dissatisfaction with not being involved in treatment decision making when their male partner’s sought treatment for erectile difficulties, and that they would have welcomed a couple approach that equally emphasized her own sexuality and pleasure [278]. A medically-induced erection has also been found to lead to resistance in some women as it is perceived that the erection is unrelated to her partner’s desire for her [279].

2. **Duration of the relationship and routine:**

Some community surveys have shown that the duration of relationship is inversely correlated to sexual desire and arousal [280] (Level 3).

3. **Global dissatisfaction with the relationship:**

Compared to women without HSDD, women with HSDD report poorer dyadic adjustment, greater dissatisfaction with conflict resolution in their relationship, and less attraction to and emotional closeness with their partners. Furthermore these women found that relationship factors were major contributors to their sexual desire problems [280] (Level 3).

4. **Communication deficits:**

Difficulties expressing sexual needs, wishes and fears between partners are frequently an immediate and direct factor which impacts negatively on the woman’s desire to engage in sexual activity. Men seem to have more inhibitions to talk about emotional and sexual issues [281-283] (Level 2 and 3).

5. **Cultural issues:**

Sexual desire is significantly lower in East Asian compared to Euro-Candian/American samples, and increasing acculturation to the mainstream culture is associated with higher levels of sexual desire [284-286]. This relationship between culture and sexual desire appears to be mediated by sexual guilt [287] in that the link between being an East Asian woman and having lower sexual desire is mediated by higher levels of sex guilt. Moreover, as sexual desire increases with increasing westernization, there is a concomitant decline in sex guilt (Level 3). The extent to which these findings apply to other ethno/cultural groups remains to be determined.

**Recommendations:**

The above mentioned biological and psychosocial factors have been discussed as separate entities. In clinical practice they usually interact in the individual patient with HSDD and FSAD and it is the task of the clinician to disentangle these factors, assess their pathogenetic importance and their accessibility to change. A biopsychosocial approach, advocated by many experts is recommended. In this approach (see **Table 4**) the factors are grouped into biological, psychosexual, and contextual, and are subdivided along a timeline in predisposing, precipitating, and maintaining considerations. A fuller diagnostic workup using this model is likely to help clinicians to come to a further understanding of the patient’s desire and arousal difficulties. **GRADE C**

3. **Treatment issues specific to low desire**

The general lifestyle approaches to improving sexual desire (e.g., diet, sleep, appropriate exercise, improved general health) as well as psychoeducation on the normality of age- and relationship duration-associated declines in sexual drive are a logi-
cal first step in treating the woman with distressing low sexual desire. Using a circular model of women's sexual desire that emphasizes the responsive nature of women's desire (Figure 1), the clinician provides psychoeducation and explains our current understanding of how desire is triggered [131]. That women provide a variety of reasons and incentives for engaging in sexuality is also emphasized [25-26]. Encouraging women to consider their own reasons for sexual activity and challenging their belief that “sex should only happen when I am ’in the mood’” can be therapeutic. For women with a DSM-IV-TR diagnosis of HSDD but who retain the ability to become sexually excited during the sexual encounter, this process of discussing incentives for sexual activity is especially important [288]. For some women, these steps are sufficient for improving their sexual desire and sexual well-being (Level 4). For other women, however, more intensive strategies will be required. These can be divided into: psychosexual, hormonal, and non-hormonal medications.

a) Psychosexual treatments for low desire

Unfortunately there have been very few psychological outcome studies of treatments focusing specifically on low desire. When the low desire is better accounted for by depression, poor body image, sexual assault sequelae, or other more general personality or relationship factors, then those factors must be addressed either in conjunction or before the low desire itself is targeted.

CBT is an extremely versatile treatment modality used across a variety of psychological conditions. It is based on the theory which states that thoughts, feelings, and behaviors interact and mutually influence one another. By targeting negative or maladaptive thoughts, both behaviors and affect will improve. The behavioral component includes attending to a problematic sexual context or behaviours in either partner which reduce attractiveness or trust and ability to focus on the sexual stimuli and feelings. The cognitive component of CBT targets maladaptive thoughts that foster negative emotions and maintain problematic behavior such as avoidance. This may include identifying and challenging beliefs that she is unattractive, idealizing an unrealistic mode of sexual response portrayed by media, or challenging beliefs that unless she feels a high level of desire all the time, then she is dysfunctional. Group CBT improves sexual desire disorder in 74% of couples and this effect was maintained in 64% at one year [289] (Level 2). A modified Masters and Johnson sex therapy was also found to improve sexual function in 57% of women with sexual desire disorder [290] (Level 3). Other psychological modalities have also been investigated and may target more distant factors in the woman's history such as unresolved themes from childhood including abuse or neglect, control issues, low sexual self image. There has been only one published study utilizing such an approach, however, there was a benefit to sexual desire in women [291] (Level 3).

More traditional sex therapy approaches, with their origins in the work of Masters and Johnson [292] and Kaplan [293,294] have also been studied. This includes sensate focus exercises consisting of exchanging physical touch, moving from non sexual to sexual areas of the body, with partners taking turns and giving feedback. Among the very limited available empirical literature, one study showed that 65% of 365 married couples improved by clinical judgment at the end of therapy [295] (Level 3).

Most recently, a mindfulness-based CBT administered to women with mixed HSDD and FSAD has also been explored in an uncontrolled trial. Mindfulness is an eastern practice with roots in Buddhist meditation which focuses on present moment, non-judgmental awareness. Women were taught in-session mindfulness exercises and encouraged to practice approximately 5 hours every 2 weeks of mindfulness between sessions. A mindfulness-based CBT administered in group format to women with HSDD and FSAD resulted in significant improvements in sexual desire and many other domains of sexual response and mood [296] (Level 3).

Recommendation:

Psychological approaches to low desire have a long history and have been found to be effective immediately after treatment with sustained improvements over time. Moreover, they are without adverse side effects. Newer cognitive-behavioural treatments which integrate mindfulness meditation have shown excellent promise for sexual desire problems but await randomized controlled testing. There is also evidence that brief cognitive behavioural interventions are helpful for improving desire. Overall there is an urgent need for more randomized controlled investigations of psychological therapy for low desire in women.

GRADE C

b) Hormonal treatments for low desire

Testosterone has been used in the treatment of low sexual desire since the 1930s; however, systematic study of it is only relatively recent. This topic is covered more thoroughly in Chapter 23. Briefly, although the US Food and Drug Administration has not approved testosterone for this purpose, it is commonly prescribed off-label, despite recommendations against doing so by the American Endocrine Society (due to lack of long-term safety data). Studies in surgically menopausal estrogen-replete women who reported a decline in their desire for sex since BSO have found, in general, a benefit of testosterone administered via a 300µg/day patch,
but no significant beneficial effect of either 150 µg/day or 450 µg/day compared to placebo [297-299] (Level 2). Similar effects were found among naturally menopausal, estrogen replete women [300].

A review of testosterone trials among estrogen replete surgically and naturally menopausal women found that those women receiving the 300 µg/day patch reported an increase in sexually satisfying events of 1.9 per month. Interestingly, a significant benefit was also found across placebo groups of approximately 0.9 events per month [301]. Among 814 naturally and surgically postmenopausal women with HSDD and not receiving estrogen, there was a significant beneficial effect of 300 µg/day patch, but not of 150 µg/day patch on sexually satisfying events. When natural versus surgical menopausal women were compared, this beneficial effect was only seen in the naturally menopausal women. Both testosterone doses produced a significant increase in desire for sex, above placebo. Importantly, 30% of the testosterone group experienced androgenic side effects, and there were 4 new cases of breast cancer in the testosterone but not placebo group [302]. In contrast, among estrogen-deplete cancer survivors with HSDD, testosterone treatment was found to be without benefit on any measure of sexual response or activity [303].

Most recently, testosterone among premenopausal, estrogen-replete women has been studied. When 260 premenopausal women (aged 35-46yrs) with HSDD were given a transdermal testosterone spray for 16 weeks (or placebo), only the 90 microL spray (the middle dose used) led to a significant increase in sexually satisfying events over placebo [304]. In addition, the level of free testosterone was supraphysiological in the majority of women. Notably, in all of these testosterone trials, a strict entry criterion was a certain baseline frequency of sexual activity and most women experienced 2-3 sexually satisfying episodes per month. Compared to the majority of women seeking treatment for sexual difficulties, where sexual frequency may take place on a once every several month basis, women recruited for research trials have a much higher level of sexual response and frequency. It is unknown if testosterone therapy would be of benefit to the large majority of women seeking treatment for sexual desire concerns.

Despite its lack of approval, many women seek out testosterone therapy for problematic low desire. In such instances, the clinician and patient should engage in a careful discussion of the benefits and hazards of such treatment. In light of the finding of increased prevalence of breast cancer when estrogen-depleted menopausal women are receiving testosterone [302], an informed discussion about the potential risk of breast cancer must take place. This is especially important given the finding in an epidemiological review that endogenous androgen levels are associated with risk for breast cancer [305] (Level 2). This area is open to debate given that there has been another study showing antiproliferative effects of testosterone [306]. Other risks of testosterone therapy include the link with cardiovascular health. Estrogen is required with testosterone administration given that women with high endogenous testosterone-to-estrogen ratios have more cardiovascular disease and insulin resistance [307,308] (Level 3) although estrogen use is also not without risks [309] (Level 1).

The androgenic, progestogenic, and estrogenic synthetic hormone, tibolone, is available in Europe and has been investigated in a Dutch study of women with various sexual complaints. Scores on the FSFI among the sample of 400 women were lowest for the desire domain suggesting that many of them may have met criteria for HSDD. Twenty-four weeks of tibolone resulted in a significant increase in all scores on the FSFI and there were no differences from women treated with combined transdermal estradiol/norethisterone (50 µg/140 µg) [310] (Level 1). An earlier placebo-controlled cross-over study in 38 Dutch postmenopausal women, heterogeneous with respect to sexual functioning, found that tibolone 2.5 mg/day was associated with significant increases in sexual desire, and the frequency of arousability and sexual fantasies compared with placebo [93] (Level 1).

Vaginal lubrication was significantly improved on tibolone. In addition, tibolone significantly increased baseline VPA levels and VPA response to sexual fantasy but not to visual stimulation, suggesting two possible pathways of sexual response (an androgen-dependent and an androgen-independent pathway). A recent study found that tibolone increases the risk of recurrence in breast cancer patients (HR 1.44), while relieving vasomotor symptoms and preventing bone loss [311] (Level 1).

**Recommendations:**

Testosterone therapy is effective for estrogen-replete naturally menopausal women, and marginally effective for premenopausal women, though it produces supraphysiological levels in the latter. Among estrogen-depleted women, there are conflicting data with no effect among cancer survivors with HSDD but a positive effect among menopausal women without cancer. The long-term risks of testosterone therapy on breast cancer, insulin resistance, and metabolic syndrome are unknown,
so a careful discussion with patients evaluating the potential hazards must take place before any testosterone supplementation is considered. Because positive studies of testosterone have required women to be engaging in sexually satisfying events 2-3 times per month, the efficacy of testosterone on women in the larger population of treatment-seekers is unknown. Future research should aim to use stricter inclusion criteria for low desire. GRADE B.

c) Non-hormonal medications for low desire

Non-hormonal medications that have been investigated for low sexual desire have typically had a mechanism of action that was centrally-acting. In non-depressed women with HSDD, the antidepressant bupropion, which blocks norepinephrine and dopamine reuptake, was found to significantly improve sexual arousal and orgasm, but not sexual desire [312] (Level 2). In women with SSRI-associated mixed sexual symptoms, 4 weeks of treatment with the addition of bupropion led to a significant increase in self-reported feelings of desire and sexual activity, but no significant effect on sexual thoughts [313] (Level 1). The most recently investigated of the centrally-acting agents for HSDD has been fibanserin. Fibanserin's mechanism of action is not yet fully understood but it acts as a 5-HT1A serotonin receptor agonist and 5-HT2A serotonin receptor antagonist. At present, no peer-reviewed publications concerning efficacy of fibanserin on women's sexual desire are available, but results of three large US and European RCTs with fibanserin 100mg taken daily were made public at the European Society of Sexual Medicine annual meeting in November 2009 and summarized at the Boehringer Ingelheim website[314] (level1). Of note, Boehringer Ingelheim categorizes HSDD as a medical disease, but unclear is how it was established that the complaints were of medical etiology and not resulting from other sources. The primary endpoint was frequency of satisfying sexual events(SSE) following 24 weeks of treatment, or the number of sexual events (defined as sexual intercourse, oral sex, masturbation or genital stimulation by the partner) which were satisfying for the woman (i.e. gratifying, fulfilling, satisfactory and/or successful), irrespective of whether women had an orgasm or whether the event was satisfying for the partner. The pooled analysis of 1,378 premenopausal US women showed a statistically significant increase in the frequency of SSEs in women taking fibanserin (from 2.8 at baseline to 4.5), versus placebo (2.7 at baseline increasing to 3.7), an increase in the FSFI total score and a reduction in FSDS-R sexual distress. An analysis of the 634 premenopausal European women showed women taking fibanserin 100mg had statistically significant improvements in their level of sexual desire as measured by the eDiary and a reduction in FSDS-R sexual distress but not significant change in SSEs. Most adverse drug reactions with fibanserin 100mg were mild to moderate and included dizziness, nausea, fatigue, somnolence and insomnia. Given that fibanserin's mechanism of action is not understood, it is as yet unclear which women, in the long run, may or may not benefit from its use, whether long term use will prove to be safe, and whether, on a long term basis, fibanserin is the best treatment for women with no/low sexual desire.

Recommendation:

Centrally acting agents show promise for targeting low desire in women but published RCTs are required and an evaluation of their safety remains to be studied. GRADE A

IV. ISSUES SPECIFIC TO LOSS OF AROUSAL

1. COMPONENTS OF SEXUAL AROUSAL, INCLUDING PSYCHOPHYSIOLOGICAL MEASUREMENT

An ideal protocol for the assessment of FSAD should be constructed following theoretical and factual knowledge of the physiological, psychophysiological, and psychological mechanisms involved. The protocol would describe the most parsimonious route from presentation of complaints to effective therapy. Unfortunately, we are at present far from a consensus on the most probable causes of FSAD. Despite this disagreement, at least two diagnostic procedures should be considered. Firstly, assessment of sexual dysfunction in a biopsychosocial context should start with a verification of the chief complaints in a clinical interview. The aim of the clinical interview is to gather information concerning current sexual functioning, onset of the sexual complaint, the context in which the difficulties occur, and psychological issues that may serve as etiological or maintaining factors for the sexual problems, such as depression, anxiety, and personality factors, negative self- and body image, feelings of shame or guilt that may result from religious taboos. Sexual problems are common complications of anxiety disorders and impair sexual desire, arousal and satisfaction. Laboratory studies suggest potential enhancement of genital arousal by some types of anxiety, but the precise cognitive, affective, or physiological processes by which anxiety and women's sexual function are related have as yet to be identified [46]. The ongoing work of Bancroft and colleagues exploring a dual control model of sexual excitation and inhibition in men as well as in women, may clarify the role of anxiety in women's predisposition to sexual inhibition and to sexual excitation [315]. Like men, in women close to normal distributions of sexual inhibition...
and excitation are found. Such distributions lend support to the idea that variation in excitation and inhibition proneness is normal, and that the midpoint of the range represents adaptive levels of inhibition. There is some suggestion that sexual inhibition is associated with difficulty experiencing orgasm [6], evidence that would fit their basic inhibitory model. However, this study involved a nonclinical sample of women; future research should involve clinical samples of women.

One of the most important but difficult tasks is to assess whether inadequate sexual stimulation is underlying the sexual problems, which requires detailed probing of (a variety of) sexual activities, conditions under which sexual activity takes place, prior sexual functioning and sexual and emotional feelings for the partner. Several studies have shown that negative sexual and emotional feelings for the partner are among the best predictors for sexual problems [33,316]. The clinician should always ask if the woman has ever experienced sexual abuse, as this may seriously affect sexual functioning [217-219] (Level 2 and 3). Some women do not feel sufficiently safe during the initial interview to reveal such experiences; nevertheless, it is necessary to inquire about sexual abuse to make clear that traumatic sexual experiences can be discussed. The initial clinical interview should help the clinician in formulating the problem and in deciding what treatment is indicated. An important issue is the agreement between therapist and patient about the formulation of the problem and the nature of the treatment. To reach a decision to accept treatment, the patient needs to be properly informed about what the diagnosis and the treatment involve.

If psychophysiological tools are available (although these are typically reserved for the research setting), observation of the genital arousal response to adequate stimulation by means of audiovisual, cognitive (fantasy) and/or vibrotactile stimuli, may be useful. However, it is important to note that this often does not correlate with the woman’s subjective report of (impaired) sexual arousal. Although psychophysiological testing to date is not a routine assessment, such a test may be crucial in establishing the etiology of FSAD for two reasons. A recent study by Laan and colleagues demonstrated how difficult it is to rule out that sexual arousal problems are not caused by a lack of adequate sexual stimulation [44]. In addition, they showed that impaired genital response cannot be assessed on the basis of an anamnestic interview. Women with sexual arousal disorder may be less aware of their own genital changes, with which they lack adequate proprioceptive feedback that may further increase their arousal. If a genital response is possible, even when other investigations indicate the existence of a variable that might compromise physical responses, an organic contribution to the arousal problem of the individual women is clinically irrelevant. They argued that sexual arousal problems in medically healthy women are most likely more often related to inadequate sexual stimulation due to contextual and relational variables than to somatic causes. For estrogen deplete women, care must be taken not to simply facilitate painless intercourse in the nonaroused state with a lubricant, but to consider the possibility that estrogen lack has unmasked long-term lack of sexual arousal that is of contextual etiology [45]. Of note, nonresponse in the psychophysiological assessment does not automatically imply organicity. The woman may have been too nervous or distracted for the stimuli to be effective, or the stimuli offered may not have matched her sexual preferences. This problem of suboptimal sensitivity is not unique to this test, many other well established diagnostic tests of this nature have a similar disadvantage [317].

Two other procedures could be used to corroborate findings from the clinical interview and the psychophysiological assessment. The first is the use of self-report measures to supplement the clinical interview. The Female Sexual Function Index [203] (Table 5) is currently the most often used measure. Diagnostic cutoff scores were developed by means of sophisticated statistical procedures [318]. Together with a Female Sexual Distress Scale [32] score of 11 or higher, indicating distress, there is some evidence to suspect sexual dysfunction [319]. Use of self-report measures alone are not very useful for clinical purposes because they lack sensitivity and specificity with regard to causes of the individual patient’s dysfunction.

Secondly, a careful focused pelvic exam is needed when there is a complaint of loss of genital response. Normal findings can be therapeutic by directing the woman to focus on what goes on in her mind rather than assuming she has a genital abnormality. As well an exam is essential when lack of arousal is accompanied by complaints of pain or vaginistic response during sexual activity. Common (e.g. vulvo vaginal atrophy) or rare diseases such as connective tissue disorder, can be identified. Often, the purpose of the exam may be more educational than medical, for instance to observe the consequences of pelvic floor muscle activity [46,317]. In women with neurological disease affecting pelvic nerves or with a history of pelvic trauma a detailed neurological genital exam may be necessary, clarifying light touch, pressure, pain, temperature sensation, anal and vaginal tone, voluntary tightening of anus, and vaginal and bulbocavernosal reflexes [46]. The clinician should be aware of the emotional impact of a physical examination and the importance of the timing. When a woman is very anxious about being examined it may be appropriate to wait until she feels more secure. In case of women who are not familiar with self-examination of their genitalia,
it is preferable to advise self-examination at home before a doctor carries out an examination [320]. It is recommended that the procedure is explained in detail, what will and what will not take place, and the woman’s understanding and consent obtained. It is important to realize that any medical exam is not able to examine function, because the genitalia are examined in nonaroused state. As such, a medical exam can never replace a careful detailed interview. Psychophysiological assessment may be an integral part of the clinical assessment in the future.

Recommendation:

A thorough assessment of FSAD must include an in-depth personal interview during which adequacy of sexual stimuli is assessed. Psychophysiological tools may be helpful though, at present, are reserved primarily for the research setting. Self-report measures may corroborate information obtained from an interview. A carefully focused genital/pelvic examination is necessary when there are complaints of loss of genital sensitivity or pain or vaginistic reactions. GRADE C

2. TREATMENT ISSUES SPECIFIC TO LOW AROUSAL

a) Psychological treatments

Currently, we are in a climate that overlooks and dismisses psychological treatments [321]. One of the reasons for this may be that due to sociocultural pressure in the medical and larger culture, psychological treatments are seen as superior [322]. The emphasis on impaired genital responsiveness in the DSM-IV definition of FSAD and the success of pharmacological treatments for men’s erectile dysfunction have undoubtedly contributed as well.

Prior to publication of Masters and Johnson’s seminal book on sex therapy [292], sexual problems were seen as consequences of (nonsexual) psychological conflicts, immaturity, and relational conflicts. Masters and Johnson proposed to directly attempt to reverse the sexual dysfunction by a kind of graded practice and focus on sexual feelings (sensate focus). If sexual arousal depended directly on sexual stimulation, that very stimulation should be the topic of discussion (masturbation training). A sexual dysfunction was no longer something pertaining to the individual; rather, it was regarded as a dysfunction of the couple. It was assumed that they did not communicate in a way that allowed sexual arousal to occur when they intended to “produce” it. Treatment goals were associated with the couple concept: the treatment goal was for orgasm through coital stimulation. This connection between treatment format and goals was lost once Masters and Johnson’s concept was used in common therapeutic practice. People came in for treatment as individuals. Intercourse frequency became the gold-standard indicator of sexual function. Male orgasm through coitus adequately fulfills reproductive goals, but it is not very satisfactory for many women because they do not easily reach orgasm through coitus [35,323] What has remained over the years since 1970 [292] is a direct focus on dysfunctional sex and a focus on sexual sensations and feelings as a vehicle for reversal of the dysfunction.

Psychological treatment of sexual arousal problems generally consists of sensate focus exercises and masturbation training, with the emphasis on becoming more self-focused and assertive [324]. A lack of meaningful treatment goals for women, the difficulty in obtaining adequate control groups, and the lack of clear treatment protocols, may explain the paucity of well-controlled randomized trials of psychological therapy.

Almost all of the data on psychological treatments were collected in the mid-1980s or earlier. The high success rates published by Masters and Johnson have never been replicated. There are no randomized controlled trials of psychological treatments for FSAD. Instead, as described in the earlier section on low desire, there is mounting evidence from two uncontrolled trials that a mindfulness-based cognitive behavioral intervention is helpful for women with HSDD and/or FSAD [296,325]. In these studies, the eastern practice of mindfulness, or non-judgmental, present moment awareness, was combined with cognitive therapy of dysfunctional thoughts associated with poor arousal (e.g., “my body is incapable of being aroused”), as well as behavioral techniques (e.g., sensate focus, exploration of a woman’s body and her genitals) and was found to lead to significant improvements in self-reports of sexual arousal as well as a marginal improvement in physiological sexual arousal (Level 3). Although promising, these data await replication in a randomized controlled trial.

Recommendations:

Despite our support for evidence-based practice, care for people with sexual problems, according to the rules of “good clinical practice”, must continue, even without solid proof of efficacy. There clearly is a great need for controlled efficacy studies in this area. From our review that the majority of sexual arousal problems in healthy women are not related to impaired genital responsiveness it follows that we recommend psychological treatments for FSAD. GRADE C

b) Hormonal Pharmacotherapy for FSAD

1. Testosterone

A limited number of studies have investigated potential beneficial effects of testosterone on sexual arousal. In a placebo-controlled study in hypogonadotropic hypogonadal women, treatment with tes-
testosterone undecanoate, 40 mg orally per day during an 8-week period, enhanced genital arousal as measured by VPA [326] (Level 2). Because women swallowed the capsules each morning, while the measurements were performed in the afternoon, it was assumed that this effect on genital sexual responding could be caused by a time-dependent effect of testosterone. To test this hypothesis, eugonadal and sexually functional women were administered a single dose of testosterone sublingually (0.5 mg). Such pulsed testosterone delivery produces supraphysiological testosterone levels 15 minutes after treatment, with levels returning to normal within 1.5 hours [327]. A 4-hour delay effect of testosterone on VPA was demonstrated [327,328]. This finding was replicated in another laboratory [329] (all four studies Level 2).

2. Estrogen

There is evidence that treatment with local and systemic estrogen benefits vulvo-vaginal atrophy and relieves vaginal dryness and dyspareunia [330,331] (Level 1).

3. Selective Tissue Estrogenic Activity Regulator (STEAR):

Tibolone. Tibolone is a 19-nor testosterone derivative which is metabolized into three main metabolites: the 3α-hydroxy and the 3β-hydroxy, which are estrogenic, and the 8-4 isomer, which has progestagenic and androgenic properties. Tibolone is a selective tissue estrogenic activity regulator (STEAR). In postmenopausal women, it acts as an estrogen on brain, vagina, and bone, but not on endometrium and breast.

A randomized, double-blind, cross-over study was conducted in 38 postmenopausal women who received tibolone 2.5 mg/day and placebo. Vaginal blood flow during erotic stimulation was measured using a vaginal photoplethysmograph and subjects completed sexual function questionnaires and daily diaries. Women receiving tibolone showed a significant increase in VPA in response to erotic fantasy but not during erotic film stimulation. Tibolone was associated with significant increases in sexual desire, and the frequency of arousability and of sexual fantasies compared with those with placebo. Vaginal lubrication was significantly improved on tibolone [93]. In another study, 72 women were randomized to treatment with either tibolone or continuous combined conjugated equine estrogens 0.625 mg/day and medroxyprogesterone acetate 5 mg/day (CEE/MPA). After 6 months of treatment, both groups were associated with significant self-reported improvements in sexual function, but women receiving tibolone had significantly higher sexual desire, sexual excitement, intercourse frequency and vaginal dryness scores [332] (Level 2).

A Selective Estrogen Receptor Modulator was originally defined as a compound that binds with high affinity to the estrogen receptor (ER), without significant binding activity to any other nuclear receptor; which induces “estrogen agonistic” activities in some tissues, and “estrogen antagonistic” activities in others. Emerging data show that the interaction between a particular SERM and the ER results in a response in a given tissue which cannot necessarily be characterized simply as either “agonistic” or “antagonistic”. Each SERM may have a unique set of clinical responses, which are not always predictable from those seen with another SERM. Ospemifene (formerly named FC-1271a) is a novel SERM developed for the treatment of vaginal atrophy in postmenopausal women (which also shows promise in the prevention and treatment of osteoporosis). The effects of ospemifene on urogenital atrophy in postmenopausal women are currently being assessed in Phase III studies [333].

5-Hormone Precursor Replacement Therapy (HPRT): DHEA

A recent phase III prospective RCT studied the effect of the vaginal application of 0.25%, 0.50% or 1.0% DHEA on signs and symptoms of vaginal atrophy in 216 postmenopausal women. All three doses induced a rapid beneficial change in the maturation of the vaginal epithelial cells and vaginal pH [334]. In addition, the beneficial effects induced by DHEA in the vagina had parallel positive consequences in sexual desire/interest, sexual arousal, orgasm and pain as measured by validated sexual function questionnaires [335]. This effect is attributed to the tissue specific local conversion of the inactive precursor DHEA into androgens as well as estrogens, exerting benefits on all the three layers of the vaginal wall. Preclinical data obtained in the rat have shown beneficial effects of androgens made locally from DHEA on collagen fibers of the lamina propria and on the muscularis [336]. While local DHEA was found to be an efficient treatment, all serum steroids (DHEA and its 11 metabolites) measured by validated mass spectrometry remained within the reference range observed in postmenopausal women, indicating a strictly local action with no systemic exposure to sex steroids [337]. On another note, a recent study has shown a fivefold increase in serum estradiol measured by mass spectrometry assays, in postmenopausal women using local vaginal formulations after 1 week of daily treatment [338] (Level 1).

c) Non-hormonal Pharmacotherapy for FSAD

In the relatively short time span (compared to psychological treatments) that pharmacological treatments have become available for men in 1998, the effect of pharmacological treatments in women
with sexual arousal problems has been investigated in several controlled and uncontrolled studies. To date, none of the treatments that are listed in Table 10 have been approved.

1. Phosphodiesterase Inhibitors.

Sildenafil is the first pharmacological treatment that has been investigated on a reasonable scale in controlled studies with female subjects. In the very first laboratory study, which was done on sexually healthy women, 50mg sildenafil produced an increase in physiological but not subjective sexual arousal [339]. In a large study of diagnostically heterogeneous women, 10-100mg sildenafil similarly showed no benefit on subjective sexual response [340]. In general, the literature has conflicting findings with some studies showing a benefit [341-343] and others failing to find a significant benefit over placebo, and one study showing that the benefit depending on psychophysiolologically-measured impairments in sexual arousal [43]. In small studies of women with impaired genital arousal due to spinal cord injury [42] or diabetes [344] there does appear to be a significant beneficial effect of sildenafil.

A new approach to the study of efficacy of PDE5-inhibitors is combining this drug with testosterone. The rationale for such an approach is that activation of central sexual mechanisms is necessary for the interpretation of stimuli as sexual, by which these stimuli can produce (behavioral) sexual responses (i.e., an increase in sexual desire and motivation; inducing sexual approach behavior). Activation of central "sexual" mechanisms is a necessary condition for activation of the nitric oxide pathway, which in turn is necessary for a PDE5-inhibitor to be effective. The authors argue that centrally working drugs will increase the sensitivity for sexual stimuli, and may induce a condition required for a PDE5-inhibitor to be effective [225,226] (Level 2). Color naming latency times in a Stroop test was the measure of preconscious attentional bias for sexual cues. In the initially low-attention group preconscious attentional bias increased with testosterone, in the other group attentional bias decreased with testosterone. Only in the former group did the combination of (0.5 mg sublingual) testosterone (producing high supraphysiological levels) and (10 mg) vardenafil cause an improvement in genital response (VPA) and subjective indices of sexual functioning, supporting the idea that testosterone sensitizes the brain, paving the way for vardenafil to be effective [225]. The high dose of testosterone administered in this study limits the generalizability of the findings.

In 2004 Pfizer ended their program of testing sildenafil in women, perhaps resulting from the conflicting findings in medically healthy women [345]. It would be theoretically and clinically meaningful to investigate which factors may have been responsible for these inconsistent findings. Possible candidates are: inadequate sexual stimulation (sildenafil will not be effective without sexual stimulation that is useful—i.e., that causes subjective arousal to trigger the genital response); inadequate outcome measures; wrong patient group (e.g. women with sexual problems unrelated to genital responsiveness); estrogen depletion, although in larger studies of sildenafil, the majority of participants were premenopausal (estrogen-replete) women. In most studies prior to this decision, women excluded from the trials. That may have been an unfortunate choice. Women with various medical conditions, and not medically healthy women [44], may have an impaired genital response and may therefore have more to gain from a genital arousal enhancing agent such as sildenafil. PDE5-inhibitors combined with testosterone may have a beneficial effect over placebo in certain groups only [225,226].

2. L-Arginine

The nitric oxide precursor L-arginine was investigated in a double-blind, placebo-controlled study combined with yohimbine, an adrenergic antagonist, in women with FSAD [346] (Level 2). The combination significantly enhanced VPA but had no effect on subjective measures of arousal or affect.

3. Prostaglandins

One placebo-controlled, single-blind, dose response study of alprostadil found no significant benefit over placebo [347] (Level 2) whereas another small trial in postmenopausal women found a significant benefit on genital sensation, subjective sexual arousal, and sexual satisfaction [348].

4. Phentolamine

Two controlled studies have investigated the effect of alpha-1 and alpha-2 adrenergic receptor antagonist phentolamine based on the hypothesis that, as in men, the smooth muscle surrounding the vaginal arterial vascular bed is mainly alpha adrenergically innervated. In a small study of six postmenopausal women with FSAD, it showed a positive effect on subjective and genital sexual arousal (VPA) [349] (Level 3). In the second, a placebo-controlled administration of both oral and vaginal applications in 41 estrogenized and non-estrogenized postmenopausal women found a benefit to genital response and subjective sexual arousal but only in the estrogenized women [349,350] (Level 2). It should be noted that the pharmaceutical company previously sponsoring these trials of phentolamine has no longer sponsored additional (larger) trials. Also, it is important to note that most women who present with sexual arousal concerns have normal genital congestion when measured in the laboratory [44].

5. Dopamine Agonists

Dopaminergic drugs might be interesting because other than the previously discussed drugs, they have a direct effect on the brain and may therefore have a positive influence on sexual arousal and desire. Levodopa significantly enhanced the Achilles tendon reflex in men, indicating somatic motor readiness [351]. However, apomorphine significantly improved sexual function in 44 women with HSDD and FSAD. Side-effects were mainly nausea, vomiting, and dizziness [352]. Sumanireole is a dopamine agonist that specifically targets D2-receptors. The effect of this drug in women with complaints of sexual arousal and desire were studied in an unpublished, placebo controlled laboratory study where no effects on genital or subjective sexual arousal were found.

6. Buproprion

Buproprion was used in one uncontrolled study to counteract the sexual side-effects of selective serotonin reuptake inhibitors. Keeping in mind that no adequate control was used, the authors concluded that the results point to relief of the sexual complaints [353] (Level 4).

7. Bremelanotide

Bremelanotide is an analogue of the naturally occurring peptide alpha-melanocyte-stimulating hormone (alpha-MSH). A single intranasal dose of this melanoctin receptor agonist resulted in increased reports of sexual desire and arousal in premenopausal women with sexual arousal disorder [354]. After this initial favorable result, studies were suspended due to undesirable side-effects.

d) Physical aids for FSAD

In the past 10 years, a new, non-pharmacological approach to FSAD was developed. The EROS Clitoral Therapy Device (CTD) consists of a small cup that can be placed over the clitoris, and a pump that creates a vacuum over the clitoris. A study in 20 women with FSAD and 12 healthy controls found improvements in genital sensation, vaginal lubrication, ability to reach orgasm, and sexual satisfaction relative to pretreatment [355] (Level 3). The authors speculated that “the increased vaginal lubrication resulting from clitoral engorgement with the EROS-CTD is due to activation of an autonomic reflex that triggers arterial vasodilatation with subsequent increases in transudate and lubrication”. This ‘medical’ device again demonstrates that, if proven effective in larger groups of women with sexual arousal difficulties, many if not most sexual arousal problems are due to a lack of adequate sexual stimulation.

Recommendations:

Although testosterone showed a beneficial effect on sexual arousal as measured with a vaginal photoplethysmograph, these are supraphysiological levels with an unknown long-term safety profile. There is no evidence for increased subjective excitement or pleasure. Currently, no recommendation for pharmacotherapy for FSAD can be made due to lack of efficacy and/or unwanted side-effects. Women with various medical conditions rather than medically healthy women may have an impaired genital response and may therefore gain from peripheral, genital arousal enhancing agents. GRADE C

IV. ISSUES SPECIFIC TO LOSS OF ORGASM

1. DEFINITION OF ORGASMIC DISORDER IN WOMEN

In the recent Prevalence of Female Sexual Problems Associated with Distress and Determinants of Treatment Seeking (PRESIDE) study, a cross-sectional population-based survey of female adults in the United States, 18 years and older, FOD was present in 20.5% of the 31,581 respondents, being a distressing problem in 4.7% [31]. Cross-cultural data of women aged 40-80 show an incidence of 16%, with the greatest prevalence in Asia and the lowest in Northern Europe [50].

In the DSM-IV, FOD is defined as: “Persistent or recurrent delay or absence of orgasm following a normal sexual excitement phase” [1]. The international committee assembled in 2003 by the AUAF proposed an alternative definition of Women’s Orgasmic Disorder (Table 1) that emphasized that the diagnosis could only be made if high levels of sexual arousal were able to be attained by the woman [41]. In other words, according to these definitions, the woman who does not experience orgasm but also does not experience a sufficiently high level of sexual arousal (presumably to facilitate orgasm) would not be given a diagnosis of FOD, but rather just FSAD. With the publication of DSM-V in 2013, there have been proposed new criteria for FOD[356]. The main difference between DSM-IV - TR and proposed criteria for DSM-V is the addition of “markealy reduced intensity of organic sensation”.

2. ETIOLOGY OF ORGASM DISORDER

Orgasm has been the subject of interest and research for many years. Both the study of the biological aspects, the subjective appraisal of the events and the correlation between the two have been examined. While the early studies contemplated physiological parameters such as heart rate, blood pressure, contraction of “target organs” [10,357], later studies have focused on the involvement of the peripheral nervous system, spinal cord pathways and brain areas engaged, as well as neuroendocrine influences.
An extensive review of the literature has been published following the previous 2003 International Consultation on Sexual Dysfunctions [358] and at the time of this publication, there are no significant new data on the subject except what is briefly discussed below.

The pathophysiology of orgasmic disorders involves biological as well as psycho-social predisposing and precipitating factors. A genetic influence on variation in female orgasmic function has been assumed, since the intra-class correlation for frequency of orgasm during intercourse and masturbation has been found higher for monozygotic twins (31% and 39%, respectively) than for dizygotic twins (10% and 17%; p=0.0001) [359] (Level 3). Moreover, the heritability for orgasm problems in intercourse is approximately 31%-34% and for orgasm problems with masturbation is approximately 37%-45% [360,361] (Level 3). Data from a recent twin registry database on 2,035 British women indicate that some measures of personality (e.g., introversion, emotional instability, not being open to new experiences) and emotional intelligence were associated with orgasmic dysfunction in women [362,363] (Level 3) though these data need to be replicated.

In their 1997 review, Heiman and Meston concluded that only Directed Masturbation treatment for primary anorgasmia fulfills the criteria of “well-established”, and Directed Masturbation studies for secondary anorgasmia fall within the “probably efficacious” group [364]. This conclusion is still valid up to date. Directed Masturbation in conjunction with sex education, anxiety reduction techniques and CBT remain the main therapeutic tools. No effective pharmacological treatments have been found to date for FOD [365].

In 98 women with SSRI-induced FOD who were recruited over four years across 7 American treatment centers, half were randomized to receive 50 or 100mg sildenafil and the other half the placebo pill [366]. Those in the treatment group had significantly fewer negative sexual side effects. However, the highly specific inclusion criteria calls into question the generalizability of the findings.

**Recommendations:**

There are no significant new data on FOD since the 2003 International Consultation meeting. There are some preliminary genetic research from twin registries showing a significant heritability factor to orgasmic problems with intercourse and masturbation. There is one published RCT of sildenafil showing positive effects on orgasmic disorder in a highly selective sample of women with SSRI-induced FOD. **GRADE C**

---

**V. THE PLACEBO RESPONSE**

It has become increasingly apparent in pharmaceutically sponsored RCTs that there is a notable placebo response among women randomized to the placebo arm of a drug trial. For example, in studies of sildenafil, the placebo response was at least 40% [340,341]. In recent testosterone trials, there is also a notable placebo response. For example, among estrogen depleted postmenopausal women, the increase in sexually satisfying events in the placebo group (0.7 units) was no different than the increase seen in the 150µg group (1.2 units) – although both groups were lower than the 300µg testosterone group [302]. Among surgically menopausal women, the placebo response was comparable to the increase in sexually satisfying events seen in both testosterone groups. Among premenopausal women, 43.5% of women in the placebo group experienced a significant increase in sexually satisfying events which was comparable to the proportion experiencing benefit in the one 56-µL spray (46.2%), one 90-µL spray (57.8%), and two 90-µL spray (54.7%) groups [304].

Recently, there has been a systematic effort to better understand the placebo response in pharmacological trials for female sexual dysfunction and there have been three studies by Bradford and Meston to this effect.

In a review of 16 placebo-controlled pharmacological trials in women’s sexual dysfunction, Bradford and Meston attempted to quantify the degree of placebo response [367] (Level 3). Their review focused on trials of women seeking treatment in which a placebo effect could be calculated. Studies employing a retrospective design and/or studied postmenopausal women, and studies focusing on sexual desire (as opposed to sexual arousal) endpoints were more likely to show placebo effects.

Bradford and Meston [368] (Level 2) then examined correlates of the placebo response among 16 women receiving the placebo arm in one of their randomized controlled trials of gingko biloba. The pre- to post-treatment change in overall FSFI scores was 4.66, representing a large effect size of d = 0.73. Age, length of relationship at baseline, and changes in relationship adjustment, were all significantly correlated with the placebo response whereas psychological symptoms, baseline sexual function, and baseline relationship adjustment scores were not. Married women showed a stronger placebo response whereas SSRI use was associated with a smaller effect. There were no significant differences in the magnitude of the placebo response based on ethnicity or based on diagnosis (either FSAD or FOD).

In an unpublished examination of placebo effects, 50 women participating in a pharmaceutically-sponsored trial of Cialis versus placebo for FSAD, Bradford and Meston found that the strongest predictor of the pla-
As well as spontaneous orgasms in some cases. Vaginal contractions, throbbing, pressure and pain, include clitoral tingling, irritation, vaginal congestion, sexual interest or desire. Complaints by sufferers genital arousal occurring in the absence of subjective distress [369] although improvements in sexual satisfaction also correlated with the placebo response. In fact, this study found no significant difference in improvements in sexual frequency between the placebo and treatment groups. Interestingly, this study also found that the placebo group resulted in a significant increase in genital stimulation received by a partner.

In speculating about the potential mechanisms by which the placebo response occurs, Bradford and Meston [367] reasoned that expectancies may partially explain this effect (e.g., expecting an enhanced sexual response). However, it is also possible that other mechanisms, such as desirable responding, regression to the mean, and effects of repeated measurement may have underlined this effect. Study design related factors, such as investigator effects, assessment strategy, duration of treatment, dosing schedule, selection criteria, and treatment procedures, may also have affected the placebo response [367] and the finding that studies which employ identical methodologies show comparable rates of placebo effects supports this possibility. The authors also speculated that enrolling in a treatment trial that requires a minimum number of sexual events per week may enhance communication between partners and subsequently enhances sexual response [368]. However, they also acknowledged that enhanced sexual response may have facilitated emotional intimacy and communication between the partners.

**Recommendations:**

Clearly, statistical significance is not a sufficient indicator for determining treatment response between placebo and active treatment arms of a particular trial. Instead, the magnitude of placebo effects is important to consider as well as the clinical meaningfulness of the group differences. In the future, the magnitude of placebo effects and the correlates of the placebo response may also be used to guide thinking about a particular sexual dysfunction’s etiology. **GRADE B**

**VI. PERSISTENT GENITAL AROUSAL DISORDER**

1. **WHAT IS PERSISTENT GENITAL AROUSAL DISORDER?**

Persistent Genital Arousal Disorder (PGAD) is a perplexing condition characterized by high levels of genital arousal occurring in the absence of subjective sexual interest or desire. Complaints by sufferers include clitoral tingling, irritation, vaginal congestion, vaginal contractions, throbbing, pressure and pain, as well as spontaneous orgasms in some cases. Attempts to quell the genital arousal by engaging in masturbation or sexual activity usually provides only temporary relief or even more arousal and activation. Although it is not a formal category of dysfunction in the DSM-IV-TR, PGAD might currently be diagnosed as a Sexual Dysfunction Not Otherwise Specified.

The diagnosis of PGAD is made based on the presence of all five of the following features: (a) the physiological responses characteristic of sexual arousal (genital vasocongestion and sensitivity) persist for an extended period of time (hours to days) and do not subside completely on their own; (b) the genital arousal does not resolve completely despite one or more orgasms; (c) the persistent genital arousal is experienced as unbidden, intrusive and unwanted; (d) the persistent genital arousal may be triggered not only by sexual activity but by nonsexual stimuli as well (e.g. vibrations from a car) or triggers may not even be apparent; and most importantly, (e) there is at least a moderate or greater feeling of distress associated with the experience [370]. Hypersexual states often associated with mania, sexual compulsivity or stimulating social drugs preclude a diagnosis of PGAD.

2. **PGAD PREVALENCE**

Leiblum and her colleagues have published three internet based studies on PGAD using data from women who completed web-based surveys concerning the condition [370-372] (Level 3). These research reports found high levels of stress and anxiety among sufferers as well as a greater incidence of obsessive-compulsive and somatization symptoms in PGAD women. Unlike women who met some, but not all features of the condition (a non-PGAD group), PGAD women reported that the genital arousal they experienced was more intense, continuous, unwanted and distressing than that of the non-PGAD women, many of whom enjoyed the unsolicited genital arousal.

Although in many cases, the dysphoric mood of PGAD sufferers preceded their first experience of unsolicited genital arousal, the unremitting nature of the symptoms coupled with the lack of relief predisposes some women to become severely depressed and even suicidal [373]. The distress associated with the disorder is compounded by the fact that many women feel embarrassed and humiliated about revealing the condition to intimate partners and health care providers. The shame and embarrassment attached to the symptoms has most likely contributed to the phenomenon going unrecognized and underreported. As a result, there are currently no reliable figures on the prevalence of PGAD, although it may not be as rare as initially described.

3. **PGAD ETIOLOGY**

At this time, there is little consensus regarding the etiology of PGAD. Based on individual case reports or
small series of cases, Goldstein [374] has suggested the following major etiological possibilities: (i) central neurological changes (e.g., post-injury, specific brain lesion anomaly) (ii) peripheral neurological changes (e.g., pelvic nerve hypersensitivity or entrapment) (iii) vascular changes (e.g., pelvic congestion), (iv) mechanical pressure against genital structures, (v) medication-induced changes, and (vi) psychological changes (stress) or some combination of all of the above. There have been case studies that document the onset of PGAD secondary to neurological pathophysiology [374]. Leiblum and Goldmeier [375] note that some women have associated the onset of PGAD symptoms with the initiation of treatment with SSRIs and other mood stabilizers. Other possible triggers that have been identified include the cessation of treatment with antidepressant medication, beginning menopause, physical inactivity, and severe stress [373]. A recent study found an association between restless leg syndrome and PGAD and suggested that the pharmacological treatment of the former may be helpful to women with PGAD [375].

From a psychological perspective, Leiblum and Chivers [376] have postulated that women with PGAD may be more vigilant in monitoring small changes in their physical well-being than women who simply report unsolicited but untroubling genital arousal. This tendency may reinforce a possible underlying pathophysiological mechanism, and lead to perpetuation of the arousal. It is not known at this time whether the distress experienced by PGAD patients as compared with non-PGAD women stems from the kind, intensity or duration of the genital sensations, or how these women label and account for the arousal.

4. PGAD TREATMENT

While there is no generally accepted treatment for PGAD, current interventions [377,378] focus largely on symptom management (Level 4). Guidelines have been published but notably they are based on case reports and not on RCTs [379]. Psychoeducation and social support are often the first steps as patients are relieved to discover that they are not alone in their experience and become aware of the stimuli which exacerbate symptoms. In addition, a first step should involve reducing or eliminating any identifiable factors which have exacerbated the symptoms. Anesthetizing agents or ice may be used to numb the area. Pelvic massage or stretching exercises are sometimes helpful in reducing pelvic tension. Medication management is largely achieved by trial and error as certain medications may be associated paradoxically with either alleviation or activation of the symptoms. Mood stabilizing, anti-seizure medications such as valproic acid (Depakote) have helped some women, while others report relief with SNRIs (Selective Norepinephrine Reuptake Inhibitors). Cognitive-Behavioral interventions have been used to enhance coping skills and assist in interrupting the cycle of anxiety and catastrophizing of the symptoms. Mindfulness based intervention has also helped since anxiety worsens symptoms by leading to more autonomic nervous system activation, and often, more genital arousal [379] (Level 4).

5. FUTURE DIRECTIONS WITH PGAD

More research is clearly needed to investigate the etiology, causes and treatments of PGAD. In addition to extensive medical histories and psychological evaluations, the collection of comprehensive physiological data including gynecologic examinations, thermograph measurement of the genital area, pelvic floor muscle tone data, the measurement of hormone levels, fMRI brain scan information, evaluation of the sensitivity of the genital tissue areas, etc., will be key in elucidating the disorder. Since little is known about the range and diversity of women’s sexual response, investigations into PGAD will likely shed light on the dynamics of arousal, desire, and female sexual functioning.

Recommendations:

PGAD is a distressing intrusive condition that is relatively new to the sexual dysfunction lexicon. Data on prevalence, pathophysiology, and treatments is very scant and there are no randomized controlled trials on any available treatment method. Psychoeducation and support are important in the early stages of intervention. There may be relief with medications (e.g., mood stabilizers, SNRIs), anesthetizing medications, pelvic floor physiotherapy, psychological therapy, and mindfulness may be helpful for the condition and may be tried alone and/or in combination with one another. **GRADE C**

1208
I. INTRODUCTION

The sexual pain disorders, dyspareunia and vaginismus, have provided special challenges to health professionals. The primary challenge, perhaps, has been the continuing controversy concerning how to conceptualize and treat sexual pain. Robert Latou Dickinson noted this as early as 1933 by writing:

"The surgeon thinks of difficult coitus in terms of a knife passed through muscles in spasm; the psychiatrist thinks of dyspareunia as a mental knot to be disentangled by analysis; the gynecologist who is weary of patching - poor and late patching - begins to think in terms of prevention through routine premarital examination and instruction"[1].

This continuing uncertainty about treatment is complicated by the clinical challenge of dealing with highly distressed patients. Sims [2] described this in the following way:

"From personal observation I can confidently assert that I know of no disease capable of producing so much unhappiness to both parties of the marriage contract... ([2] p. 361).

The combination of professional uncertainty and patient distress often makes standard examinations and interviews lengthy and difficult. Understandably, many professionals have avoided treating and investigating dyspareunia and vaginismus. Although there has been increased clinical and research attention in the last 10 years, there is still much basic missing information.

1. TERMINOLOGY

The term "vaginismus" was coined by Sims in the second half of the 19th century and continues to be used today by gynecologists, mental health professionals, sexologists and physicians in general. By contrast, a very large number of labels and classification terms have appeared which describe painful intercourse or dyspareunia without known pathological causes. These include terms such as (generalized, localized, dysesthetic, essential or (hemi) vulvodynia, clitorodynia, vulvar dysesthesia, focal vulvitis, vulvar adenitis, vulvar vestibulitis, (provoked/unprovoked/generalized/localized) vestibulodynia, burning vulva syndrome, pelvic pain, etc. In recent years, there has been an increased emphasis in describing and classifying vulvar pain whether or not it is linked to a pathological state. The International Society for the Study of Vulvar Disease (ISSVD) has recently published updated versions of their classifications of vulvar pain [3]. There has not been parallel activity in describing and classifying deeper vaginal/pelvic pain. For many women who complain of pain during intercourse, there is a combination of superficial (vulvar) and deeper (vaginal/pelvic) pain. For many women who complain of pain during intercourse, there is a combination of superficial (vulvar) and deeper (vaginal/pelvic) pain. In addition, it is often unclear whether the pain can or should be attributed to a disease process or not. The term "sexual pain" was introduced in the DSM-III-R and refers to both dyspareunia and vaginismus when they are not directly caused by physical pathology. The rationale for the introduction of this term is not clear [4].

While such nosological and terminological confusion is not uncommon in the health sciences especially when multiple disciplines are involved, it has impeded research and clinical communication. In this chapter, we will for convenience sake continue to use the traditional mental health terms vaginismus.
and dyspareunia. When there is a focus on vulvar pain and the literature warrants it, we will use diagnostic terms such as “provoked vestibulodynia” (PVD) as suggested by the new ISSVD classification. Developing a uniform, comprehensive and reliable nosology remains a challenge.

2. CLASSIFICATION AS A SEXUAL DYSFUNCTION, DISEASE OR PAIN SYNDROME

The diagnostic operationalization of vaginismus by Sims (1861) as a spasm of the pelvic floor muscles remained virtually unchallenged until recently [2]. The presumed etiology of this spasm, however, has been attributed to varying causes, ranging from a psychosomatic fear of sex and/or vaginal penetration to the repeated or imagined experience of pain during intercourse. Typically, once anatomical and disease-related causes of pain or difficulties in penetration were excluded, vaginismus was considered by most authorities and classification systems as a sexual dysfunction. While the ICD-10 continues in this tradition, it also allows for the classification of vaginismus as a pain syndrome.

Dyspareunia has traditionally been conceptualized either as the direct result of physical and anatomical factors or as a reflection of psychological/sexological difficulties. Some recent research and theorizing suggests that these two views might be usefully combined under the rubric of pain syndrome, though many consider this approach controversial [5].

Whichever conceptualization one adheres to for the understanding of “sexual pain”, it is clear that both vaginismus and dyspareunia are frequently comorbid with DSM-IV sexual dysfunctions such as hypoactive sexual desire disorder, female sexual arousal disorder and orgasmic disorder.

3. SEXUAL PAIN AND EVIDENCE-BASED REPORTING

The Oxford system of levels of evidence is unfortunately not well suited to this literature since there are not many high quality studies or systematic reviews. Nonetheless, each relevant study cited in this chapter is graded according this system. This will allow for comparisons of the quality of evidence concerning dyspareunia and vaginismus with other problems covered in this volume. In comparing the number and quality of studies available for this chapter as compared with those available for the 2004 version, it is encouraging that there are many new studies and several replications of previously reported findings. It is also very encouraging that the first randomized controlled trial (RCT) for the treatment of vaginismus has been published [6]. These developments bode well for the future of the field.

II. NEUROBIOLOGY OF THE PELVIS

A basic understanding of the neurobiology of the pelvic floor is paramount to gain further insight into the pathophysiology of urogenital disorders (which are characterized by disturbances of sensation and motility) and to develop effective clinical management strategies for patients presenting with these syndromes [7].

Over the last 15 years, the basic neurobiology of the pelvic floor, despite its complexity, has come to be a reasonably well-developed discipline owing to an increasingly refined knowledge of principles pertaining to the neuroanatomy and neurochemistry of pelvic functions [8].

It is important to note that this summary attempts to derive as much information as possible from investigations involving humans although some generalizations are necessarily taken from animal studies, recognizing that much research in this field is still in its infancy. Many of the animal studies concerned with the characterization of the autonomic outflow to the pelvis (unless they were specifically designed to assess the female reproductive tract) have primarily been conducted in male animals. This caveat is important since there is some evidence to suggest that pelvic floor and perineal innervation may differ between men and women [9].

1. NEUROANATOMY OF THE PELVIS AND PELVIC FLOOR

The pelvis and pelvic floor are innervated by both divisions of the autonomic nervous system, the sympathetic and parasympathetic divisions, as well as by the somatic motor and sensory nervous systems (Grade A). In a broad anatomical view, dual projections from the thoracolumbar and sacral segments of the spinal cord carry out this innervation, converging primarily into discrete peripheral neuronal plexuses before distributing nerve fibers throughout the pelvis (Figure 1). Interactive neuronal pathways routing from higher origins in the brain through the spinal cord add to the complexity of neuronal regulation in the pelvis. While it is important to appreciate the influence of supraspinal centres in the coordination of pelvic organ activities, it is beyond the scope of this review to discuss these interactions in further detail [10-16].

The nomenclature of the various plexuses, ganglia, and nerves in the pelvic cavity is varied and sometimes confusing, presenting designations from both Nomina Anatomica and clinical usage [17, 18]. In this review, we have used the anatomical nomenclature, the clinical usage is given in brackets: superior hypogastric plexus (presacral nerve), hypogastric plexus (hypogastric nerve), inferior hypogastric plexus (pelvic plexus) and pelvic splanchnic nerve (pelvic nerve).

a) Pelvic Autonomic Innervation

Within the pelvis, the inferior hypogastric plexus is regarded to be the major neuronal integrative center [19]. Neuropathological studies have confirmed its retroperitoneal location adjacent to each lateral aspect of the rectum, with interconnections between the left and right inferior hypogastric plexuses at the posterior aspect of the rectum [20-22]. It innervates multiple pelvic organs, including the urinary bladder, proximal urethra, distal ureter, rectum and internal anal sphincter, as well as genital and reproductive tract structures [23]. The anterior part of the inferior hypogastric plexus, associated with the distal extent of the hypogastric plexus (hypogastric nerve), is referred to as the paracervical ganglia. These ganglia are situated in the parametrium lateral to the cervix and the upper part of the vagina, and they distribute nerve fibers to the corpora cavernosa of the clitoris, vagina, and periurethral tissues [24].

Neuronal input to the inferior hypogastric plexuses involves sympathetic and parasympathetic systems. Sympathetic nerves originate in the thoracolumbar segments of the spinal cord (T10-L1) and condense into the superior hypogastric plexus located just inferior to the aortic bifurcation. Pre-ganglionic efferents originate largely in the intermediolateral cell column, whereas afferents have their cell bodies located in dorsal root ganglia of these segments. Nerve fibers project from the superior hypogastric plexus as paired hypogastric plexuses (hypogastric nerves) and fuse distally before diverging bilaterally into branches destined for the inferior hypogastric plexuses. Additional sympathetic innervation to genitourinary organs may involve pre-ganglionic nerves which synapse on postganglionic nerves originating in sympathetic chain ganglia; these postganglionic nerves join sacral nerves and course to their destinations via pelvic somatic neuronal pathways (see description below) [25]. Parasympathetic preganglionic nerve efferents are thought to arise from cell bodies of the sacral parasympathetic nucleus located in the intermediolateral gray matter of the sacral spinal conus (S2-S4) and fuse as the pelvic splanchnic nerve before entering the inferior hypogastric plexus [26, 27]. Parasympathetic afferents have cell bodies located in the S2-S4 dorsal root ganglia and course also within the pelvic splanchnic nerve. In addition to its parasympathetic efferent and afferent component, the pelvic splanchnic nerve also receives postganglionic axons from the caudal sympathetic chain ganglia [28].

A distinctive distribution of pelvic autonomic innervations is recognized at the urogenital organ level. In women, it involves inferior hypogastric plexus projections deriving primarily from the paracervical ganglia part of the plexus. Conspicuous nerve trunks run in the adventitia of the vagina parallel to its long axis, sending off anterior branches that course to the clitoris and periurethral tissues and local branches which enter the vaginal smooth muscle walls [18, 29]. A network of nerve fibers tends to follow vascular distributions and conspicuously terminates at the junction between the subepithelial connective tissue and the vaginal epithelium as well as within the epithelium. Nerve density is observed to be greater in the distal vagina compared with proximal regions and in the anterior vaginal wall as compared to the posterior vaginal wall [29, 30]. These regional differences in vaginal innervation are supported by psychophysical studies, which have identified a relative sensitive position to electrical stimuli in the anterior vaginal wall as compared to other vaginal areas [31]. A network of nerves rather than discrete nerves...
pierce the urogenital diaphragm to supply the vulvar tissues which engorge with sexual arousal.

Recent research data from spinal cord transected rats and women with spinal cord injury suggest that the vagus nerves can convey genital sensory input directly to the brain, completely bypassing the spinal cord [32-35]. Vaginal-cervical mechanical self-stimulation in women diagnosed with spinal cord injury at the T10 level resulted in activation of brain regions to which the vagus nerves project, the Nucleus of the Solitary Tract, as demonstrated in PET [33] and fMRI [35] studies.

**b) Somatic Innervation**

Somatic efferent and afferent innervation to the pelvis is generally understood to involve the sacral nerve roots (S2-S4) and their ramifications. Somatic efferents arise within Onuf's nucleus situated in the ventral horn of the S2-S4 spinal conus, and afferents reach the dorsal horn with their cell bodies in dorsal root ganglia of these segments [36]. Central projections of somatic afferents overlap with pelvic nerve afferents within the spinal cord, which theoretically allows coordination of somatic and visceral motor activity [25].

The sacral nerve roots emerge from the spinal cord forming the sacral plexus, from which the pudendal nerve diverges (S2-S4, with the S3 segment providing the largest contribution) along with the sciatic nerve diverging (S2-S4, with the S3 segment providing the largest contribution) along with the sciatic nerve. The pudendal nerve divides into upper and lower trunks [38]. The lower trunk or both trunks and provides innervation to the ischiocavernous, bulbocavernous and superficial transverse perineal muscles and the striated urethral sphincter and labial skin [38].

Many anatomical texts have described that the pelvic floor muscles receive a dual innervation by the pudendal nerve and direct branches of the third and fourth sacral motor nerve roots [42-44]. However, a study in female cadavers published in 2002 found that a nerve directly originating from sacral foramina S3 to S5 crosses the superior surface of the pelvic floor to innervate the three levator ani muscles: ilio- coccygeal,pubococcygeal, and puborectal muscles [38]. No pudendal nerve branch that innervated the levator ani muscles could be identified in this study. Branches of S4-S5 nerve roots forming the coccygeal plexus distribute to perineal, perianal, and labial (or scrotal) skin [40].

**c) Innervation of the Vulvar and Vaginal Area - Clinical Relevance**

Most studies on vulvar/vaginal innervation have been derived from animal studies [7, 45]. Compared to other areas of neuroscience little is known about the functional neural correlates that signal the wide range of sensations from the vulvar and vaginal area ranging from pleasure to pain. The vulva is densely innervated by branches of the pudendal nerves (somatic nerves), conveying information about gentle and intense mechanical stimulation to the sacral spinal cord (S2-S4). The vagina is innervated by the pelvic nerves (parasympathetic nerves). The cervix and adjacent fornix region of the vagina are innervated more densely than the rest of the vagina by the pelvic and hypogastric nerves. Information arriving from the vulva, vagina, and cervix is conveyed to widespread regions of the CNS, implying that stimulation of these regions can affect a wide range of physiological and perceptual functions [15, 46-48]. Fibers innervating the vagina are activated by both gentle and intense mechanical stimulation, including noxious stimuli [46, 49]. Mechanical probing (non-noxious stimuli) of the vagina and/or cervix has produced antinociceptive effects in rats and analgesia in women [50, 51]. The urogenital sinus of the embryo differentiates into the adult urachus, bladder, urethra, and vestibule, which in the adult comprises a shallow funnel of endodermal origin, sandwiched in between the (ectodermally derived) vulva and vagina proper [52-55]. The human vulvar vestibule contains free nerve endings but has no specialized nerve endings such as Meissners or Pacinian corpuscles [30]. The first survey of the innervation pattern in the human vagina using a pan-axonal marker was published in 1995 [29]. Free intraepithelial nerve endings were only detected in the introitus vaginae region. These very superficial free nerve endings are considered to
be nociceptive or thermoceptive [56]. Studies in rats have demonstrated, as the extent of the vaginal innervation varies as a function of the gonadal hormonal status [57]. This plasticity of the innervation is not restricted to the vagina, but has been reported in other parts of the female reproductive tract as well: remodeling of the innervation has been described in the rodent and human uterus during the estrous cycle and during gestation. Estrogen seems to be a major factor, but not the only one, determining the level of innervation during the reproductive cycle [58]. Interestingly, four independent studies reported vestibular neural hyperplasia in women with vulvar vestibulitis, which might provide a morphological explanation for the vestibular hyperalgesia reported by these patients [54, 59-61]

d) Sexual Pain

Pain arising from within the pelvis and pelvic floor involve diverse neuronal mechanisms, although there are some general characteristics. In general, sensations from the pelvic viscera are conveyed within the sacral afferent parasympathetic system, with a far lesser afferent supply from thoracolumbar sympathetic origin [62]. Receptive fields in the perineum are understood to be carried out primarily by sensory-motor discharges associated with pudendal nerve afferents [62, 63]. Entrapment of the pudendal nerve has been considered as one of the causes of urogenital pain [64]. While the interactions of sensory afferents are quite complex, likely possibilities by which these pathways exert effects on autonomic efferent function include mediating effects on spinal cord reflexes and modulatory effects on efferent release in peripheral autonomic ganglia and in peripheral organs.

2. NEUROCHEMISTRY

An elaborate neurochemical coordination of all components of the central and peripheral nervous systems is necessary for the performance of autonomic and somatic events in the pelvis. As indicated previously, the inferior hypogastric plexus represents the major neuronal center in the pelvis providing a relay station for interconnecting nerve pathways, but it also represents a critical integrative site for the neurochemical influences operative in the pelvis [36, 63, 65]. The structure contains multiple subpopulations of cells, defined by their putative neurotransmitter contents, and displays a highly specialized synaptic organization and system of signal processing. For example, while cholinergic preganglionic neurons provide a primary excitatory input to cholinergic postganglionics, postganglionic nicotinic receptors can provide feedback inhibition on preganglionic acetylcholine release. Similarly, noradrenergic sympathetic fibers synapsing on cholinergic postganglionic neurons or interneurons in the inferior hypogastric plexus impede cholinergic synaptic transmission [63]. In fact, neuropeptides, purines, kinins, monoamines, and amino acids, as well as local factors such as prejunctional muscarinic receptors and non-neuronal endothelins, may all serve as co-transmitters or neuronal modulators of classical neurotransmitter (acetylcholine and norepinephrine) release. A major sensory role for urothelially released ATP acting via P2X3 receptors on a subpopulation of pelvic afferent fibers has been documented in P2X3 knockout mice [66].

Surprisingly, there had been little focus on neurotransmitters in the vulvo-vaginal area. However, recently several reports have been published both in animal models and in humans. In rabbits hypothalamic neuropeptides have a contractile and relaxant effect on vaginal strips and arteries [67]. In female rats estradiol down-regulates estrogen-receptor alpha and up-regulates progesterone-receptor expression in the vagina [68]. Several studies have focused on steroid receptor expression in the vaginal epithelium and in the vulvar vestibular mucosa as a function of hormonal contraceptives and the menstrual cycle. Steroid-receptor expression in human vaginal epithelium was altered by long-term use of depot medroxyprogesterone acetate injections. The relation to other types of contraceptives did not show a clear picture and there were no differences observed between the follicular and luteal phase samples [69]. Estrogen-receptor beta was more abundant in the vulvar vestibular mucosa of women using combined oral contraceptives (COC) than in women without COC use. During the menstrual cycle, progesterone-receptor B was more abundant in the stromal tissue of the vulvar vestibular mucosa in the follicular phase than in the luteal phase in healthy women [70]. In women with PVD, there was a higher expression in estrogen-receptor alpha in the vulvar vestibular mucosa, but the epithelial morphology seemed unaffected [71].

CGRP, a neuropeptide known to exist in nociceptive afferent nerves, was the only neuropeptide detected in the superficial nerves of the vestibular epithelium in an earlier study by Bohm-Starke et al [72]. Afferent nerve distributions within the vascular and nonvascular smooth muscle of the vagina contain the neuropeptides galanin, and substance P [65, 73] while extensions into the epithelium and between epithelial cells primarily contain substance P and CGRP [73]. Studies using vestibular biopsy tissue from patients with PVD have demonstrated an increase in vanilloid receptor TRPV1 (a receptor expressed by nociceptors) innervation as compared to controls [74].

Clitoral and vaginal vasodilation is generally associated with parasympathetic vasodilator mechanisms, among which acetylcholine, VIP, and nitric oxide appear to be contributing neurotransmitters [73, 75]. Flaccid genital organ states appear to be tonically governed by adrenergic and possibly peptidergic sympathetic mechanisms [76]. It is contended that parasympathetic mechanisms also account for
vaginal fluid transudation, which accompanies vaginal vasodilatation, and that neuropeptides are primary candidates for this regulatory function [65, 77, 78].

These recent studies on neurochemical substrates in the female urogenital area provide a basis for future research on peripheral neurochemical mechanisms involved in the etiology of the sexual pain and sexual arousal disorders. There is already an impressive body of literature on visceral nociceptive processing and potential novel drug targets [79, 80]. Future studies could extend these findings to sexual pain and arousal disorders and might lead to the identification of peripheral targets for treatment.

**III. CHRONIC PAIN PHYSIOLOGY AND SEXUAL PAIN DISORDERS**

1. CURRENT NEUROMATRIX THEORY OF PAIN

Pain is a complex sensation involving sensory-discriminative (localization of the stimuli, detection of intensity and quality discrimination), affective-motivational (encompassing emotional reactions, an arousal and selective attention to the painful stimuli) and cognitive-evaluative aspects (anticipation, attention to the painful stimuli and comparison with past experience) (Grade C) [81].

The classical pain theory that has been established over the last 40 years states that there are two parallel pain processing systems operating at a cortical and subcortical level; the lateral and medial pain systems [81]. The lateral pain system, comprising the lateral projections of the spinothalamic tract, is also termed the neospinothalamic pathway. This pathway projects to the lateral thalamic nuclei and subsequently to the primary and secondary somatosensory cortex, and also to the parietal operculum and the insula. By contrast, the medial pain system, also termed the paleospinothalamic pathway, projects to the intralaminar and medial thalamic nuclei and further to the anterior cingulate cortex, insula, amygdala, hippocampus, and hypothalamus; the spinoreticular tract projects to the parabrachial nucleus and the locus coeruleus, and the spinomesencephalic tract projections to the periaqueductal grey matter. Whereas the lateral pain system is mainly associated with the sensory-discriminative aspects of pain processing, the medial pain system plays a crucial part in the motivational-affective and cognitive-evaluative aspects of pain processing, memory for pain, and the autonomic-neuroendocrine responses [82, 83].

The neuromatrix theory of pain proposes that pain is a multidimensional experience produced by characteristic “neurossignature” patterns of nerve impulses generated by a widely distributed neural network the "body-self neuromatrix" in the brain. This theory suggests a new conceptual framework for understanding chronic pain disorders. It proposes that the output patterns of the body-self neuromatrix activate perceptual, homeostatic, and behavioral programs after injury, pathology, or chronic stress. Therefore, pain results from the neural network in the brain rather than directly by sensory input evoked by injury, inflammation, or other pathology (Grade C) [84].

2. NEUROGENIC INFLAMMATION

It is of interest that there are several urogenital and pelvic pain syndromes in which pain seems to be related to an inflammatory etiology: interstitial cystitis, irritable bowel syndrome, prostatodynia (prostatitis) and PVD. However, despite numerous research efforts, no causes for such inflammatory changes have been identified thus far. It has been suggested that the pathological changes in PVD occur at three interdependent systems (See Figure 2) including the vestibular mucosa, pelvic floor muscles and central nervous system (Grade B) [85].

![Figure 2](image_url)

**Figure 2.** Neurogenic inflammation is thought to be involved in the pathogenesis of numerous conditions including chronic pain such as osteoarthritis, migraine, dental disease, pancreatitis, virus-associated respiratory infection, nonproductive cough, allergic rhinitis, asthma, chronic bronchitis, sarcoidosis, inflammatory bowel disease, rheumatoid arthritis, and painful conditions in general [86-91]. Recent evidence indicates that neurogenic inflammation plays a role in the development of pelvic pain disorders (e.g., interstitial cystitis [92-95]), which suggests that PVD is probably multifactorial.

The relationship between the inflammatory process and the nervous system is two-fold. The nervous system is activated by inflammation processes which cause inflammatory pain. Conversely, the nervous system reacts to the peripheral process by activating primary afferent fibers and subsequent neurogenic
inflammation. In these conditions, an initial nervous system dysfunction or injury may trigger the neural release of inflammatory mediators and subsequent neurogenic inflammation. This neuro-inflammatory process is believed to be mediated by the release of vasoactive peptides such as substance P, neurokinin A, and calcitonin-gene-related peptide (CGRP). These inflammatory mediators trigger vasodilatation, extravasation of proteins, and release of bradykinin and nitric oxide. These mediators can also cause degranulation of peripheral mast cells which, in turn, releases histamines and serotonin, causing a long-lasting lowering of nociceptive thresholds (i.e. peripheral sensitization [96]).

Given that there is no direct evidence for inflammatory changes in PVD and that, under certain circumstances, non-noxious stimulation evokes pain, it is possible that additional mechanisms are involved. Recent studies suggest that such pain syndromes are associated with hypersensitivity to both visceral and somatic stimuli (Grade B). Thus, enhanced or altered pain sensitivity arising from within the viscus at the peripheral or central level may play a role. Over time, afferent signals from both primarily affected viscera and secondarily sensitized nociceptors lead to increased afferent excitability and central sensitization to facilitate chronic pain disorders [97, 98]. It may be assumed that such inflammation-evoked processes lead to plasticity in pain modulation pathways and chronic pain.

In visceral pain conditions, neurogenic inflammation may also appear to be an important mechanism in referred pain [99]. For example, pain of acute myocardial infarction may sometimes induce a left scapulohumeral periarthritis, an inflammatory condition in the referred zone [100]. It could be hypothesized that neurogenic inflammatory mechanisms in the referred zone might play a role in interstitial cystitis and vulvodynia, vulvodynia, or pelvic pain in which an inflammatory painful condition develops in the referred zone (the urogenital floor) of the urinary bladder or the pelvis. Evidence for neurogenic inflammation in the somatic referred zone triggered by inflammation of a viscus has been demonstrated in an animal model of uterine pain in the rat, supporting the above hypothesis [101]. In humans, the increasing evidence that most of the urogenital and pelvic pain syndromes occur together in some women over time support also this hypothesis [102]. Neurogenic inflammation may result from changes at the local/peripheral level but also reflect changes at the central level. Quantitative sensory testing (QST) studies that involved the application of various modalities of experimental noxious stimuli to evaluate A-β fiber function revealed altered pain processing in visceral pain conditions. According to most of these studies enhanced pain perception at the local as well as the systemic level exists [103, 104]. Local hypersensitivity was found in PVD women via increased innervations and/or sensitization of thermoreceptors and nociceptors in their vestibular mucosa [105-107] add more references). Nevertheless, more and more studies support the role of enhanced systemic pain response to noxious stimuli applied to remote body areas, indicating that there might be general hypersensitivity in those patients. In this line, low pain thresholds, high magnitude estimation of supra-threshold stimuli and altered central sensory processing have been observed [108-111]. Enhanced response to punctate hyperalgesia and dynamic allodynia evoked by capsaicin injection extending far beyond the anatomic location of the primary complaint provide an additional support for the role of systemic hypersensitivity in PVD [112]. In this line, the augmented pain response to supra-threshold stimuli applied to the forearm in PVD women has been also found to be associated with lower efficacy of treatment [113]. Moreover, Bohm-Starke et al. [114] noted increased vestibular pain thresholds, reduced dyspareunia, and improved bodily pain in women with PVD versus control women in response to various treatments. However, despite the improvement of the superficial dyspareunia the general hypersensitivity was not affected by the treatment. These studies suggest that pain mechanisms in PVD (and probably other pelvic pain disorders) cannot be solely attributed to neurogenic inflammation occurring at the local level (Grade B).

Ness et al [115] also suggests altered central mechanisms in the processing of sensory events from the bladder of interstitial cystitis (IC) patients who demonstrated hypersensitivity to somatic stimuli applied to deep tissue at the forearm and the bladder. Similarly, generalized cutaneous hypersensitivity to thermal or vibratory stimulation among painful bladder syndrome (PBS) patients has been found [98]. Warren et al. examined IC/PBS patients and concluded that multiple sites of pain (including pain in the genital area) in the same patient could be attributable to a single illness [116]. Central sensitization probably explains the multiplicity of pain sites in patients with IC/PBS.

The role of alterations in central pain processes is also supported by other psychophysical studies. Recently, a brain imaging study using functional magnetic resonance imaging (fMRI) in PVD women indicated that painful genital stimulation led to increased activation of brain areas associated with pain modulation (limbic and sensory brain regions) as compared to control women [111]. In addition, a second study by the same group [117] showed morphological alterations in supra-spinal pain modulation areas in women with PVD. Specifically, women with PVD had greater gray matter density in the parahippocampal gyrus/hippocampus and basal ganglia as compared with non-affected women.
3. NEUROPATHIC PAIN: CENTRAL AND PERIPHERAL MECHANISMS

The accumulative reports that suggest systemic hypersensitivity to noxious stimuli raise the issue of whether pain that is attributed to neurogenic inflammation can also be considered as part of neuropathic pain. It may be assumed that nerve injury associated with neurogenic inflammation leads to non-reversible changes that represent the clinical picture of neuropathic pain. There is experimental evidence from several QST studies, suggesting that neuropathic pain mechanisms might be involved in PVD [105, 107, 112, 114, 118, 119]. Nevertheless, most of the PVD patients report spontaneous or provoked pain with no other symptoms of neuropathic pain such as paraesthesias and dysesthesias. It may be assumed that PVD (and other related pain conditions) encompass both mechanisms of neurogenic inflammation as well as neuropathic pain, the combination of which may lead to the development of these disorders in patients with less efficient pain modulation processing.

There is general consensus today that both peripheral and central nervous system mechanisms play a role in neuropathic pain [120]. Briefly, neuropathic pain is typically characterized by spontaneous paraesthesias, dysesthesias, and by evoked pain (for example, pain provoked by mechanical stimuli, such as the pain elicited by tampon insertion or sexual intercourse in patients with PVD). Under normal conditions, pain is experienced when impulses reach the brain via A-delta-fiber or C-fiber nociceptive afferents. Minor tissue injuries can cause a reduction in the threshold of nociceptors, resulting in “peripheral sensitization”. This change in threshold is caused by the release of chemical inflammatory mediators into the tissue. Sensitized nociceptors respond to weak, non-noxious stimuli - a clinical phenomenon called “alldynia”. Further, noxious stimuli result in an exaggerated pain response - “primary hyperalgesia”, in which the magnitude of pain sensation no longer matches the intensity of the noxious stimulus. Psychophysical tests reveal lower pain thresholds at the vestibule. In addition, the differences between threshold and supra-threshold pain sensitivity at the vestibulum region among women with moderate and severe PVD support the clinical picture of peripheral sensitization, suggesting that PVD is compatible with the definition of neuropathic pain condition [107, 121].

The clinical phenomena of alldynia and hyperalgesia can also be due to abnormal signal amplification of dorsal horn cells in the CNS, a process called “central sensitization”. In the presence of central sensitization, signals entering the CNS via non-nociceptive A-β touch afferents may evoke pain. The exact mechanisms that lead to increased descending excitatory signals and/or decreased inhibitory signals and their role are unclear. Although most PVD women are characterized more by provoked pain and less by paraesthesias, and dysesthesias, the role of a neuropathic pain origin should be considered in the pathogenesis of this pain disorder.

It is not clear whether an enhanced or altered systemic pain response leads to greater neurogenic inflammation response after stress or injury at the local level, or if an exposure to noxious events leads to central sensitization that, in turn, leads to greater pain sensitivity. The typical initiation and exacerbations of the pain of PVD after severe stressful life events fits the model of central sensitization [117]. The existence of pain in other body sites and the reports of other idiopathic pain disorders in PVD patients emphasizes the complexity of this issue [122].

A major modulation process of endogenous analgesia is exerted by the descending endogenous analgesia system, and includes the spinal-bulbo-spinal pain inhibition mechanism which is responsible for the ‘pain inhibits pain’ phenomena termed ‘diffuse noxious inhibitory control’ (DNIC). Impairment of DNIC (obtained via experimental pain tests) has been suggested in various chronic pain conditions with a female predominance, such as fibromyalgia and temporomandibular disorders. The role of dysfunctional central pain modulation and altered mechanisms of endogenous analgesia has been also been proposed in PVD. Recently, Johannesson et al., [123] suggested a systemic hypersensitivity in women with PVD that may support the role of altered endogenous pain modulation in PVD women. A similar approach has been reported in patients with IC [124]. Thus, it may be assumed that the less efficient pain modulation processing contributes to the development of hypersensitivity and to chronic neuropathic changes which characterize pelvic pain disorders.

IV. VULVOVAGINAL DISORDERS AND SEXUAL PAIN

1. INTRODUCTION

Disorders of genital skin and mucous membranes are common and many interfere with sexual contact causing pain (Grade A). Most of these painful disorders are transient and are caused by inflammation from acute genital infections. Infections that most commonly cause vulvo-vaginal inflammation include acute episodes of candidiasis, trichomonas, genital herpes, human papilloma virus infection (HPV), furuncles, and infection of the greater vestibular glands. The cause of the acute inflammation usually is readily discernable by the clinician and treatment usually resolves both the inflammation and the pain.
Chronic genital pain is more problematic because the causes are often difficult to discern. A comprehensive review provides a systematic approach to vulvar disease and offers a detailed list of diseases to consider [125]. Vulvar dermatoses are chronic inflammatory conditions, frequently affecting the vulvar skin and mucosa. A deficiency in the autoimmune system is thought to be the major etiologic factor (Grade B) and most dermatoses respond to topical corticosteroids [126]. However, depending on what area of the vulva is affected and the severity of the condition, pain and dyspareunia are common symptoms. Genital infections such as candidiasis, herpes and bacterial vaginosis have high recurrence rate and might also lead to chronic pain and discomfort in young sexually active women.

Unfortunately, iatrogenic inflammation of the vulvar skin is common from self-treatment or contact with irritants [127]. Nearly all women with chronic vulvar symptoms first use over-the-counter anti-fungal medication (Grade B). This self-treatment may be associated with increased duration of symptoms, which suggests a detrimental effect from the medication [128, 129].

2. VULVODYNIAS

a) Generalized Vulvodynia

Generalized vulvodynia may be provoked or unprovoked. The pain is usually described as burning and may affect the major part of the vulva [3, 130, 131]. In the unprovoked form, pain is not aggravated by physical or sexual contact. Here all the vulvar structures are of normal appearance and no obvious underlying causes are found. Women with generalized vulvodynia are often older than women with PVD, but data on incidence and prevalence are scarce. Furthermore, these data are often included under the general term vulvodynia, not separating the generalized and localized form [132, 133]. As compared to PVD, less research has been conducted and the underlying pain mechanisms are not fully understood. The symptoms of continuous burning pain and discomfort share many common features with neuropathic pain conditions. The syndrome might be difficult to treat. Therapies using tri-cyclic antidepressants or anticonvulsants usually offer alleviation, but not always a resolution for the pain [134].

b) Provoked Vestibulodynia (PVD)

PVD represents one of the most common causes of genital pain and pain with intercourse in premenopausal women. Pain is usually noticed with attempted vaginal penetration, although in more severe cases, pain will be present with other activities like sitting or running as well. Besides pain, a sensation of vulvar burning may occur. These symptoms cause physical, sexual, and psychological distress (Grade B) [135]. Primary PVD is defined as superficial dyspareunia ever since first intercourse attempt, whereas secondary PVD occurs after a period of pain free vaginal penetration. It has been suggested that these two subgroups differ in etiological, clinical and genetic variables (Grade C) [108, 136-139].

Community studies suggest vulvar pain is common, but the prevalence varies widely from 3-18% [133, 140]. PVD has been described in up to 15% of gynecologic outpatients and was thought to primarily affect Caucasian women [141-143]. A recent survey of ethnically diverse women gave similar lifetime prevalence rates of chronic vulvar burning or pain on contact [144].

Although PVD is easy to diagnose for the experienced clinician, the mean time between the onset of symptoms and diagnosis usually reaches two years or longer. Diagnostic criteria were initially defined for the former vulvar vestibulitis syndrome, but these criteria are still used for PVD: 1) pain with penetration during vaginal intercourse; 2) tenderness of the vestibular area upon even light touch with a cotton applicator; and 3) variable erythema of the vestibular area [145]. Symptom duration of at least 3-6 months is also usually included as a criterion. The areas of allodynia (sensation of pain from a light touch stimulus) are typically between 4 and 8 o'clock on the introitus, just exterior to the hymeneal ring [105]. However, in severe cases the hypersensitivity may involve the mucosa around the whole introital ring, including the openings of the Skene's ducts, and may extend laterally to labia minora [109, 118].

1) ETIOLOGY

No single causative factor has yet been identified for PVD and the etiology is considered multi-factorial (Grade B). Most probably a vast number of "triggers" may initiate the pain and if not taken care of properly, a more or less chronic pain condition might develop. A combination of causes might include psychosocial factors as well as more obvious physical trauma to the tissue such as recurrent infections. The pain mechanisms involved are in detail described in the paragraph on "Chronic pain physiology and sexual pain disorders". The most important etiological factors will here be discussed.

2) INFLAMMATORY REACTIONS

It has been proposed that PVD may represent a chronic local inflammatory condition with a wide variety of etiologic causes (Grade B). T-cell lymphocytes make up most of the inflammatory cells present in vulvar biopsies obtained from those with PVD [146, 147]. The infiltration is located in the subepithelial part of the lamina propria and is described as a non-specific chronic inflammation by pathologists. Plasma cells indicative of ongoing chronic infection are present, but not in large numbers. Mast cells and eosinophils indicative of an allergic condition are less common. However, similar infiltration of inflammatory cells
is also seen in healthy women and cannot serve as a histological indicator of PVD [60, 148]. Two studies on pro-inflammatory mediators have been published with conflicting results. Foster and Hasday found elevated tissue levels of interleukin I-ß (IL-1) and tumor necrosis factor alpha (TNF-α) in vulvar tissue of patients with PVD, but these pro-inflammatory mediators were actually at higher levels in the surrounding vulvar tissue than in the area of inflammation, confirming the clinical finding of a wider area of involvement beyond the area of erythema [149]. These results were not supported in a study by Eva et al, who did not find any differences between patients and controls regarding these mediators [150].

The two inducible enzymes nitric oxide synthase (iNOS) and cyclooxygenas 2 (COX 2) are hardly detectable in the skin and mucosa under normal conditions. However, its expression increases in response to various mediators released at the site of inflammation [151, 152]. COX 2 and iNOS are not up-regulated in biopsies obtained from the vestibular mucosa in women with PVD as compared to healthy controls. This finding is inconsistent with an ongoing cell-mediated inflammation and also explains why corticosteroids are not helpful for PVD [130, 153].

3) Infections and antigen

If a possible antigen has induced PVD for an individual, it could still be present in vulvar tissues in a small concentration, or the antigen could have stimulated an inflammatory response but be gone by the time patient usually presents with PVD. The most likely antigen candidate would be from microbes that commonly affect the vulva. Human papillomavirus (HPV) was first considered, but in multiple studies, HPV was as common in controls as women with PVD [154-157]. Herpes simplex virus (HSV) is also a common vulvar infection, but, to date, HSV does not appear to cause PVD [54, 158]. Bacterial vaginosis (BV) with an overgrowth of vaginal bacteria is also a common cause of vaginitis in young women [159]. According to case-control studies, women with PVD are more likely to report a history of BV than asymptomatic controls (Grade B) [160-162].

Candida is an antigen present in the vulva more frequently than HPV or HSV. Up to 75-80% of women develop symptomatic candidiasis during their lifetime [163]. Patients with PVD in many cases have a history of candidiasis, often recurrent [160, 164]. Candida might be identified by potassium hydroxide wet mounts, which require about 105 microbes to be positive. Candida is often isolated on culture from women with PVD, although extensive comparisons with control groups are lacking [160, 164]. Some patients with chronic recurrent vulvovaginal candidiasis (VVC) are noted to develop PVD when they are prospectively followed. Further, some women relate the onset of PVD to an acute episode of VVC and patients cured of PVD often develop recurrent genital pain when another episode of VVC occurs. Recently a new promising animal model of vulvodynia has been developed using repeated candida infections to produce dyspareunia in the mouse [165].

According to one study, a subset of PVD women is sensitized to seminal fluid. Thus, allergic reaction to seminal fluid may initiate pain symptoms in some women [166]. Undoubtedly, other microbial antigens from bacteria, viruses, or other microbes or non-microbial antigens that are present in the environment or in chemicals that come in contact with vulvar skin could also cause PVD.

4) Genetics

Recent work points to a possible genetic involvement [167, 168]. In fact, as is common for inflammatory conditions, allele 2 of the IL-1ß gene was found in significantly more women with PVD (40%) than controls (25%) [169]. In yet another study, an association of primary PVD and gene polymorphism of the mannosebinding lectin (MBL) gene was reported together with a reduced capacity for TNF-α production in response to microbial components in patients [137]. It has also been suggested that women with fair skin are more susceptible to PVD. An increased risk of PVD was found in cases with polymorphism of the melanocortin-1 receptor (MC1R) gene in a retrospective case-control study [170].

5) Hormonal influence

The first modern report of women suffering from PVD appeared in 1976, approximately 10-15 years after combined oral contraceptives (COCs) were introduced in the US. However, when reviewing historic medical texts, vulvar hypersensitivity without obvious infectious or dermatological etiology was described in the European and American textbooks of gynecology over 100 years ago [171]. Since then, COCs have been modified to contain less ethinyl estradiol and various progestins. A possible etiological correlation between COCs and PVD has been investigated in various epidemiological studies. In a clinic-based study from 2002, the results showed a 6.6 relative risk of PVD (95% confidence interval 2.5 - 17.4) for ever-users of OC compared to non-users. When OCs were used before the age 16, the relative risk reached 9.3 and increased with the duration of OC use up to 2-4 years. The relative risk was higher when the pill used was of high progestogenic, high androgenic, and low on estrogenic potency [172]. These findings were not, however, confirmed by a population-base case-control study from 2008 [173].

The hormonal effect of COCs on genital mucosa has mainly been studied in the endometrium. Recently, it was observed that the vestibular mucosa of healthy women on COCs undergoes changes compared to non-users [70]. The dermal papillae become
shallow and sparser which might result in a more fragile and sensitive mucosa [174]. It has also been reported that women without dyspareunia who use COCs have lower vestibular pain thresholds to mechanical stimuli [106]. These findings are thought to be reflective of a gestagenic effect, and they support the data of an increased risk of developing vestibular pain from using pills with gestagenic potency. However, more data are needed. The current recommendation is to continue to prescribe the pill when needed, but both users and prescribers should be aware of side-effects such as dryness, soreness and pain [174].

Results from studies investigating the expression of estrogen receptor alpha (ERα) in women with PVD are difficult to interpret. Initially, decreased expression of ERα in the vestibular mucosa was reported [175]. In a more recent but small study, biopsies were taken in the same phase of the menstrual cycle and a significant increase in ERα was found in patients compared to controls [159]. The clinical implication of these results suggests that topical estrogen might have a role in the treatment of PVD [71].

6) Psychosocial and sexual factors
Increased prevalence of comorbid psychopathology has been reported in women with PVD. In an etiological context, it is not clear how these findings relate to PVD since they might be considered either a cause or a consequence for different individuals. Psychological and sexual factors in PVD will be discussed in detail in the section on “Psychological aspects of sexual pain disorders”.

3. CHRONIC VULVAR DERMATOSES
A wide variety of chronic vulvar skin conditions can cause sexual pain both intermittently and continuously. While not common in the general population, lichen simplex chronicus, lichen sclerosis, and lichen planus can cause chronic vulvar inflammation and, hence, vulvar pain [125, 176, 177]. The diagnosis of these conditions can be easily discerned by experienced clinicians. Lichen simplex chronicus originates from chronic scratching, which produces inflammation of the skin and results in an itch-scratch cycle. The cycle can be interrupted by topical steroid and oral antihistamine therapy [178]. Lichen sclerosis is an indolent chronic condition of unknown etiology. The clinical signs are characteristic white hyperkeratotic papules and plaques of the vulvar skin. The areas most often affected are the clitoris which becomes buried, the labia minora (which disappear), and the perineum. Underlying subepithelial inflammation results in mild to intense itching and the first line treatment is potent topical steroids [179]. Erosive lichen planus usually affects the vulvar mucosa. Superficial ulcers and erosions of the superficial epithelium may develop, often resulting in intense pain and itch. Patients can have concomitant vaginal mucosal inflammation that results in a profuse, irritating vaginal discharge. Often, patients with lichen planus have evidence of inflammation in other mucous membrane areas such as ulcers of the gums, esophagus, or bowel in a Behcet-like syndrome. Prolonged topical steroid, topical tacrolimus (an inhibitor of interleukin-1) or other anti-inflammatory therapies are needed of the ulcerated and inflamed areas [180]. Raised vulvar lesions usually do not cause pain but must be accurately diagnosed and treated.

4. GENITAL INFECTIONS
a) Candidiasis
Episodic vulvovaginal candidosis is a very common genital infection in fertile women. Approximately 5-8% of women will experience recurrent vulvovaginal candidosis infections (RVVC), defined as at least 4 episodes every year [163]. The infection generates an inflammatory response in genital skin and mucosa. Cell-mediated immunity is the predominant host defense against RVVC but the innate immune system is also thought to play a major role in the defense mechanisms [181, 182]. Uncomplicated infections are treated with either topical or oral antifungal medication. Management of recurrent infections is more problematic and might require weekly administration of oral antifungals over a period of 2-3 months for clearance [125]. Candidiasis is considered risk factor for PVD, although the cause-and-effect relationship has not been proven [161, 183]. Women with PVD often report a history of vulvovaginal candidosis, and frequent use of topical and oral anti-fungal treatments has, in many cases, preceded the onset of dyspareunia. After treatment, the characteristic white sticky discharge and itch disappear, but the stinging pain at contact may remain. Lately, over-the-counter topical anti-fungals have been discussed as frequent use may cause an irritation of the vulvar tissue; furthermore, it has been shown that only one-third of women purchasing the medications actually have candida [126]. In the clinical setting, it is important to rule out or treat a concomitant candidiasis infection in women with PVD.

b) Human papillomavirus (HPV)
Detection of HPV infection in the vulva may be difficult. Condyloma acuminata is easy to detect, whereas subclinical HPV infections appearing as aceto-whitening lesions or as papillomatosis are more controversial [184]. Exophytic genital warts found predominately on the labia minora, vestibule, fourchette, perineum, and perianal areas are usually not painful. The warts are manifestation of low-risk HPV infection and may clear spontaneous after a period of time. In more persistent infections, itch and pain from fissures in the affected areas may occur. Current methods for treating HPV lesions include cryotherapy, immune
stimulation with imiquimod and laser and surgical debulking. Virtually all of these methods are painful, irritating, or both. Much caution regarding treatment choice and performance is recommended [185].

c) Herpes simplex virus (HSV)

The most common etiology of ulcers in the lower genital tract is HSV 1 and 2. Primary infection presents with multiple and painful ulcerations [125]. Inguinal lymphadenopathy, fever and malaise may coexist with the ulceration. Recurrent lesions are usually less severe, but might be more difficult to diagnose. For women with frequent recurrence, the infections may severely interfere with sexual activity. Antiviral therapy is used for acute symptoms and prophylactic treatment.

d) Bacterial vaginosis (BV)

BV is the most common cause of vaginitis in fertile women. It causes profuse and fishy-smelling discharge. The condition is characterized by decrease in hydrogen peroxidase-producing lactobacilli and an overgrowth of bacterial species that are part of the normal flora of the vagina, including Gardnerella vaginalis, Mobiluncus spp., Mycoplasma hominis and a variety of anaerobic bacteria [186]. BV may occur and remit spontaneously. Although BV requires no treatment in asymptomatic non-pregnant women, it has several serious medical consequences in pregnant women, such as preterm delivery. In addition, it increases the susceptibility to sexual transmitted diseases, including HIV [159]. Profound vaginal discharge with extensive use of hygiene pads may irritate the vulvar skin and mucosa. In three case-control studies, BV was identified as a risk factor for PVD [160-162].

5. VULVAR DYSPLASIA

During the last 30 years, the incidence of vulvar intraepithelial neoplasia (VIN) has significantly increased, particularly in younger women. The symptoms may vary from an incidental finding during a gynecological examination to pruritus, soreness and/or dyspareunia. The lesions demonstrate diversity in clinical features and may affect both the vulvar skin and mucosa. Common findings are white, slightly raised lesions, sometimes with a wart-like appearance with or without pigmentation that might be mistaken as condylomas. Most lesions are visible to the naked eye but magnification with a colposcope, using an application of 5% acetic acid, is usually helpful [187]. It has been recommended to divide VIN in two groups: VIN usual type and VIN differentiated type. The usual type occurs predominantly in younger women and is related to HPV infection. These lesions are often multifocal, causing chronic irritation and soreness. The differentiated type is less common and is seen in older women, often in association with lichen sclerosus or planus. These lesions are important to discern as they have a greater malignancy risk [188]. Lichen sclerosus lesions that do not clear should be biopsied.

VIN has an invasive potency that is likely rather low. However, many lesions need to be excised or treated. In younger women with usual type VIN, much caution should be taken in trying to avoid vulvar scarring which might cause dyspareunia.

6. UROGENITAL ATROPHY

Symptomatic estrogen deficiency affects approximately 40% of postmenopausal women (Ref). Other causes of estrogen loss than the natural menopause are bilateral oophorectomy and chemotherapy which might result in reduced ovarian steroid-hormone production. Another group of patients to be aware of are women treated with radiotherapy for gynecological malignancies. The major complaints are dryness, vaginal irritation and dyspareunia, but urinary symptoms are also common. Urogenital atrophy due to estrogen loss causes several physiological changes of the vaginal mucosa. The epithelium becomes thin and the normal rugation is lost. Vaginal fluid secretion decreases and becomes more alkaline (pH ≥ 5) and there is an increased susceptibility to infections. Systemic or local estrogen replacement treatment, if not contradicted, usually provide rapid symptomatic relief and the physiological changes can partially or completely be restored [189].

V. PELVIC FLOOR AND SEXUAL PAIN DISORDERS

NORMAL PELVIC ORGAN SUPPORT

In normal conditions, pelvic organs are supported by the pelvic floor musculo-fascial complex (See Figure 3). Pelvic floor muscles, also called levator ani muscles (LAM) are divided in an anterior part, the pubo-visceralis and pubo-coccygeus muscles and a posterior part, the ilio-coccygeal and coccygeal muscles. The vagina, urethra and anal canal pass across the genital hiatus formed by the pubo-visceralis muscle. Posteriorly, pelvic floor muscles form a horizontal shelf called the levator plate on which pelvic organs can rest. Levator ani muscles are covered on their internal surface by a layer of connective tissue called the endopelvic fascia (EPF) that supports pelvic organs and anchors them to the pelvic sidewall.

1. PELVIC ORGAN PROLAPSE (POP)

Pelvic organ prolapse (POP) happens when LAM are weakened and the EPF is distended or torn. Bladder and urethra are in close contact with the
anterior vaginal wall. Anterior vaginal prolapse is also called a cystocele or a urethrocele depending on which organ is descending. Similarly, a rectocele or posterior vaginal prolapse is caused by a defect in the posterior EPF layer. Vaginal vault prolapse is caused by a defect in apical ligaments such as uterosacral and cardinal ligaments.

POP is a prevalent condition among women, with about 10% of the female population requiring surgical correction for POP [190]. Swift et al. [191] demonstrated that about half of parous women presented some degree of vaginal relaxation. Pelvic organ prolapse symptoms include dragging pain, vaginal bulging or exteriorization and may be associated with urinary incontinence.

Anterior vaginal prolapse surgical repair involves either direct suture of the anterior EPF through an anterior vaginal incision or by reattaching lateral vagina to the pelvic sidewall. New techniques involving the insertion of a synthetic mesh or xenografts have been developed to decrease the recurrence rate.

Abdominal or laparoscopic sacrocolpopexy is one of the most efficient procedures to treat vaginal vault prolapse [192]. It involves placement of a synthetic mesh between the vaginal apex and the sacral promontory. Complications include erosion of the adjacent organs such as the rectum or ureter. Other procedures have been described through the vaginal route involving a suture between the vaginal wall and the sacro-spinous ligament [193], the pre-spinous fascia [194] or the utero-sacral ligaments [195]. The vaginal route is preferred when correction of other compartments is required.

Correction of the posterior compartment involves a repair of the posterior EPF and reinforcement of the perineum. The perineum is repaired by suturing the perineal membrane (perineorrhaphy) or by levator ani muscle plication. The latter gives excellent anatomic results at the expense of a high rate of dyspareunia [196]. Use of mesh in the posterior compartment is controversial given the excellent results (85-90%) of traditional repairs. A randomized trial by Milani et al. [197] comparing the traditional levator plication with and without mesh reinforcement concluded that dyspareunia was significantly more frequent after mesh usage, although other authors found opposite results in non-randomized trials [198].

2. DYSPAREUNIA

a) Sexual function in women with POP and/or urinary incontinence (UI)

A few studies have specifically addressed the issue of sexual function in patients with pelvic floor dysfunction [199-203]. In these studies the proportion of sexually active patients varied from 56 to 68.6%. Sexual function does not seem to be affected by POP. Age is found in two studies to be the major factor impacting on declining sexual function. Dyspareunia did not vary by grade of prolapse although increasing grade of prolapse predicted interference with sexual activity. UI significantly affects sexual function especially when coital incontinence is present (45% of patients with UI).

b) Sexual function after pelvic floor surgery

A multicenter prospective trial [204] comparing sexual function measured by the Pelvic Organ Prolapse/Urinary Incontinence Sexual Questionnaire (PISQ) score [205] before and after surgery for UI (82.4%) and/or POP (76.5%) in 75 patients found that despite an improvement in continence, PISQ total scores declined significantly. While 29% of women had an improvement in sexual function, 71% reported lower
sexual function was improved in both groups [211]. Frequent in the posterior repair group although global repair with those who did not. Dyspareunia was more for PoP and compared those who had a rectocele.

More recently, a study compared patients operated plication to reconstruct the posterior compartment. From 18% to 27% postoperatively used levator authors reporting an increase in dyspareunia after defect specific or midline fascial plication. The latter procedure has been reported by several authors to create narrowing of midvagina with a high percentage of postoperative dyspareunia [208-210]. Dyspareunia appears to be improved from a mean of 31.8% preoperatively to 18.5% postoperatively either after defect specific or midline fascial plication. The only authors reporting an increase in dyspareunia from 18% to 27% postoperatively used levator plication to reconstruct the posterior compartment. More recently, a study compared patients operated for POP and compared those who had a rectocele repair with those who did not. Dyspareunia was more frequent in the posterior repair group although global sexual function was improved in both groups [211].

c) Anterior POP repair

One study [206] comparing three surgical techniques of anterior colorrhaphy found a reduction of dyspareunia from 30% preoperatively to 22% postoperatively. Colombo [207] found that 13 of 23 patients (56%) who had an anterior repair for urinary stress incontinence and cystocele had mild to severe dyspareunia after eight years follow up. However, all the patients also had a posterior colporrhaphy and perineorrhaphy at the same time so it is impossible to conclude that any one procedure is to blame. Care needs to be taken in combining anterior and posterior repair as this can cause mid-vaginal stenosis and create dyspareunia.

d) Posterior POP repair

Reconstruction of the perineum is an important part of posterior repairs. It involves either an approximation of the superficial perineal musculature or a LAM plication with suture of the pubovisceralis muscle. The latter procedure has been reported by several authors to create narrowing of midvagina with a high percentage of postoperative dyspareunia [208-210]. Dyspareunia appears to be improved from a mean of 31.8% preoperatively to 18.5% postoperatively either after defect specific or midline fascial plication. The only authors reporting an increase in dyspareunia from 18% to 27% postoperatively used levator plication to reconstruct the posterior compartment. More recently, a study compared patients operated for POP and compared those who had a rectocele repair with those who did not. Dyspareunia was more frequent in the posterior repair group although global sexual function was improved in both groups [211].

e) Vault prolapse

Vaginal vault prolapse can be repaired by the vaginal or abdominal route (sacrocolpopexy). Sacrospinous fixation is the most popular vaginal procedure. Sexual function after sacrospinous fixation can be altered either because of pain, vaginal narrowing or pudendal nerve function alteration.

Baessler and Schussler [212] found that dyspareunia ceased after sacrocolpopexy in all but one of nine patients (n=31) presenting with prolapse related dyspareunia preoperatively. At the same time, two patients developed pain at the mesh fixation points. Pilsgaard and Mouritsen [213] reported that none of the three patients (n=35) with preoperative coital impairment complained of this symptom postoperatively, whereas Virtanen et al. [214] found that 44% (7/16) complained of dyspareunia 3 years after abdominal sacrocolpopexy.

Two RCTs compared vaginal and abdominal approach for vaginal vault suspension with conflicting results. Benson [215] found that 15 of 26 (58%) patients in the sacrospinous group developed dyspareunia compared to 0 of 15 patients in the abdominal group, although this difference was not statistically significant. In contrast, Maher et al. [216] found no difference between the two groups (n=95), with 28% and 21% of patients who were not sexually active preoperatively resuming sexual activity. Preoperative dyspareunia was resolved in 56% and 43% in the abdominal and vaginal group, respectively. Dyspareunia developed de novo in two women in the abdominal and three women in the vaginal group.

Abdominal sacrocolpopexy seems to be superior to sacrospinous fixation regarding post operative dyspareunia.

f) Use of mesh for pelvic organ prolapse repair

Mesh erosions, mesh shrinkage and extensive fibrosis around the mesh may cause pain and dyspareunia. Synthetic and donor grafts are being increasingly used to reinforce vaginal repair to improve the long-term results and prevent prolapse recurrence. Dwyer and O'Reilly [198] reported their results using polypropylene mesh to reinforce anterior and posterior compartment repair in 97 women with recurrent or large vaginal prolapse. Dyspareunia decreased significantly postoperatively from 26% of women to 6% at 6 months, 8% at 12 months and 9% at 24 months. In three patients, the dyspareunia occurred de novo following surgery. These results are in contradiction with those of Milani et al. [197] who found a 20% increase in dyspareunia following anterior repair and 63% after posterior repair reinforced by polypropylene mesh. Several studies have shown increased or de novo dyspareunia happening after mesh usage for vaginal repair [217, 218]. To date, there is no evidence of clear benefit for the use of mesh in pelvic floor repair surgery. Dyspareunia seems to be a real concern and patients should be aware of this complication before surgery (Grade B) [219, 220].

g) Conclusions

POP is a frequent condition and may be associated with UI. Treatment should aim at improving quality of life rather than to restore anatomy so that conservative management should be offered before surgery. Patients should be thoroughly informed about potential deleterious impacts of the surgery on sexual function.
3. VAGINISMuS
Vaginal or pelvic loor muscle contraction or spasm
has long been considered the distinctive symptom
allowing for the differential diagnosis of vaginismus
from dyspareunia. However, this difference is debated
as several studies have shown that these entities
are dificult to distinguish [221, 222]. This has led to
a new deinition suggested by Basson et al. [223]:
“persistent or recurrent dificulties of the woman to
allow vaginal entry of the penis, a inger, and/or any
object, despite the woman’s expressed wish to do
so. There is variable (phobic) avoidance, involuntary
pelvic muscle contraction and anticipation/fear/
experience of pain. Structural or other physical
abnormalities must be ruled out/addressed”.
This new deinition encompasses dyspareunia
and vaginismus as a global entity although the
notion of muscular contraction is acknowledged.
The etiology of muscular spasm is not clear. Van
der Velde suggested that involuntary contraction
of pelvic loor muscles occur during exposure to
threatening situations [224] rather than to sexual
situations. Muscular contraction also takes place
in other muscle groups suggesting that it is part of
a global reaction to a situation felt as threatening.
Reissing showed that vaginal muscle spasm does
not characterize vaginismus and that different pro-fessionals diagnose spasm very differently [225].
Treatment of vaginismus has long been directed
towards relief of vaginal spasm by progressive
dilatation of the tightened vagina. Several meth-ods have been described including combinations
of systematic desensitization together with the use
of graded dilators; sex therapy, in which a gradual
approach is taken to overcoming the disorder, in-cluding education and cognitive therapy, relaxation
therapy, looding where the patient watches in a mir-ror while the therapist and then the subject inserts
a inger into the vagina. Other approaches include
pharmacotherapy, hypnotherapy, and Botulinum
toxin injections have also been reported. In review
of the Cochrane database about interventions for
vaginismus, only three controlled studies could be
included for analysis. They compared two forms of
systematic desensitization. In one study [226] both
groups received information and relaxation exer-cises. In the irst group, the physician introduced an
appropriately sized dilator. In the second group, the
physician provided verbal instruction for introducing
the dilator. The program included a desensitization
exercise and journal entries after each exercise. The
patients were told to perform the exercise for 10 to
15 minutes, ive times per week. Therapy sessions
were conducted every two weeks to follow and sup-port the progress made in the treatment. Throughout
sexual therapy, the patients were advised to refrain
from coitus. No difference was found between the
two forms of treatment. Until recently, there was only

limited evidence from uncontrolled trials and one con-trolled trial which lacked a waiting list group as con-trol to suggest that desensitization is an effective and
recommendable method to treat vaginismus [227].
A recent prospective trial [228] investigated the
effectiveness of therapist-aided exposure for
lifelong vaginismus. 10 women were evaluated
during 24 weeks. During exposure, patients
performed vaginal penetration exercises on
themselves, in the presence of a female therapist.
Nine of 10 participants reported having intercourse
after treatment, and in 5 of 9, intercourse was
possible within the 1st week of treatment. The
results were sustained at 1-year follow-up.
Botulinum toxin has been advocated by some
authors [229, 230] as an effective mean of relieving
muscular spasm associated with vaginismus. In one
uncontrolled study, Botulinum toxin (150-400 mIU)
was injected into the puborectalis muscles in 3 sites
on each side of the vagina to treat moderate to severe
cases according to the Lamont classiication [231].
Twenty-three patients (95.8%) had a vaginal
examination that showed no or little resistance, 18
(75%) achieved satisfactory intercourse after the
irst injection, 4 (16.7%) had mild pain, and 1 was
cured after a second injection. only one controlled
study [232] compared injection of 25 IU of botulinum
toxin into each of the bulbo-spongiosus muscles in
8 patients to saline in 5 patients. All the patients in
the botulinum toxin group improved with couples
achieving intercourse compared to none of the
control group. No complications were reported in
either study. Botulinum toxin may have a place
in the treatment of vaginal spasm associated with
vaginismus although many questions remain
regarding the dose, the injection sites and the need
for other form of support.

VI. FEMALE GENITAL MuTILATION
Female genital mutilation (FGM) means partial or
complete non-therapeutic removal or injury of each
of the female genitals for religious or cultural reasons.
Four types of FGM are described (See Figure 4):
Type I (also called Sunna): Removal of the clitoris
foreskin.
Type II Removal of the clitoris with partial or total
excision of the labia minora.
Type III (“Inibulation” or “pharaonic circumcision”)
Removal of the clitoris and the labia minora and
majora, sewing up of the oriicium vaginae, leaving
only small opening for urine or menstruation blood.
Type IV other types like pricking, piercing, stretch-ing of clitoris or vulva, scraping of the vagina.



comitte 25.indd 1223

8/25/2010 1:21:41 PM


FGM affects about 130 million women or girls in the world, with about 2 million girls undergoing the procedure every year [233]. Instruments used for FGM may be sterilized instruments when performed by doctors or midwives, but any cutting instruments such as razors or piece of broken glass are often used. Consequences depend on the experience of the operator and the hygienic conditions. Heavy bleeding, causing anemia or death, may occur. Local infection, infection of the uterus and adnexae, tetanus, gangrene, or sepsis may also result. After type III FGM, the risk of infertility is around 25-30% because of tubal obstruction or tightness of the vagina preventing intercourse.

There is a general assumption made that all women who have undergone FGM suffer from pervasive sexual dysfunction and a total loss of sexual pleasure. However, recent evidence does not support this idea in all women. For example, 250 patients of Maternal and Childhood Centers in Ismailia (of whom 80% were circumcised) were examined and interviewed to investigate their psychosexual activity. Results indicated that, although the circumcised group complained significantly more frequently of dysmenorrhea (80.5% vs. 56%), vaginal dryness during intercourse (48.5% vs. 30%), lack of sexual desire (41.5% vs. 16%), less initiative during sex (11% vs. 22%), experiencing less pleasure from sex (44% vs 14%), and being less orgasmic (29% vs. 44%) than uncircumcised women, other psychosexual problems, such as loss of interest in foreplay and dyspareunia, did differ significantly between groups [234]. However, other studies demonstrate that sexual pain and dysfunction are significant issues among women who have undergone FGM. For example, dyspareunia was reported among almost one-third of circumcised women in an Egyptian sample, and 23% of these women perceived personal distress related to their sexual problems [235]. Additional evidence exists that when dyspareunia is present, it is most commonly reported with first intercourse and/or in the initial period after marriage, and with attempts made after re-infiltration [236]. Thus, FGM may not affect all aspects of sexual function in a persistent and uniform manner [237]. Further research is needed in order to determine the outcomes of FGM, specifically of the FGM subtypes, as wide variations in the type, depth, and extent of tissue damaged/excised may range from minimal to severe. Damage to any of the neural networks associated with the vulvar and perineal areas may alter genital sensation [237], resulting in pain and other sensory outcomes.

VII. PSYCHOLOGICAL ASPECTS OF SEXUAL PAIN DISORDERS

1. OVERVIEW AND DATABASE

The following psychological factors associated with the sexual pain disorders will be discussed:

a. Psychological vulnerability factors for developing sexual pain; specifically, empirical findings with regard to individual differences on personality traits, personality disorders, and psychiatric comorbidity are reviewed.

b. Characteristics of the sexual relationship of women with sexual pain disorders, compared with asymptomatic women.

c. Psychological variables that are found to predict outcome of treatment of sexual pain disorders.

The evidence for psychological factors associated with the sexual pain disorders is grouped into the following categories:

I. Psychometric data, showing differential presence of psychopathology and personality levels (state and trait) in patients and non-patient comparison groups (Table 25.1a,b,c). Note that psychopathology and impaired psychological functioning found in observational or cross-sectional studies may be a cause as well as an effect of the various forms of sexual pain;

II. Experimental data on sensory perception and cognitive-affective processes (Table 25.2);

III. Outcome data of treatment studies of sexual pain disorders, and psychometric data that predict treatment outcome (Table 25.3); These data will be reviewed in the following subParagraphs as they pertain to, respectively, PVD (see Table 25.1a), superficial dyspareunia not identified as PVD (DYS; see Table 25.1b), and vaginismus (VAG; see Table 25.1c). Asterisks are added in the text to provide an index of the robustness of the findings that are mentioned: **: If more than one study with results pointing in the same direction are retrieved; *: if only single study results were retrieved.
2. PROVOKED VESTIBULODYNIA (PVD)

a) Individual Psychological And Personality Characteristics

1) PSYCHOPATHOLOGY

Higher rates of psychopathology in women with PVD were found with regard to depression** and anxiety disorders* through assessment using both structured interviewing and self-report instruments (Grade B; see Tables 25.1 & 25.4). As to self-reported symptoms of depression, state anxiety, phobic anxiety, social anxiety, and obsessive-compulsive behavior, results are conflicting, finding both higher** and equal** scores compared with normative groups.

2) PERSONALITY CHARACTERISTICS

Using self-report measures (see Table 25.1a), several differences on continuous dimensions were found between women with PVD and asymptomatic women. Women with PVD scored higher on trait anxiety**, shyness*, hysterical personality*, perfectionism*, reward dependency**, low self-esteem*, fear of negative evaluation, and harm avoidance**.

In contrast with the deviant scores on these primarily social- and evaluation anxiety-related aspects of personality, other personality features in women with PVD were indistinguishable from asymptomatic women. Scores on neuroticism of women with PVD were in the normal range in most studies**. Women with PVD had normal scores on extraversion*. With some exceptions, women with PVD had normal scores on hostility**, obsessive-compulsive problems**, paranoid ideation**, and psychoticism**. Results on interpersonal sensitivity, novelty seeking*, and somatization** are equivocal, with studies finding both higher and equal scores than non-affected women.

With regard to personality traits more directly related to the domain of sexuality, women with PVD scored higher on erotophobia*, and had more self-reported difficulties with sexual arousal and vaginal lubrication during partner interaction** as compared to their functioning during masturbation*. They were also found to lack sexual pleasure more often*.

Women with PVD have more catastrophic thoughts** about the pain they (will) experience during sexual interaction, and about other, problem-related issues, such as the negative consequences of the pain problem for the partner and the threat that it poses for the (longterm) durability of the relationship. The strength of positive* and negative sexual selfschemas* was equal to normative groups*. There are indications that the population of women with PVD may consist of different subtypes of women with primary vs secondary PVD [108], characterized by different physical aspects (e.g., systemic pain sensitivity, lower pain threshold) and aspects of personality (e.g., somatization, pain catastrophizing, trait anxiety) [238-241]. These findings require further replication studies.

b) Sexual Relationships Of Women With PVD

Women with PVD were found to have more negative feelings about sexual partner contact**. Their marital satisfaction regarding non-sexual aspects of the relationship was equal to normative groups**. The level of pain ratings in PVD patients is predicted by their level of marital adjustment*, where lower marital adjustment is associated with higher pain ratings.

c) Psychological and Psychophysical Processes in Women with PVD

Heat pain thresholds and unpleasantness thresholds in women with PVD are lower compared with asymptomatic women** (See Table 25.2, and perceived pain during suprathreshold heat stimulation is higher in women with PVD*. The thresholds for tactile (pressure) sensitivity at several vestibular sites, over the labia minora, and on the deltoid muscle are lower in women with PVD* compared with asymptomatic women. This lowered sensitivity is stable over time. Pressure pain thresholds at vestibular sites, over the labia labia minora, and on the deltoid and voral forearm are lower in women with PVD*. Women with PVD report higher distress for sustained suprathreshold pressure, and tolerate less pressure than controls*. Higher suprathreshold pain ratings are associated with stronger traits of harm avoidance and reward dependence in women with PVD*.

Using fMRI-recording, women with VVS had significantly higher activation levels in the insular and frontal cortical regions than control women during pressure described as painful [111].

Stronger attentional bias toward pain-related stimuli is demonstrated in women with PVD* compared with asymptomatic women, suggesting hypervigilance for pain-related stimuli*. The level of hypervigilance is largely accounted for by state and trait anxiety levels. Speeded detection of sexual pain-related stimuli, reflecting attentional bias towards such stimuli, has also been investigated with other methodologies. When using a modified pictorial Affective Simon Task (a reaction time task that assesses the strength of automatic associations of stimuli with positive vs. negative valence), women with superficial dyspareunia were not different from asymptomatic women indicating the absence of an automatic affective bias. On the self-report level, however, deliberate affective associations with sex cues were significantly more negative for women with dyspareunia than for asymptomatic women [242].

Compared with asymptomatic women, women with PVD respond with equal levels of genital sexual arousal, but with lower levels of subjectively experienced sexual arousal** [243, 244]. This pattern was

Dysfunction type: PVD = provoked vestibulodynia; VAG = vaginismus; PCS = Pain Catastrophizing Scale; FSFI = Female Sexual Function Index, STAI = State-Trait Anxiety Inventory, BDI = Beck Depression Inventory-II, BSI = Brief Symptom Inventory, SCL-90 = Symptom Checklist-90, MMQ = Maudsley Marital Questionnaire, GRISS = Golombok-Rust Inventory of Sexual Satisfaction, MPQ = McGill Pain Questionnaire, SHF = Sexual History Form, DSFI = Derogatis Sexual Functioning Inventory.
found both with stimuli depicting intercourse and nonintercourse erotic stimuli. In two studies, women with dyspareunia responded with equal genital arousal to nonintercourse erotic stimuli, but with a lower genital response to stimuli depicting intercourse [245, 246]. When fear of pain was induced during visual erotic stimulation, both women with PVD and asymptomatic women responded with decreased genital sexual arousal [245].

d) Psychological Variables and Treatment Outcome (Grade C)

The psychological treatment of PVD has been evaluated in three controlled trials [114, 247, 248]. Significant improvement in experienced pain and in intercourse frequency and other measures of sexual functioning was reported after cognitive-behavioral therapy (CBT) and CBT combined with vestibulotomy, and these results were found to be maintained over time. Electromyographic biofeedback treatment and topically applied lidocaine were equally effective regarding pain reduction [114]. Prediction of treatment outcome by means of psychological or psychosocial variables (see Table 25.3) has been investigated in women with PVD. Psychosocial variables predictive for positive outcome were: higher socioeconomic status*, lower education*, and childlessness*. Psychological and relational factors at treatment onset and psychological test scores (marital adjustment, neuroticism, psychopathology) were not predictive*. Willingness to be psychologically evaluated was highly predictive for positive outcome of limited vestibulotomy*, as was cooperation of patient in postoperative counseling*, low erotophobia score*, and lower pretreatment pain intensity*. High scores on instruments measuring fear of negative evaluation by others, phobia related to vaginal entry and the Personality Assessment Screener have been associated with poor outcome. No replications of prediction models have yet been reported.

e) Conclusions Regarding Women with Dyspareunia Resulting From PVD

In sum, in women with PVD, increased prevalence of comorbid psychopathology was found, specifically depression and anxiety disorders. These findings were not consistently reported and only one study [249] employed an instrument producing DSM-IV diagnoses. The crosssectional design of the relevant studies precludes conclusions regarding the causal direction of the association between affective disorders and PVD.

Furthermore, both more problematic and non-affected psychological functioning have been reported in women with PVD. Although this could reflect differences in study samples and instrumentation, it could also indicate true heterogeneity of women with PVD. Increased trait anxiety, pain catastrophizing, reward dependency and harm avoidance in women with PVD, however, have consistently been found in multiple studies, and may represent a complex of stable characteristics that suggest an important contribution to the etiology of PVD of avoidant, dependent, and obsessive-compulsive personality features.

Single study findings of women with PVD included elevated rates of shyness, perfectionism, low self-esteem, and negative feelings towards sexual interaction, erotophobia, and problems with subjective sexual arousal and lubrication during sexual interaction with partner, but not during masturbation. Women with PVD have been found to be more sensitive to thermal, pain, and tactile stimulation, reflected in lowered thresholds for sensitivity, and they experience heightened pain in response to painful stimulation as compared with non-affected women. An etiological element may be the deficits in information processing, i.e., hypervigilance for pain-related stimuli. These latter findings require replication in future studies.

3. SUPERFICIAL DYSpareunIA NOT IDENTI FIED AS PVD (DYS)

a) Individual Psychological And Personality Characteristics

It is not known whether or not participants in studies of superficial dyspareunia not identified as PVD (DYS) meet the clinical criteria for PVD. Higher rates of psychopathology in women with DYS were found with regard to depression** and anxiety disorders*, more specifically: generalized anxiety disorder*, simple phobia*, obsessive-compulsive disorder*, and social phobia*. Equal rates of psychopathology in women with DYS, compared with healthy controls, were found with regard to posttraumatic stress disorder* and eating disorder* (see Table 25.1b).

Frequency of (childhood) sexual trauma was found equal in women with DYS** compared with the general female population or asymptomatic women, such as women seeking routine gynecological examination. On self-report measures (see Table 25.1b), women with DYS were found to have higher scores on neuroticism*, depression** and state anxiety**. Phobic anxiety in women with DYS was found higher**, as were obsessive-compulsive behaviors**, and social phobia (interpersonal sensitivity)**. This pattern of results is strikingly different from that of women with PVD; however, an unknown proportion of women with PVD may have in fact been included in the samples of these studies. Scores on most psychological features that were investigated in women with DYS were elevated, whereas comparisons of women with PVD with control women on the same variables yielded equivocal findings.

Women with dyspareunia also reported more symptoms of hostility**, more (psycho)somatic complaints...
(somatization)*, higher paranoid ideation*, and more psychotic symptoms*.

**b) Sexual Relationships in Women With DYS**

With regard to personality traits more closely related to the domain of sexuality, women with DYS are found to score higher on erotophobia* than healthy control women. With regard to sexual functioning, they also appear to have lower sexual arousal** in response to sexual intercourse stimuli. Furthermore, they more often report relationship discordance**.

**c) Psychological Processes InWomen With DYS**

With respect to psychological processes that cause or maintain dyspareunia (see Table 25.2), the level of pain ratings in dyspareunia patients is predicted by their level of depression*, where higher depression scores are associated with higher pain ratings.

The role of low sexual response, potentially (but not empirically demonstrated to be) accompanied by lack of vaginal lubrication in medically unexplained superficial dyspareunia, may be seen as pivotal in our understanding of the etiology of this invalidating condition in women. In a first experimental study [246], genital response in women with DYS was compared with that of asymptomatic women. In women with DYS, genital response was lower to audiovisual representation of penile-vaginal penetration*, compared with stimuli depicting other forms of sexual activity (oral heterosexual stimulation). Subjective sexual arousal did not differ between women with and without dyspareunia*.

However, in more recent studies [242, 243, 245], women with DYS and healthy control women were found to exhibit equivalent genital responses to, respectively, 1. stimuli depicting oral sex vs. penile-vaginal penetration, 2. induction of pain-related fear, and 3. induction of negative vs. neutral vs. positive appraisal of a situation in which they viewed erotic films. Both groups of women showed identical patterns of genital sexual arousal, but several differences were found regarding subjectively experienced sexual arousal, and negative and positive affect.

Neither psychological treatment of superficial dyspareunia (not identified as PVD) nor prediction of treatment outcome by psychological or psychosocial variables has been investigated in controlled comparisons.

**d) Conclusions Regarding Women with Superficial Dyspareunia Not Identified As PVD (DYS)**

In summary, women with DYS were found to have elevated rates of clinically relevant comorbid depression and anxiety disorders. Sexual traumatization appears not to play a significant role in etiology. Self-report measurement of psychological characteristics corroborates the presence of depressive and anxious symptoms, both on the experiential and the behavioral level. Experiential and behavioral signs of hostility and psychotic symptoms also appear to be more frequently present. With respect to sexual functioning, women with dyspareunia are found to be more erotophobic, reflecting negative and conservative attitudes towards sex, and aversion to engage in sex. Findings with regard to sexual arousal problems in women with DYS have thus far been contradictory. Relationship discord was found to be increased in women with DYS.

Lower genital response during laboratory investigation to specific sexual stimulation (audiovisual representation of penile-vaginal intercourse vs. oral sex) in women with DYS, compared with control women, was found in one study, whereas more recent studies found absence of genital response differences between these groups, whereas subjective arousal and other affective responses were different between these groups.

The controversy that has arisen regarding the role of low vaginal vasocongestion and lubrication response to erotic stimulation in women with DYS warrants further study.

**4. VAGINISMUS**

**a) Individual Psychological and Personality Characteristics**

Higher rates of psychopathology in women with vaginismus were found with regard to agoraphobia without panic disorder* and obsessive-compulsive disorder* (see Table 25.1c). In women with vaginismus, when compared with the general female population, equal frequency* of childhood sexual trauma was found in one study, whereas another study found elevated frequency*.

On self-report measures (see Table 25.1c), many conflicting findings were reported. Women with vaginismus were found to have equal and higher scores on neuroticism**, depression**, state anxiety**, phobic anxiety**, social phobia**, obsessive compulsive behavior**, paranoid ideation*, psychoticism**, somatization**, and hostility**. Compared with asymptomatic women, women with vaginismus had increased catastrophic thinking* both for non-genital and genital pain. Compared with both women with dyspareunia (including PVD) and asymptomatic women, women with vaginismus had higher disgust propensity*.

With respect to dispositional traits, women with vaginismus were equal to the normal population on extraversion** and negative sexual self-schema*. They showed elevated traits of low self-esteem*, less positive sexual self-schema*, and hysterical personality*. 
b) Sexual Relationships of Women with Vaginismus

Rates of marital discord were equal to the general population*. With regard to their sexual functioning, women with vaginismus reported less self-stimulation*, and more problems with sexual desire* and arousal*.

c) Psychological Processes in Women with Vaginismus

With respect to psychological processes causing or maintaining vaginismus (see Table 25.2), women with and without vaginismus are found not to differ in baseline pelvic floor muscle tension*, or in the ability to control pelvic floor muscles while performing exercises (short flick contractions and 10-sec holding contractions)*. Women with vaginismus and asymptomatic women do not differ in their EMG measured pelvic floor muscle response to physically-threatening or sexually-threatening stimuli*. Compared with control women, women with vaginismus (28%) had higher incidence of vaginal spasm*. Visual erotic stimulation does not increase the pelvic floor muscle activity in women with vaginismus. However, subjectively experienced threat of the stimuli correlates significantly with EMG-measured muscle activity*. A randomized controlled trial of standard cognitive-behavioral treatment for vaginismus yielded better response of CBT (27% successful intercourse) compared to a waiting-list control condition (0%) [6]. Reduction of penetration-related fears was found to mediate positive response to treatment [250].

d) Prediction of Treatment Outcome (Grade B)

Prediction of treatment by means of psychological, psychosexual and psychosocial variables has been investigated in vaginismus in three non-controlled studies and one RCT of CBT (see Table 25.3).

Psychological variables predictive for better outcome were: attribution of problem to psychological causes*, positive attitude towards own genitalia*, strong wish to become pregnant*, better sexual knowledge*, good compliance with homework assignment by third treatment session*, and lower pre-treatment ratings of marital tension in the female partner*. Peri-treatment reduction of fear of penile-vaginal penetration was found to be predictive of successful intercourse after CBT*.

Negatively associated with treatment length were: pre-treatment sexual desire problems*, fear of sexually transmitted diseases*, negative parental attitudes towards sex*, having undergone previous operations for vaginismus*, and history of organic abnormality (septum, vaginitis)*.

No predictive value was found with respect to history of sexual abuse* or presence of additional sexual dysfunctions in either partner*. No replications of prediction models have been reported.

e) Conclusions Regarding Women with Vaginismus

In summary, women with vaginismus were found to have significantly increased comorbid anxiety disorders (agoraphobia without panic disorder, obsessive-compulsive disorder), while depression rates were not found to be increased. The role of childhood sexual trauma is unclear since different frequency rates were found, and the presence of increased rates of posttraumatic stress disorder has not yet been investigated. Psychological characteristics, measured with self-report instruments, only partially lend clear support to the role of anxiety symptoms in the etiology of vaginismus. Interpersonal sensitivity (social evaluation anxiety) was found increased in women with vaginismus**, although absence of difference in this respect has also been found*. Personality features found to be more often present in this group suggest the presence of pain catastrophizing cognitions, disgust propensity, and a specific fear of penile-vaginal penetration in the etiology or maintenance of vaginismus. Sexual functioning may be impaired with regard to sexual desire and arousal response during sexual activity. Experimental evidence thus far has documented the role of experienced threat in increased pelvic floor muscle tension, but did not discriminate between women with and without vaginismus. In sum, whether vaginismus is caused or maintained by psychological factors requires additional investigation. Fear of penetration, anxiety and disgust, and other aspects of negative affect may play a role.

VIII. CLINICAL PRESENTATION OF SEXUAL PAIN DISORDERS

1. PREVALENCE

Prevalence estimates for dyspareunia range from 6.5-45% in older women and from 14-34% in younger women [318-327]. Estimates vary according to several factors, such as culture [326-332], setting (population-based or clinic-based) [325, 327], the time frame specified by researchers [318], the presence of chronic disease [333, 334], the duration of menopausal status [335, 336], body mass index [335], depression [336, 337], the degree of perineal trauma experienced during vaginal delivery [325], and, most importantly, the physician's initiative to bring up the topic [338]. Therefore, in order to detect sexual concerns, explicit questions must be asked.

Prevalence rates for vaginismus are scarce, without the benefit of multiple studies on specific populations. Population-based estimates for vaginismus range from 1 to 6% [323, 339, 340].
2. PHYSICAL CONDITIONS ASSOCIATED
WITH PAIN ON ATTEMPTED OR
COMPLETED VAGINAL ENTRY

Table 25.4 summarizes various conditions that may be associated with varying degrees of chronic dyspareunia (See Table 25-X).

3. GENERAL SEXUAL HISTORY FOR SEXUAL PAIN DISORDERS

Gynecological complaints, diagnostic procedures, and/or treatment may have consequences on the sexual functioning of the patient and her partner. It is therefore advisable for health care providers to ask each patient whether she has any sexual concerns. In addition, asking about any past negative sexual experiences prior to procedures and treatments is recommended, as tailored approaches may be necessary for such patients [341]. Given that women with sexual pain may experience embarrassment, shame, guilt, low self-esteem, frustration, and other negative emotions in addition to their dyspareunia, it is crucial that the clinician uses communication skills that enhance openness, comfort, trust, and confidence within a non-judgmental context.

Obtaining a psychosexual history is recommended as it can provide invaluable information about predisposing and maintaining factors; however, of more direct relevance in the initial interview is the assessment of the pain experience itself (Grade C). Allowing the patient to describe her difficulties and reasons for seeking treatment in an open-ended manner can communicate much information about her psychological disposition toward the problem. This part of the interview is then followed by more specific questions about the pain (see Table 25.5). Questions about the properties of the pain are essential for diagnosis [251] and include questions regarding the lifetime onset and temporal pattern of the pain as well as questions on pain duration, location, quality, and severity. Questions focusing on whether the pain is exacerbated with a male partner’s ejaculation, the presence of post-coital burning, and post-coital dysuria should also be asked. In addition to this information, questionnaires may be administered in order to more formally capture scores for empirical comparison and/or to track treatment progression (see below). Second, questions about pain mediators are crucial as pain is a complex subjective experience that can be impacted by a range of factors. Thus, asking whether any factors (e.g., intercourse positions, level of arousal, time of menstrual cycle) improve or exacerbate the pain may provide clues to management [342].

Third, queries about what activities have been affected by the pain and any comorbid issues (e.g., problems with sexual function, relationship distress, psychological issues) allow for a comprehensive understanding of the patient’s experience and may lead to additional treatment avenues. Furthermore, inquiring about patients’ theories regarding their pain can be important, as research has shown that psychosocial – as opposed to physical – explanations for the pain are related to higher distress and lower relationship adjustment [251]. Fourth, questions related to previous treatments undertaken and their outcomes can be useful in treatment planning [342]. Throughout the assessment, it is important to keep in mind that sexual pain problems are embedded in a somatic, psychological, relational, and social context which must be assessed in order to make adequate decisions regarding diagnosis, treatment, or referral.

4. EDUCATIONAL GYNECOLOGICAL SEXOLOGICAL EXAMINATION

In order to detect or exclude physical illness or abnormalities that cause pain on (attempted) vaginal entry (Table 25.4), the patient and physician have to work together. Especially in the case of dyspareunia or vaginismus, it is not always desirable or practical to perform a medical examination right away. The patient and care provider must make decisions together about timing, who is present, and the extent of the examination. The examination technique to search for the cause of dyspareunia is more detailed and requires much more finesse than a routine pelvic examination (Grade C). When conducted correctly, it can be highly therapeutic. This is especially true when the sexual partner is also present. Often referred to as an “educational gynecological sexological examination”, the patient watches in the mirror as the doctor gathers information and tells the patient about her genital anatomy, clarifying normal (or abnormal) structures. This examination can correct misinformation and negative self-image, and can clarify how physical changes can relate to sexual problems [341].

Essentially, the patient’s personal boundaries must be respected and safeguarded throughout the process [343]. It is she who decides who is going to be present during the examination and how far the examination will proceed. Before the examination occurs, it is important to inform the patient how it will be performed and to ensure her that, during the exam, she will be told when the next step of the examination will be taken. In addition, clarifying that she can interrupt the examination at any stage – and that doing so is not considered a failure – is essential. Through the examination, the foundations are present for a meaningful discussion afterwards, in which all the findings are explained and at which time, further sexual complaints may come to light. Although based on level 5 evidence, this process is recommended to lessen the common occurrence of women having to seek multiple health care providers before an accurate diagnosis is made.

a) The Context

When dyspareunia and vaginismus are suggested by the history, the patient is told ahead of time that the use of a speculum or other means of internally examining the pelvis will not necessarily be part of the examination. It is recommended to ask the woman if there is anything she can think of that will facilitate the exam and to impart to her a sense of control with respect to what will happen in the examination. The physician should be seated comfortably and the examination couch should be adjusted for the woman to be sitting up so that she may see the examination of her genitals in a hand mirror; her wish to not watch, however, should also be respected. Verbally checking how the woman is coping with the exam during the process is recommended. Non-verbal communication – the patient’s behavior and that of her partner (if present) – are noted. In addition, the physician must also be aware of his or her own non-verbal behaviors.

1) Pain

Have you had the pain since your first vaginal penetration attempt, or did it occur after a period of pain-free vaginal penetration? Where does it hurt?

How would you describe the pain?

When does the pain first start (e.g., during initial vaginal penetration, once the object has been partially/fully inserted, etc), or is it always there? If it is always there, does vaginal penetration make it worse?

Does the pain only occur in response to touch of the area, or is it present most of the time?

How long does the pain last during intercourse (only during initial penetration, only once the object has fully entered, during thrusting, afterwards, the whole time?)

What makes the pain better or worse? Specifically ask questions related to post-coital pain, pain with ejaculation fluid, post-coital dysuria, pain with arousal, and pain with orgasm.

On a scale from 0 to 10 (where 0 is no pain at all and 10 is the worst pain felt), how would you rate the intensity of the pain?

Does touching elsewhere in the genital area cause pain?

Does the area hurt during non-penetrative activities (e.g., riding a bicycle, wearing tight clothes)?

Does other forms of penetration hurt (tampons, fingers)?

What do you believe is the cause of your pain?

2) Pelvic Floor Muscle Tension

Do you find that your body/pelvic area tenses up when you are faced with vaginal penetration activities? If so, does this tension make vaginal penetration impossible sometimes/always?

Do you experience the same tension in non-sexual situations that involve vaginal penetration (e.g., gynecological examinations, tampon insertion)?

Have you ever been able to have full vaginal penetration?

3) Arousal

Do you feel sexually excited when you engage in sexual activity?

Does your vagina feel wet?

Does your vagina feel dry before or during sexual activity?

Does the use of a lubricant help?

<table>

</tbody>
</table>
What are your thoughts and feelings before, during, and after sexual activity?

4) CONSEQUENCES OF THE COMPLAINT

What do you do when you experience pain during sexual activities? (Continue/stop intercourse/continue to make love without intercourse?)

Do you find yourself avoiding activities (sexual/non-sexual) that involve vaginal penetration?

Do you currently engage in activities involving vaginal penetration?

What sexual activities do you engage in?

Do you express affection with your partner in non-sexual ways?

What consequences does the pain have on your sexual functioning and intimate relationships?

What consequences does the pain have on your self-image, psychological well-being, quality of life?

5) ANTECEDENTS

When and how did the pain start?

What diagnostic tests have been done?

What diagnoses have you received?

What was happening in your life at the time that the pain started (e.g., health issues, stressful events)?

What treatment/s have you tried? Which treatments helped, and which ones did not?

What other things have you done to try to alleviate the pain?

(end of Table)

b) Adequate Spreading

Permission is asked to gently spread the labia majora or the patient is asked to spread them herself with her fingers. This enables her to observe the consequences of pelvic floor muscle activity. By bearing down or coughing, she is able to see the introitus becoming larger. The vulva is carefully inspected, including the skin of the outer part of the vulva, labia minora, labia majora, the crease between the labia, the clitoral hood and clitoris, the posterior fourchette, vestibule, hymen, and hymenal edge. For women with introital dyspareunia, sites of allodynia are investigated using a cotton-swab (Q-tip), applying light pressure along the outer edge of the hymen where it meets the inner edge of the internal surfaces of the labia minora. In cases where vaginal discharge is noted, relatively pain-free samples for vaginal pH and microscopy using a cotton-swab are possible to obtain. Additional testing is indicated by clinical findings; however, routine bacterial vaginal cultures are generally not useful.

c) Internal Exam

It may be possible to proceed to the internal exam, with the woman’s permission, on this first visit when the characteristic features of vaginismus are not present in the history or during the exam. With the woman is bearing down, the insertion of physician’s finger (or if necessary, something smaller such as cotton-swab) confirms vaginal entry without pain. If possible, additional examination using a small speculum, careful palpation of the uterus and adnexa, and/or transvaginal sonographic assessment for deep dyspareunia or ovarian abnormality might be performed [344].

d) Pain Measurement In Vestibulodynia

For the purpose of diagnosis and treatment outcome, it is advisable to measure the pain in the genital region. In order to diagnose PVD, the cotton-swab test is used (Grade C) [52, 145]. The cotton-swab test consists of palpating different areas of the vulva, including the vulvar vestibule, with a cotton-swab and asking whether the pressure is painful or not. Some clinicians also ask that the patient rates the pain intensity of the pressure on numerical rating scales (e.g., from 0-10). If the cotton-swab test reveals a pattern of sensitivity in which the pain is localized to the vestibule, then the diagnosis of PVD is made. It is important to note that different health professionals conduct the cotton-swab test in different ways; however, the order of the palpations should be randomized as it has been demonstrated that sensitization may occur when adjacent areas are palpated [304]. In addition, different clinicians may apply different amounts of pressure [345]. As such, the cotton-swab test is prone to measurement error when used for experimental purposes or to measure treatment outcome. Therefore, a new mechanical device, the vulvalgesiometer (see Figure 25.5), has been developed [121, 304, 345]. The vulvalgesiometer has been shown to discriminate between women with and without PVD [111, 121, 304], and has demonstrated that, in women with

Figure 25.5: Vulvagesiometer
PVD, painful levels of stimulation replicate the quality of the pain reported during vaginal penetration (i.e., burning, sharp) [121, 304]. Although specific studies are currently lacking, the vulvalgesiometer can be used as a diagnostic tool capable of differentiating women with different types of genital pain. In addition, because of its large range of exertable pressures (3-950 g), it may aid in quantifying the severity of pain (mild, moderate, severe) experienced by these women. The vulvalgesiometer has been used to measure changes in vestibular pressure-pain sensitivity as a result of treatment [114, 312, 316, 346].

Methods to assess vaginal pressure-pain sensitivity may be useful in conditions in which vaginal dyspareunia is the main complaint. The vaginal algometer [347] assesses pressure-pain threshold on the lateral walls of the vagina with a thimble-like probe worn on the clinician’s finger. It is well tolerated by healthy women and is capable of discriminating between women with and without chronic pelvic pain [348]. Devices with which to measure genital sensitivity to other forms of stimulation (e.g., thermal, vibratory) also exist and are empirically useful; however, they may not be practical for clinical settings [342].

e) The Pelvic Floor

Involuntary contraction on the gynecology table does not infer that this response is also necessarily present at home. Conversely, some women can undergo a gynecological examination without any problem, but have vaginismic reactions in other circumstances, depending on what they find threatening. Instead of asking a patient to relax, offering her information and tools is usually more successful to decrease anxiety and hypertension of the pelvic floor muscles [341]. In many cases, the pelvic floor muscles are chronically contracted and feel like “steel cables”.

Physician assessment of pelvic floor muscle tone is imprecise but still of some value (Grade C) [349]. The physician places his or her finger between the woman’s labia just in front of the vaginal opening and applies gentle pressure. The woman is asked to bear down while the physician (slowly) moves the finger inside, keeping it dorsally curved to feel the pelvic floor muscle without touching painful areas at the vestibular margin. At the end of the examination, the finger is slowly withdrawn as the patient bears down. The use of a lubricant will facilitate the examination and prevent tissue damage.

It has been proposed that surface electromyographic (sEMG) biofeedback is a useful method to detect pelvic floor hypertension and dysfunction in women with PVD [350]. Although more recent data do not support these findings and sEMG biofeedback is no longer recommended for assessment in the routine clinical setting [351], it has been shown to be a valuable tool for restoring pelvic floor function and improving dyspareunia in PVD patients [247, 346].

5. THE USE OF SELF-REPORT MEASURES IN PATIENTS WITH DYSPAREUNIA

Measures of psychological function may also aid in treatment planning. For example, if anxiety or depression is suspected, the Beck Depression Inventory-II [272] and the Beck Anxiety Inventory [357] can be used. Additionally, the Personality Assessment Inventory [358] yields a global profile of psychological function, and it has been validated with chronic pain populations. The administration of any measure of psychological symptomatology should be prefaced with a clear explanation of its function (i.e., to investigate pain mediators); otherwise, the patient may believe that her pain is not being taken seriously [342].

IX. MANAGEMENT OF SEXUAL PAIN DISORDERS

1. GENERAL REMARKS

Sexual pain disorders are heterogeneous, multisystemic and multifactorial disorders that should be treated in a multimodal way according to etiological factors, risk profile and context. The following algorithm with three distinctive characteristics meets these requirements.

a) General Recommendations (Grade C)

A multidimensional and multidisciplinary approach with specific attention to 6 areas: the mucous membrane, the pelvic floor, the experience of pain, sexual & relationship function, psychosocial adjustment and genital mutilation/sexual abuse. There is no “one size fits all” approach and no “or-or” approach but an “and-and” approach is recommended. Simply focusing on one symptom or facet of the experience may lead to improvement in that single area; however, this sole effect may not impact other areas of function that are in need of improvement.

Individualized treatment After careful listening to her story and after she has been well informed about the condition, its natural course, and possible treatment options and management tips, a treatment plan is made.

Patient-focused approach: it is up to the woman and her partner to decide which treatment avenue they wish to pursue. If the assessment of psychological function has revealed some issues, this aspect should be treated first with psychotherapy and/or medications. By involving patients in the decision process with regard to potential treatment avenues, the clinician and patient share the responsibility for treatment choice; this involvement is known to have a positive effect on the treatment outcome [359]. Shifts in preference for a certain approach will depend on the country in question, the woman’s attitudes regarding treatment
options, the individual health care systems, and the cost effectiveness of the various modalities, e.g. for PVD, surgery, CBT, biofeedback/physical therapy, transcutaneous electric nerve stimulation (TENS) or a combination of these treatments.

b) A Counseling Model

This approach implies that the health care provider has to be familiar with the counseling model. He or she is an advisor and counselor but it is the patient who is in full command of the situation. Treatments for sexual pain disorders are time-consuming, and they require great patience and empathy, sensitivity to non-verbal signals and insight into relational interactions. The treatment provider should be able to identify any ambivalent feelings on the part of the patient regarding coitus, sexuality, her partner, her own body, and her desire to have children. The health care provider must be able to bring to light serious relational problems or severe traumatic experiences (sexual violence) in addition to recognizing that sexual pleasure may be a goal over and above that of tolerable vaginal penetration.

2. THERAPEUTIC OPTIONS

In table 25.7 the various treatment modalities for subtypes of chronic dyspareunia in women are outlined. They include chronic pain medications along with sexual and psychological counseling. In this chapter, the treatment modalities and prognostic factors of PVD and vaginismus are discussed in detail.

a) General Recommendations (Grade C)

1) MEDICAL INTERVENTION

In terms of medical intervention for PVD, there are only three level 2 placebo controlled RCTs. One examined the effectiveness of Fluconazol [378] one investigated the usefulness of Cromolyn 4% [379], and one assessed the effectiveness of botulinum toxin injections [380]; however, neither Fluconazol nor Cromolyn 4% proved to be more effective than placebo. Additionally, the botulinum toxin injections did not result in significantly greater improvements in pain, sexual function, or sexual distress as compared to the placebo (saline injections); in fact, the placebo group fared better than the botulinum toxin group in sexual distress scores from baseline to 6-month follow-up. These results are contrary to the pattern of findings in smaller uncontrolled studies examining treatment outcomes following the administration of these injections [381, 382].

Other medical interventions that have been tested are Corticosteroids + lidocaine [383, 384], Botulinum toxin [382, 385], Capsaicin [386, 387], Ketoconazole [388], lidocaine/xylocaine [389, 390], and amitriptyline or other tricyclic antidepressants [130, 258, 391]. Various medical regimens (tricyclic anti-depressants, SSNRI (Duloxetine), venlafaxine, anticonvulsants - usually carbamazepine or gabapentin) are typically recommended for neuropathic pain conditions [392]. Some of these have been found to offer some pain relief in women with vulvar and pelvic pain, but total pain resolution with these drugs appears to be infrequent [130, 393, 394]. With respect to antidepressant medications, low doses are indicated for neuropathic pain reduction whereas higher doses are recommended for improvement in depressive symptoms. It is not clear, however, whether the medications, regardless of dosage, have a dual effect in that both pain and depressive symptoms can be targeted simultaneously. Further research is needed to assess this issue. None of the studies cited above were controlled (level 3) and, apart from their methodological limitations, the results are disappointing. One confounding factor is a consistent improvement of 30-40% of patients with PVD when treated with placebo or with no therapy reflecting the highly active processes in the brain that are mediated by psychological mechanisms such as expectations and conditioning [395].

Despite this issue, many clinicians continue to include in their biopsychosexual therapeutic approaches, medical interventions of unknown efficacy. RCTs of carefully evaluated women who appear to have similar medical and psychological profiles are encouraged to establish efficacy of these commonly used medical adjuncts.

2) HYGIENE MEASURES (GRADE C)

Preventative hygienic measures (level 5) include recommending that the patient avoid the use of soap, vaginal douches, nylon underwear and pantyliners (mini pads), and other potentially irritating factors (e.g., direct vulvar contact with semen) and activities (e.g., wearing tight trousers). In addition, the patient is encouraged to drink sufficient fluids to produce approximately 1500 ml of non-concentrated urine daily. Hydration with sitz baths may help reduce inflammation and symptoms.

3) RECOMMENDATIONS REGARDING SEXUAL ACTIVITY (GRADE C)

As long as the pain predominates, avoidance of vaginal penetration is recommended in addition to ensuring that semen does not come into contact with the sensitive vulvar areas. Some women may feel guilty about their restricted sexual activities, which may lead to frustration in their partners. Education about the effects of sexual pain on the sexual response cycle (consisting of desire, arousal, and orgasm) is needed, as many women with sexual pain will also suffer from comorbid decreases in sexual function, in particular, lower desire and arousal which can also negatively impact orgasmic frequency. Additionally, the partner may develop lower desire and issues of his/her own in response to creating pain for the patient during sexual activity.
### Table 25.7: Subtypes of chronic dyspareunia in women and therapeutic options

<table>
<thead>
<tr>
<th>Medical Disorder</th>
<th>Type of dyspareunia</th>
<th>Findings on physical examination</th>
<th>Therapeutic options and general comments</th>
</tr>
</thead>
<tbody>
<tr>
<td>Vulvovaginal atrophy: associated with renal failure, chemotherapy-induced menopause, hypothalamic or pituitary disease, bilateral oophorectomy, or hyperprolactinemia.</td>
<td>Introital pain and with penile-vaginal movement. Possible postcoital burning. Deeper dyspareunia when vaginal atrophy advanced.</td>
<td>Pallor, dryness, increased fragility and thinning of vulvovaginal epithelium, vaginal shortening, loss of rugae, narrowing, or urethral caruncle.</td>
<td>Local oestrogen therapy is highly recommended. In case of breast cancer: local intravaginal application of DHEA achieves beneficial effects on different aspects of sexual functioning without significant systemic exposure to a drug, thus avoiding potential systemic risks. Frequent sexual arousal and (if necessary), nonpenetrative activity could promote genital health. Give dopaminergic drugs such as bromocriptine, cabergoline, or both to reduce prolactin; with surgery or radiation as appropriate.</td>
</tr>
<tr>
<td>Chronic (abdominal) pain: Endometriosis; Chronic PID; IBS; Crohn’s disease; Ulcerative colitis; Ovarian tumour; Abdominal wall pain.</td>
<td>Deep dyspareunia. IBS is also associated with introital pain from comorbid PVD.</td>
<td>General tenderness to deep bimanual examination.</td>
<td>Sexual dysfunction is highly prevalent in such patients. Women report deep dyspareunia. Organic disorders should be treated accordingly but sexual dysfunction may still need to be specifically managed. Irrespective of the organic or functional nature of the pain, a history of possible negative sexual experiences should be queried before any procedures or treatment.</td>
</tr>
<tr>
<td>Lower Urinary Tract Symptoms (LUTS) with urinary incontinence.</td>
<td>Introital and deep dyspareunia or vulvar burning after sexual intercourse.</td>
<td>Perineal and vulvar inflammation.</td>
<td>Voiding dysfunction, recurrent bacterial cystitis, hypoactive sexual desire, and sexual pain disorders are highly correlated. For recurrent cystitis give local OT; antibiotic self-treatment or preventative treatment, and recommend postcoital micturition (based on CE). In case of prolapse, surgical treatment can be curative but can also have undesired effects on sexual functioning.</td>
</tr>
<tr>
<td>Pelvic radiation.</td>
<td>Introital and deep dyspareunia.</td>
<td>Thinning and fragility of vaginal epithelium, loss of elasticity, stenosis, or foreshortening.</td>
<td>Preventive measures such as transposition of the ovaries to prevent ovarian failure. Therapeutic options based on CE include couple counselling about non-penetrative sexual activity, topical estrogen, lubricants, vaginal inserts, and vaginal reconstruction.</td>
</tr>
<tr>
<td>Chronic vulvovaginal candidiasis associated with diabetes and HIV.</td>
<td>Introital dyspareunia and with penile vaginal movement.</td>
<td>Erythema, swelling of vulva, and thick white or pale yellow vaginal discharge.</td>
<td>Oral agents recommended for recurrent symptomatic candidiasis.</td>
</tr>
<tr>
<td>Provoked vestibulodynia (PVD) associated with IBS, fibromyalgia, interstitial cystitis (IC), and other pain syndromes.</td>
<td>Superficial vulvovaginal pain on (attempted) penetration, pain on non-penetrative vulvovaginal touching, postcoital burning, or burning from partner’s ejaculation fluid.</td>
<td>Variable erythema of the vestibule. Allodynia typically located between 4 and 8 o’clock on the introitus, just exterior to the hymenal ring but can involve the skin around the openings of the Skene’s ducts or the whole introital rim. Hypertonic pelvic floor muscles. Pain with attempted digital or speculum entry.</td>
<td>Vaginal EMG biofeedback, pelvic floor physical therapy, (group) CBT, supportive psychotherapy, TENS and vestibulectomy have been shown to have clinical benefit, surgical and behavioural treatments even for a term of years. Based only on CE is treatment with topical estrogen, cromolyn, xylcaine, capsaicin, or botulinum toxoid injections. Based on CE, and the not yet proven assumption that neuropathic pain is at least in part responsible for the pain of provoked vestibulodynia, give TCAs or AEDs. For comorbid IC, DBPTs have shown benefit of oral intravesical pentosan polysulfate, intravesical dimethyl sulfoxide or resiniferatoxin (vallinoid). Based on CE, there may also be benefit from antihistamines, quercetin, intravesical heparin, lidocaine, or a combination.</td>
</tr>
</tbody>
</table>
### Table 25.7: Subtypes of chronic dyspareunia in women and therapeutic options

<table>
<thead>
<tr>
<th>Medical Disorder</th>
<th>Type of dyspareunia</th>
<th>Findings on physical examination</th>
<th>Therapeutic options and general comments</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Generalized vulvodynia.</strong></td>
<td>Introital dyspareunia and pain with penile-vaginal movement. The pain is always/almost always constant, covers the entire vulvar area, and may or may not be present/increased upon provocation.</td>
<td>None.</td>
<td>Vulvar burning and pain that causes sexual and psychological distress accompanied by the complete absence of any physical abnormality on examination, in biopsies or culture. Based on CE, TCAs or AEDs can be of partial benefit.</td>
</tr>
<tr>
<td><strong>Female genital mutilation (FGM).</strong></td>
<td>Introital pain and with penile-vaginal movement and deep dyspareunia.</td>
<td>Type I: all or part of the clitoris and its prepuce or skin excised. Type II: clitoris excised, labia minora partially or totally removed. Type III: all external genitalia excised, vaginal opening closed except for a match-sized hole to allow urine and blood to escape.</td>
<td>Experienced by an estimated 130 million women, in particular from north Africa, the middle east, and southeast Asia. Most of the studies do not support the hypothesis that FGM destroys sexual function or precludes enjoyment of sexual relations. Based on CE, use a respectful approach and provide information about health consequences. Offer sexual counselling, psychotherapy, and support groups. Offer to repair the vulva, vagina, or both. Involve the partner, the family, or both in decisions. Clarify the legal and ethical responsibility of the physician, who must decline any request to re-infibulate after childbirth. Offer specific management of sexual dysfunction as needed.</td>
</tr>
<tr>
<td><strong>Dermatological diseases.</strong></td>
<td>Can be introital dyspareunia (eg. eczema) or deep (eg. lichen planus affecting vagina.</td>
<td>Benign non-STI: can be atopic eczema, contact dermatitis (including iatrogenic), lichen simplex, lichen sclerosis, lichen planus, psoriasis, hidradenoma, fox-fordyce, chronic vestibular gland infection, pediculosis pubis, pin worm infections, Behçet’s, aphthous ulcers, cicatricial pemphigoid, pyoderma gangrenosum, anorectal Crohn’s, burn, or trauma. STD can be HSV, syphilis, chancroid, lymphogranuloma venereum, granuloma inguinale, condylomata acuminate, or molluscum contagiosum. Neonoplasia can be VIN, vulvar Paget’s, or melanoma.</td>
<td>For a benign non-STI, based on CE, give corticosteroids (oral, topical or injectable); immunosuppressive drugs (azathioprine, dapsone, tacrolimus, pimecrolimus, thalidomide, or infliximab); immune augmentation drugs (imiquimod); surgery; behavioural and physical therapy; and biofeedback. Also offer psychosexual support for sexual problems resulting from limited skin contact, visible symptoms, disrupted self-image, inability to meet a partner, shame, lack of confidence, or a combination of these. For treatment options for STI consult Guidelines from ISTI, WHO and CDC USA. Asymptomatic shedding and further infection necessitate strong encouragement of protective measures and safe sex. For neoplasia attempt surgery, laser therapy with radiation, or chemotherapy, as appropriate. Sexual activities do not stop for most couples. Based on CE, psychosexual counselling can be of benefit, in particular in the first year after treatment.</td>
</tr>
<tr>
<td><strong>Anatomical variations.</strong></td>
<td>Introital or deep dyspareunia depending on abnormality.</td>
<td>Labial fusions, rigid hymen, vaginal septum, vaginal agenesis, or hypoplastic vagina.</td>
<td>Based on CE, in case of vaginal agenesis nonsurgical options can be highly successful. Surgical intervention is recommended for imperforate hymen, labial fusions or a painful vaginal septum.</td>

However, persistent lack of sexual desire in spite of significant improvement in sexual frequency has been observed [247]. Therefore, normalizing, reframing and encouraging non-penetrative sexual activity is needed since healing may take several months, and in some cases, years. It is recommended that the couple focus on positive, pleasurable and relaxing sexual activities. Counseling related to (re-)starting a sexual relationship is recommended.

4) **Vaginal EMG Biofeedback, Pelvic Floor Physical Therapy, (Group) Cognitive Behavioral Therapy, TENS and Vestibulectomy (Grade B)**

Given that a reduction in pain during intercourse might be the most relevant treatment outcome criterion for women with PVD, focusing treatment on the tense pelvic floor might be useful. Indeed, it appears that vaginal EMG biofeedback, pelvic floor physical therapy, (group) CBT, including Kegel and relaxation exercises, TENS, mulitilevel local anesthetic nerve blockade and vestibulectomy are useful interventions (level 2b-4b) [247, 248, 314, 396, 397]. Additionally, treatment gains of vestibulectomy are maintained long term [314, 398-402]. This similarity of treatment effect may indicate a non-specific treatment effect in terms of attention, validation, and feelings of control and competence. The active constituents seem to be effective on a meta-level rather than on a content level: HOW you are doing it, may be more important than WHAT you are doing. This phenomenon strongly supports a continuous biopsychosocial conceptualization while treating patients with PVD and other vulvar and pelvic pain conditions. Due to the large number of variables, there is need of an individualized multifaceted therapeutical approach: care made to measure.

5) **Prognostic Factors (Grade C) [271, 314, 385, 398, 403-406]**

The following factors indicate poorer outcome of treatment gains associated with vestibulectomy, biofeedback/physiotherapy, and CBT for PVD and should be addressed in future studies:

a. Characteristics of vaginismus before the surgery
b. Lifelong introital dyspareunia
c. Large amount of surface area involved with allodynia
d. Involvement of the Skene’s duct openings
e. Unwillingness to have sex therapy if offered.
f. The coexistence of candidiasis and vulvar pain
g. Increased pretreatment pain
h. The coexistence of depression and anxiety
i. Erotophobia: the tendency to respond with negative affect to sexual cues
j. Disgust and contamination sensitivity

b) **Vaginismus**

Although vaginismus and PVD often overlap in terms of clinical presentation and may respond to some similar treatment options (e.g., pelvic floor physical therapy, sex therapy), treatment options for vaginismus typically tend to target the muscle spasm over and above the symptom of (feared) pain. As such, the major focus of treatment tends to be vaginal dilatation combined with progressive desensitization and a variety of relaxation techniques [407]. Additional components may also be part of the treatment regimen, ranging from sex education to decreasing penetration fear and anxiety. Some literature on less commonly used adjunct components also exists, and includes educational gynecological examinations [408], the application of topical anesthetics [409], pelvic floor biofeedback [410], botulinum toxin injections [230], anxiolytic medication [411], and surgical intervention [412]. Despite claims that treatment outcome for vaginismus is generally excellent, many treatment studies are methodologically unsound. A Cochrane review concluded that there is very limited evidence for the effectiveness of treatments for vaginismus from controlled trials [227].

Recently, however, an RCT was conducted by van Lankveld and colleagues [6]. Women with lifelong vaginismus (N=117) were randomly assigned to group CBT, bibliotherapy, or a wait-list control group. At post-treatment, 14% of the treated women were able to experience vaginal penetration as compared to none in the control group. At the 12-month follow-up, 21% of the women in the CBT group and 15% of the women in the bibliotherapy group reported successful intercourse. Results also indicated that successful outcome was mediated by changes in fear of intercourse and avoidance behaviors [250]. Based on these results, the investigators conducted a smaller treatment study to determine whether direct exposure aimed at decreasing penetration fears and avoidance behaviors would be effective for women with lifelong vaginismus (N=10). The treatment consisted of a maximum of three 2-hour sessions during a one-week period involving the participant performing vaginal penetration exercises on herself, in the presence of a female therapist. Results indicated that 90% of women were able to experience intercourse after two exposure sessions, and results were maintained at 1-year follow-up [228].

Caution should be taken when dealing with women with vaginismus about their fear of penetration. Although ter Kuile et al. [228] demonstrated that exposure can lead to sustained behavioural change in women with lifelong vaginismus, some patients and health care workers may feel that this process is intrusive. Further studies must be conducted in order to make firm conclusions, especially in terms of whether women with lifelong versus acquired vaginismus would benefit from similar or different treat-
The sexual pain disorders are challenging conditions to treat. Not only do they entail distressing amounts of pain in a ‘private’ area of the body, the pain typically occurs during sexually intimate situations with a partner. Unfortunately, little is known about dyspareunia and vaginismus; the terminology is still under development, classification issues plague the topic, and the empirical literature – while improving – is of relatively low quality overall. To further complicate the picture, clinicians who are faced with affected women struggle with the multidimensional nature of the pain condition, comorbid psychosexual issues, and the often overlapping clinical presentations of dyspareunia and vaginismus.

**2. NEUROBIOLOGY**

A basic understanding of the neurobiology of the pelvic floor is essential in gaining insight into the pathophysiology of the sexual pain disorders and effective treatment options. Although research in this area is still in its infancy, some conclusions from the existing literature (mainly male animal studies) are able to be drawn. The pelvis and pelvic floor are innervated by both divisions of the autonomic nervous system (sympathetic and parasympathetic) and by the somatic motor and sensory nervous systems. Within the pelvis, the inferior hypogastric plexus is the major neuronal integrative center. It has multiple interconnections, innervates many pelvic organs, contains paracervical ganglia, and receives neuronal input from the sympathetic and parasympathetic nervous systems. In terms of the autonomic innervations of the urogenital organs in women, nerve density has been shown to be greater in the distal (versus proximal) vagina and in the anterior (versus posterior) vaginal wall. Interestingly, recent research has demonstrated that the vagus nerves can convey genital sensory input directly to the brain, completing bypassing the spinal cord. Somatic afferent and afferent innervation to the pelvis involves the sacral nerve roots (S2-4) and their ramifications. The sacral nerve roots emerge from the spinal cord, forming the sacral plexus, from which the pudendal nerve diverges. The pudendal nerve divides into upper and lower trunks; the dorsal nerve of the clitoris is derived from the upper trunk.

The vulva is densely innervated by branches of the pudendal nerves, conveying information about gentle and intense mechanical stimulation. The vagina is innervated by the pelvic nerves and responds to gentle and intense stimulation, including noxious stimuli. The cervix and adjacent fornix region of the vagina are innervated more densely than the rest of the vagina by the pelvic and hypogastric nerves. Mechanical probing (non-noxious) of the vagina and/or cervix produces antinoceptive effects in rats and analgesia in women. Importantly, information arriving from the vulva, vagina, and cervix is conveyed to widespread areas of the central nervous system, such that stimulation of these areas can affect many physiological and perceptual functions. The vulvar vestibule contains free nerve endings, and neural hyperplasia in this area has been found in women with PVD; this morphological explanation may help explain the hyperalgesia reported by these patients. Pain arising from within the pelvis and pelvic floor involves diverse structural, neuronal, and neurochemical factors. However, more empirical investigation of these factors is needed in order to fully understand the complexity of mechanisms involved in the sexual pain disorders.

**3. VULVOVAGINAL DISORDERS**

Disorders of the genital skin and mucous membranes are common and interfere with sexual contact, often by causing pain. Most of these disorders, including candidiasis, trichomonas, genital herpes, human papilloma virus infection (HPV), furuncles, recurrent vulvovaginal candidosis infections (RVVC), and infection of the greater vestibular glands are transient and caused by inflammation. Some are chronic conditions, such as lichen simplex, lichen sclerosis, and lichen planus. These inflammatory conditions are easily diagnosed and some can be adequately treated.

Vulvar dermatoses are thought to be due, at least in some cases, to an auto-immune system deficiency. Inflammation of the vulvar skin may arise in response to contact with irritant substances and use of over-the-counter products (e.g., anti-fungal creams), whether prescribed by the health professional or not.

Provoked vestibulodynia (PVD) appears to be diagnosed in the majority of women with superficial, introital pain during (attempted) vaginal penetration; it occurs in up to 18% of women in the general population. The symptoms of PVD may lead to physical, sexual, and psychological distress. It has been suggested that lifelong (primary) PVD and acquired (secondary) PVD differ in etiological, clinical, and genetic variables. The etiology of PVD is considered multi-factorial, and includes inflammatory reactions with T-cell lymphocyte infiltration of the vulvar subepithelium. Women with PVD are more likely to report histories of bacterial vaginosis and candidiasis than asymptomatic controls. The association of (a history...
of) combined oral contraceptives and PVD has met with inconsistent results in prevalence studies. Generalized, unprovoked vulvodynia has been less intensively investigated, and is considered difficult to treat.

4. CHRONIC PAIN PHYSIOLOGY

Pain is a complex sensation involving sensory-discriminative (localization of the stimuli, detection of intensity and quality discrimination), affective-motivational (encompassing emotional reactions, an arousal and selective attention to the painful stimuli) and cognitive-evaluative aspects (anticipation, attention to the painful stimuli and comparison with past experience). The current neuromatrix theory of pain proposes that pain is produced by a characteristic “neurosignature” pattern of nerve impulses generated by the “body-self neuromatrix” in the brain. It proposes that pain results from activity in the neural network rather than directly from sensory input evoked by injury, inflammation, or other pathology, and can therefore occur in the absence of an identifiable, physical cause.

It has been suggested that PVD involves abnormalities in three interdependent systems: the vestibular mucosa, pelvic floor muscles, and central nervous system. Neurogenic inflammation is believed to be involved in PVD, with a bidirectional influence of peripheral inflammation and the nervous system, and a mediating role of vasoactive peptides (substance P, neurokinin A, and calcitonin-gene-related peptide), causing vasodilatation, extravasation of proteins, and release of bradykinin and nitric oxide. These mediators can also cause degranulation of peripheral mast cells, thus releasing histamines and serotonin, and causing a long-lasting lowering of nociceptive thresholds (peripheral sensitization).

Genital pain syndromes appear to be associated with hypersensitivity to both visceral and somatic stimuli. An underlying basis for the local hypersensitivity found in women with PVD has been found in the form of increased innervations and/or sensitization of thermoreceptors and nociceptors in the vestibular mucosa. Increasingly, a widespread hypersensitivity to painful stimuli can also be found in these patients. These findings suggest that pain mechanisms in PVD cannot be solely attributed to peripheral neurogenic inflammation.

Nerve injury from neurogenic inflammation in women with PVD produces non-reversible changes representing neuropathic pain, although other symptoms of neuropathic pain (paraesthesias and dysesthesias) are not commonly reported. Lowered nociceptor thresholds likely reflect peripheral sensitization, caused by the release of chemical inflammatory mediators. Central sensitization has not been verified in experimental research, but the initiation and exacerbations of the pain of PVD after severe stressful life events fits this model.

5. PELVIC FLOOR AND SEXUAL PAIN DISORDERS

Normally, pelvic organs are supported by the pelvic floor musculo-fascial complex. Pelvic floor muscles (i.e., levator ani muscles) consist of anterior and posterior divisions. Several conditions may affect pelvic floor muscle function and result in dyspareunia. For example, pelvic organ prolapse can occur when the pelvic floor muscles are weakened and the endopelvic fascia is stretched or torn. Prolapse can affect the anterior or posterior vagina, or the vaginal vault, and can be resolved via several treatment options involving surgical procedures. However, some treatment avenues can also lead to dyspareunia and decreases in sexual function. In particular, the use of mesh in pelvic floor repair surgery does not appear to entail any clear benefit, and patients undergoing this procedure should be informed of the associated high rate of postoperative dyspareunia.

6. PSYCHOLOGICAL ASPECTS

a) Provoked Vestibulodynia (PVD)

There is evidence of substantial comorbid presence of clinical psychopathology in PVD, especially depression and anxiety. The pervasiveness of these disorders warrants a careful assessment for the purpose of treatment planning. Several studies have documented elevated levels of depression in women with PVD. In terms of anxiety, these patients demonstrate increased attentional bias for pain-related stimuli (thermal and tactile stimulation) and increased catastrophic thinking about genital pain as compared with non-affected women. The level of hypervigilance is largely accounted for by state and trait anxiety levels. In line with this finding, women with PVD report stronger negative feelings toward sexual partner contact. However, results of studies examining sexual arousal responses to erotic stimuli in women with PVD have yielded contradictory results.

Variables that predict better outcome of psychological treatment in women with PVD were higher socioeconomic status, lower education, and childlessness. Willingness to be psychologically evaluated was highly predictive for positive outcome of vestibulotomy, as were cooperation of patient in postoperative counseling, localized disease, acquired vs. lifelong symptoms, absence of vulvodynia, and non-involvement of Skene’s duct openings.

Recent evidence suggest that the two major subtypes of PVD (i.e., primary/lifelong, secondary/acquired) may differ with respect to systemic pain sensitivity, pain thresholds, and levels of pain catastrophizing and trait anxiety. Indeed, various aspects of psychological functioning in women with PVD according to subtype require further study.

b) Superficial dyspareunia not identified as PVD
Similar to PVD, there is substantial comorbid presence of clinical psychopathology in this patient group, especially of depressive and anxiety disorders, relationship discordance, and problems with hostility. The pervasiveness of these issues warrants a thorough assessment to aid in treatment planning.

Vaginismus

Psychological etiological factors underlying vaginismus are not well understood, with some studies demonstrating elevated levels of affective and anxiety-related problems, and others finding equal levels on these dimensions when compared with asymptomatic women.

Successful treatment by means of psychological or psychosocial approaches was predicted by the reduction of penetration phobia and avoidance behavior, the presence of a wish to become pregnant, and better pretreatment relational and psychological functioning. More prospective research with special attention for predictor variables is needed.

7. CLINICAL PRESENTATION

Dyspareunia and vaginismus are prevalent conditions which may arise from multiple factors and affect many aspects of psychosexual function. Unfortunately, the diagnostic process may entail negative effects to the patient and treatment may not effectively manage all the areas of complaint. It is therefore recommended to conduct a thorough assessment of physical and psychosexual factors before, during, and after treatment. Questions pertaining to the pain and affected activities are essential, as are efforts to work with the patient on parameters surrounding the gynecological examination(s).

In patients with sexual pain, the gynecological examination technique is different than that conducted as part of a routine pelvic examination. For example, it may be negotiated that an internal examination will not be performed on the first visit. Once an examination is agreed upon and before it takes place, particular details of the process must be discussed (e.g., who is present in the room, the right of the patient to stop the examination at any point, the preference of the patient to watch the examination with a handheld mirror, and what is going to happen in terms of the examination procedure). During the examination, information about the genital structures should be provided and, if things are different than would be expected, this variability can be directly demonstrated to the patient. The health care professional should also be aware of any self or patient verbal/non-verbal indicators that can hinder the process. These steps form a critical part of the educational gynecological-sexological examination.

8. MANAGEMENT

Sexual pain disorders are heterogeneous, multi-systemic and multifactorial disorders that should be treated in a multimodal way according to etiological factors, risk profile, and context. A management algorithm is proposed comprised of three characteristics.

1) A multidimensional and multidisciplinary approach that focuses on six areas:
   a. the mucous membrane
   b. the pelvic floor
   c. the pain experience
   d. sexual and relationship functioning
   e. psychosocial adjustment
   f. genital mutilation/sexual abuse

2) Individualized treatment
   a. careful history taking
   b. provision of information about the condition, its natural course, possible treatment options and management tips
   c. treatment plan

3) Patient-focused approach; the patient and her partner decide which treatment options are to be pursued:
   a. when considered significant, therapy for individual psychological disorders and/or relationship issues should be offered
   b. preference for a certain approach will depend on the country in question, the woman’s attitudes regarding treatment options, the individual health care systems, and the cost effectiveness of treatment modalities

Treatment modalities for subtypes of chronic dyspareunia in women include chronic pain medications and sexual and psychological counseling.

a) Medical interventions

Only two level 2 placebo-controlled RCTs are available. Fluconazol and Cromolyn 4% did not prove to be more effective than placebo. RCTs of carefully evaluated women who appear to have similar medical and psychological profiles are encouraged to establish the efficacy of these commonly used medical adjuncts.

b) Hygiene measures

Preventive hygienic measures (level 4) include recommendations to avoid the use of soap, vaginal douches, nylon underwear and pantyliners (mini pads), and other irritants (e.g., direct vulvar contact
with semen, wearing tight trousers). The patient is encouraged to drink many fluids to produce sufficient non-concentrated urine daily. Hydration with sitz baths may help reduce inflammation and symptoms.

c) Recommendations regarding sexual activity (Level 5)

Until the pain remits, avoidance of vaginal penetration is recommended in addition to ensuring that semen does not come into contact with the sensitive vulvar areas. Normalizing, reframing, and encouraging non-penetrative sexual activity is encouraged to avoid development of feelings of guilt.

d) Vaginal EMG biofeedback, pelvic floor physical therapy, (group) cognitive behavioral therapy,

TENS and vestibuloplasty are efficacious interventions (level 2b-4b). Treatment gains are maintained long term.

e) Prognostic factors

Poorer outcome of treatment gains associated with vestibuloplasty, biofeedback/physiotherapy, and CBT for PVD are:

- Presence of vaginismus before the surgery
- Lifelong introital dyspareunia
- Large amount of surface area involved with allodynia
- Involvement of the Skene’s duct openings
- Unwillingness to have sex therapy if offered
- The coexistence of candidiasis and vulvar pain
- Increased pretreatment pain
- The coexistence of depression and anxiety
- Erotophobia: the tendency to respond with negative affect to sexual cues
- Disgust and contamination sensitivity

Abstract

Introduction. Sexual health is an integral part of overall health, and sexual dysfunction can have a major impact on quality of life as well as psychosocial and emotional well-being.

Aim. To provide evidence-based and expert-opinion consensus guidelines for the clinical management of sexual dysfunction in men.

Methods. An international consultation in collaboration with major urologic and sexual medicine societies was convened in Paris in July 2009. More than 190 multidisciplinary experts from 33 countries were assembled into 25 consultation committees. Committee members established the scope and objectives for each chapter. Following an exhaustive review of available data and publications, the committees developed evidence-based guidelines in each area.

Main outcome measure. New algorithms and guidelines for the assessment and treatment of sexual dysfunctions were developed. These guidelines were based on the work of the previous consultations and on the evidence coming from the scientific literature published from 2003 to 2009. The Oxford system of evidence-based review was systematically applied. Expert opinion was based on systematic grading of the medical literature in addition to cultural and ethical considerations.

Results. Algorithms, recommendations and guidelines for sexual dysfunction in men are presented. These guidelines were developed in an evidence-based, patient-centered, multidisciplinary manner. It was felt that all sexual dysfunctions should be evaluated and managed following a uniform strategy. Thus, the International Consultation of Sexual Medicine (ICSM-5), a stepwise diagnostic and treatment algorithm for sexual dysfunction in men and women, was developed. The main goal of ICSM-5 is to unmask the underlying etiology and/or indicate appropriate treatment options according to men’s and women’s individual needs (patient-centered medicine) using the best available data from population-based research (evidence-based medicine). Specific evaluation and treatment guidelines and algorithms were developed for every sexual dysfunction in men, including erectile dysfunction; disorders of libido, orgasm, and ejaculation; Peyronie’s disease; and priapism.

Conclusions. Sexual dysfunction in men represents a group of common medical conditions that need to be managed from a multidisciplinary perspective.
1. Introduction

The 2009 International Consultation on Sexual Dysfunctions was convened in Paris in 2009. It identified the following fundamental concepts as the basis for the management of sexual dysfunctions in men and women:

- Sexual health is an integral part of overall health.
- Health care providers should seek, receive, and impart information related to sexuality. Individuals have the right to receive the highest attainable standard of sexual health, including access to sexual and reproductive health care services, as a fundamental sexual right.
- Sexual dysfunctions can have a major impact on quality of life (QoL) as well as psychosocial and emotional well-being.
- The three principles for clinical evaluation and management of sexual dysfunctions are (1) adoption of a patient-centered framework, with an emphasis on cultural competence in medical practice; (2) application of evidence-based medicine in diagnostic and treatment planning; and (3) use of a unified management approach in evaluating and treating sexual problems in both men and women.
- Sexual dysfunctions are essentially self-reported conditions. Therefore, diagnostic tests or procedures should not be recommended without controlled clinical data or research-based evidence supporting their use. The International Consultation of Sexual Medicine (ICSM-5 (Fig. 1)) is a stepwise diagnostic and treatment algorithm for sexual dysfunction in men and women. The main goal of the ICSM-5 is to unmask the underlying etiology and/or to indicate appropriate treatment options according to men’s and women’s individual needs (patient-centered medicine) using the best available data from population-based research (evidence-based medicine).

- Ignorance and knowledge gaps about sexual function and dysfunction are commonplace. Misinformation or myths may lead to uninformed sexual decisions with serious consequences. During the initial phase of assessment, physicians must discriminate among sexual concerns, difficulties, dysfunctions, and disorders.

![Fig. 1 – The steps of the International Consultation on Sexual Medicine (ICSM-5).](image)

SD = sexual dysfunction; QoL = quality of life.
• For clinical purposes, sexual dysfunctions are categorized into three types according to their etiology: type I, psychogenic; type II, organic; and type III, mixed. Types II and III differ according to the absence or presence of significant mental (cognitive) or emotional (affect) distress. In type II dysfunctions, resolution of the main symptom adequately diminishes mental and/or emotional distress, whereas in type III dysfunctions, complementary psychotherapy is indicated.

• Sexual, medical, and psychosocial history is mandatory in every case.

• Physical examination and laboratory tests are strongly recommended but not always necessary.

• Specialized diagnostic procedures for women are less advanced and less widely used than those for men. Diagnostic procedures with the highest level of evidence should be used, when appropriate.

• Improved management of sexual dysfunction depends on physicians' inclination and ability to educate patients about their sexual function and dysfunction.

These principles represent the evolution of scientific thinking in the management of sexual dysfunction in both sexes. They stem from the work done in the previous consultations and the evidence coming from the literature published from 2003 to 2009.

In this article, we report the recommendations for every sexual dysfunction described in men. To facilitate reading of this article, levels of evidence and grading for each recommendation were not included but are detailed in the various articles reporting on the work of every committee. Similarly, references are not included in this manuscript but are accessible in the articles discussing each topic.

2. Erectile dysfunction

2.1. Definition of erectile dysfunction

Erectile dysfunction (ED) is defined as a man’s consistent or recurrent inability to attain and/or maintain penile erection sufficient for sexual activity. A 3-mo minimum duration of symptoms is accepted for establishment of the diagnosis. In some instances of trauma or surgically induced ED (eg, following radical prostatectomy [RP]), the diagnosis may be made prior to 3 mo. Objective testing (or partner reports) may be used to support the diagnosis of ED, but these measures cannot substitute for the patient's self-report in classifying the dysfunction or establishing the diagnosis.

2.2. Evaluation of the patient with erectile dysfunction

The 2009 international consultation supports the view that the general framework for the evaluation of patients with any type of sexual dysfunction should follow the same basic principles. The initial steps of patient evaluation, described below, should be applied uniformly regardless of the final diagnosis.

2.2.1. Initiating the discussion

In some circumstances, a single question (eg, “Do you have questions or concerns about your sexual functioning?”) may be sufficient to clarify the patient's primary issue; in other situations, a series of questions is indicated. Sexual inquiry is most often conducted in a face-to-face interview with the patient, although paper-and-pencil questionnaires or Internet-based methods may be of value. The style or manner in which sexual inquiry is conducted is important: It should reflect a high level of sensitivity and regard for each individual's unique ethnic, cultural, and personal background.

The aim of taking a sexual history should be ascertaining the severity, onset, and duration of the problem as well as the presence of concomitant medical or psychosocial factors. It is necessary to determine whether the presenting complaint (eg, ED, anorgasmia) is the primary or major sexual problem or if some other aspect of the sexual response cycle (desire, ejaculation, orgasm) is involved. Other sexual problems may exist as concomitant disorders (eg, hypoactive sexual desire) or as secondary disorders to the primary sexual complaint.

The medical and sexual history is essential and frequently the most revealing aspect of the assessment process. A comprehensive sexual history is essential in confirming the patient's diagnosis as well as in the evaluation of the patient's overall sexual function. Questions apply specifically to the evaluation of male arousal, desire, and orgasm/ejaculation difficulties. In principle, these questions can be addressed to all patients presenting with sexual difficulties.

2.2.2. Medical history

Although not always definitive, a detailed medical history may provide suggestive evidence for or against the role of specific organic or psychogenic factors and should be obtained in all cases of sexual dysfunction. Documenting a medical history has several goals. First, the physician must evaluate the potential role of underlying or comorbid medical conditions. Sexual dysfunction may be symptomatic of an underlying medical disorder, such as
atherosclerosis or diabetes. Second, the physician must actively investigate the possible association with cardiovascular conditions to differentiate among potential organic and psychogenic causes in the etiology of a patient’s sexual problem. Third, the history helps the physician assess the use of concomitant medications. Some of these medications can either cause or contribute to the patient’s sexual difficulties, and a change in medication may result in an improvement in sexual function. Additionally, the use of certain medications may be important contraindications for specific treatments. Medical history may include all medical conditions that could interfere with sexual function.

2.2.3. Psychosocial history

Potential etiologies for sexual dysfunction include a wide range of organic and medical factors, but multiple psychological or interpersonal factors (eg, anxiety, depression, relationship distress) can also be causes. A detailed psychosocial assessment is essential in every case of sexual dysfunction. Given the interpersonal context of sexual problems in men and women, the physician should carefully assess past and present partner relationships. Sexual dysfunction may affect the patient’s self-esteem and coping ability as well as his or her social relationships and occupational performance. These aspects should be assessed in each case.

The physician should not assume that every patient is involved in a monogamous, heterosexual relationship. For this reason, it is advisable to begin the history with broad questions: “Are you sexually active at the moment?” “Do you have a regular sex partner?” Then ask a follow-up question, such as, “Is this a same-sex or opposite-sex relationship?” The early stages in the development of a problem are often of crucial significance to assessment and treatment. Were there particular times of change in the sexual relationship? If so, what events occurred in the patient’s life at those times? In addition, the physician should ask questions about other relevant aspects of the patient’s life, including interpersonal relationships, occupational status, financial security, family life, and social support.

2.2.4. Physical examination

The etiology or causal factors for sexual dysfunction may or may not be apparent from the patient’s history alone. In specific sexual dysfunctions (eg, anatomic problems, ED), further investigation by means of a physical examination and selected laboratory testing may be of value in confirming or ruling out specific etiologies or comorbidities. In most cases, the physical examination will not identify the specific etiology or cause of sexual dysfunction; however, a focused physical examination is strongly recommended. This examination should include a general screening for medical risk factors or comorbidities that are associated with sexual dysfunction, such as body habitus (secondary sexual characteristics) and assessment of the cardiovascular, neurologic, and genital systems, with particular focus on the genitalia and secondary sex characteristics.

The physical examination may corroborate aspects of the medical history and can sometimes reveal unsuspected physical findings (eg, decreased peripheral pulses, atrophic testes, penile plaque). In addition to identifying specific etiologies or comorbidities, the physical examination may provide an opportunity to inform the patient about aspects of his sexual anatomy or physiology as well as to provide reassurance about body appearance and function. It should be recognized that the physical examination can also be a source of shame, embarrassment, or discomfort for many patients. Every effort should be made to ensure the patient’s privacy, confidentiality, and personal comfort during the examination.

The physician should always review the major findings of the examination and should address any questions or concerns of the patient regarding his physical appearance or normality. In some settings, it may be advisable for the physician to perform the physical examination in the presence of a nurse or chaperone.

2.2.5. Laboratory testing

Recommended laboratory tests for men with sexual problems typically include fasting glucose, cholesterol, lipids, and a hormone profile. As with the physical examination, these tests are performed primarily to identify or confirm specific etiologies (eg, hypogonadism) or to assess the role of potential medical comorbidities or concomitant illnesses (eg, diabetes, hyperlipidemia). Additional laboratory tests (eg, thyroid function) may be performed at the physician’s discretion based on the patient’s medical history and the physician’s judgment.

2.2.6. Specialized testing for erectile dysfunction

The classical specialized tests—with the exception of pharmaco-penile duplex ultrasound and measurements of nocturnal penile tumescence or sleep-related erections—are not equipped to specifically and accurately assess cavernosal neuro-endothelial function. On the contrary, these tests frequently do not add to data already available from the medical history and assessments based on patient self-report (eg, self-administered questionnaires, event logs, patient diaries), physical examination, and laboratory testing. At best, they typically confirm an expected diagnosis. Moreover, these tests are expensive, time-consuming, invasive, prone to complications (prolonged erections), and rarely conclusive except in experienced hands. A thorough description of the available specialized test
can be found in the chapter devoted to the evaluation of patients with ED.

2.3. Treatment of erectile dysfunction

2.3.1. Psychological treatment for erectile dysfunction

Psychosexologic literature has made an important contribution to the description, etiology, and diagnosis of ED, but large, randomized, and controlled studies demonstrating the efficacy of the psychotherapeutic treatment are lacking. Psychological treatment of ED consists of a variety of interventions, including psychodynamic interpretations regarding transference or anxiety, systematic desensitization, sensate focus, couples therapy, behavioral assignments, sex education, communication and sexual skills training, and masturbation exercises. It is not clear which of these interventions in combination or alone has the greatest efficacy.

Clinical experience highlights that these interventions help the patient and/or couple to improve their relationship and sexual life. Men with acquired ED demonstrated more gains than men with lifelong ED. Four goals of psychotherapy for ED have been described:

- Reduce or eliminate performance anxiety.
- Understand the context in which men or a couple make love.
- Implement psycho-education and modification of sexual scripts.
- Identify and reduce resistance to premature discontinuation of pharmacotherapy.

2.3.2. Medical treatment for erectile dysfunction

2.3.2.1. Oral agents

Medical treatment for ED has been revolutionized by the advent of phosphodiesterase type 5 (PDE5) inhibitors (PDE5-Is), which virtually represent the unique form of oral treatment for ED. A chapter is completely devoted to discussing all medical therapies for ED, and we report only the final recommendations issued by the responsible committee.

The reason for the clinical efficacy of PDE5-Is is easily understood by considering their effect on the physiology of smooth muscle relaxation. In summary, the normal pathway for penile erection is initiated by sexual arousal, which stimulates release of nitric oxide (NO) at nerve endings in the penis (Fig. 2). Another source of NO is vascular endothelial cells. NO diffuses into vascular smooth muscle cells in the penile corpus cavernosum to cause stimulation of guanylyl cyclase and elevation of cyclic guanosine monophosphate (cGMP) in these cells. This process leads to activation of cGMP-dependent protein kinase G (PKG), phosphorylation of several proteins, and

\[ GTP \rightarrow \text{Guanosine triphosphate} \]
\[ cGMP \rightarrow \text{cyclic guanosine monophosphate} \]
\[ PKG \rightarrow \text{protein kinase G} \]
\[ ATP \rightarrow \text{ADP = adenosine diphosphate} \]
\[ PDE5 \rightarrow \text{phosphodiesterase type 5} \]

**Fig. 2 – Regulation of penile corpus cavernosum smooth muscle relaxation and effect of phosphodiesterase type 5 inhibitors.**

GTP = guanosine triphosphate; cGMP = cyclic guanosine monophosphate; PKG = protein kinase G; ATP = adenosine triphosphate; ADP = adenosine diphosphate; PDE5 = phosphodiesterase type 5.
either lowering of cell calcium or reducing sensitivity to calcium, finally resulting in smooth muscle relaxation. The increased accumulation of blood in the corpus cavernosum caused by this relaxation is the underlying basis for penile erection.

Lack of proper cGMP elevation could be the result (at least in part) of insufficient release of NO from nerve endings or endothelium. PDE5-Is enhance erectile function during sexual stimulation by penetrating into smooth muscle cells and inhibiting PDE5, which is an enzyme that degrades cGMP. This results in decreased degradation of cGMP, which maintains higher cellular levels of cGMP in both corpus cavernosum and the vessels supplying it. This decreased degradation increases relaxation of the smooth muscle, which dilates the corporeal sinusoids, resulting in increased blood flow and allowing an erection to occur. The pathway shown in Figure 2 may not work properly if the cGMP level in corpus cavernosum smooth muscle cells is not elevated sufficiently or if relaxation of smooth muscle in the tissue is deficient or incomplete.

In most countries, the PDE5-Is are the initial form of pharmacotherapy for men with ED. Three such drugs—sildenafil, tadalafil, and vardenafil—are licensed for use around the world. A number of other phosphodiesterase inhibitors are available in a few countries ( udenafil, mirodenafil), and still others (avanafil, lodenafil, SLx-2101) are currently under development (Table 1).

There is robust evidence that PDE5-Is are effective, safe, and well-tolerated therapies for the treatment of men with ED. Most currently available evidence relates to sildenafil, tadalafil, and vardenafil. PDE5-Is are first-line therapy for most men with ED who do not have a specific contraindication to their use. There is no evidence of significant differences in efficacy, safety, or tolerability among the PDE5-Is, but it is important to recognize that patients who are using nitrates cannot use PDE5-Is at the same time.

### 2.3.2.2. Local therapies

The dawn of the age of pharmacologic treatment began 25 years ago with the recognition that vasoactive drugs, when injected into the penile erectile tissue, were capable of initiating and maintaining erection. Currently, alprostadil, papaverine, and the combination phenolamine plus vasoactive intestinal polypeptide are the main licensed agents for intracavernosal injection (ICI) therapy. Alprostadil is also available as an intrarectal suppository.

Both ICI and intrarectal therapy with alprostadil are effective and well-tolerated treatments for men with ED. It is recognized that the intrarectal route of administration is less effective than the intracavernosal route. Local therapies are considered second-line therapy and should be considered in patients in whom PDE5-Is are not effective and in men who have contraindications to their use. ICI should not be used in men with conditions that predispose them to priapism—most notably, men with sickle cell disease, multiple myeloma, and leukemia. Anticoagulation, however, is not a contraindication to ICI.

### 2.3.3. Vacuum constriction devices

Vacuum constriction devices (VCD) are ED treatment devices that use negative pressure to engorge the penis with blood while constriction rings artificially trap blood in the penis. VCDs are a safe and effective form of therapy for men with ED. The British Society for Sexual Medicine Guidelines, an evidence-based guideline for the diagnosis and treatment of ED, concluded that oral pharmacotherapy with PDE5-Is and VCDs are the first-line therapy for ED. However, one has to recognize that a number of studies have reported that erections obtained with a VCD are unnatural and therefore are distinctly different from physiological erections. The most common VCD side effects are painful ejaculation, inability to ejaculate, generalized pain, petechiae, bruising, and numbness.
Serious complications from VCD use are rare but include penile skin necrosis, urethral varicosities, capture of scrotal tissues within the penile shaft, development of Peyronie’s disease, and Fournier’s gangrene. The importance of proper patient selection improves outcome results, as confirmed by the experience of a number of authors. VCDs may be offered preferentially to elderly patients who partake in limited intercourse attempts versus younger patients, who document lower preference for VCDs because of unnatural erections and cumbersome application.

2.3.4. Surgical treatment for erectile dysfunction

2.3.4.1. Arterial revascularization

Many retrospective studies report outcome data for penile revascularization surgery for arteriogenic ED. These studies are limited by variable inclusion and exclusion criteria, short length of follow-up, and lack of objective follow-up data. Young men who have sustained traumatic arterial lesions appear to have better outcomes compared to elderly patients.

No comparative prospective, randomized studies have assessed the outcome of penile revascularization surgery for arteriogenic ED. Based on the evidence within the literature, this surgery may be offered to men younger than 55 years of age who are nonsmokers and nondiabetic, who have no evidence of venous leakage, and who demonstrate an isolated stenosis of the internal pudendal artery.

2.3.4.2. Surgery for cavernous veno-occlusive dysfunction

At the time of this writing, cavernous veno-occlusive dysfunction (CVOD) surgery in the management of ED remains controversial, and the weight of available evidence is contrary to routine use as a treatment option for ED. CVOD surgery, as it is practiced today, does not conform to the desiderata of good clinical practice or evidence-based medicine. The normal diagnostic values for available tests, universal diagnostic criteria for case selection for surgery, and consensus on choice of operation in a given patient have not been unequivocally established. This said, although CVOD surgery is still considered investigational, it may be offered in special situations, such as for young patients with site-specific congenital, post-traumatic, or postinflammatory venous leaks. If CVOD surgery is undertaken, the physician should be required to follow an operated patient long term (48 months).

2.3.4.3. Penile prosthetic surgery for erectile dysfunction

A patient would currently be considered a good candidate for a penile prosthesis if he had failed medical therapy or if medical therapy were contraindicated and the other therapies (eg, penile injections, intraurethral therapy, VCDs) have also failed or do not satisfy the patient. Patients who eventually opt for an implant are usually highly motivated to continue with sexual activity.

In many instances, the physician helps the patient decide which prosthesis type to choose. This decision is usually based on the physician’s comfort with the surgical approach, assessment of body habitus, manual dexterity of the patient, and overall cost. Patients with a larger penis will be best served by a three-piece inflatable device, as these devices deliver the best rigidity. Similarly, patients with shorter penises often choose the three-piece device because semirigid rods and two-piece implants are more difficult to conceal. Patients with limited manual dexterity or those who have difficulty manipulating hydraulic devices are directed toward a semirigid rod. An exception to this rule is when a motivated partner manipulates the hydraulic device for the patient.

It is important for the patient receiving a three-piece inflatable implant to understand that the postimplant size of his penis will invariably be slightly shorter than his natural erection when he was fully potent. Also, unlike a normal erection, the prosthetic erection does not result in an increase in the size of the glans. Preoperative consultation with the implant candidate should explain this loss of length but emphasize that the girth of the penis may be greater than a natural erection and that girth, not length, is responsible for penile rigidity.

Sensitivity of the penis, ejaculatory abilities, and sexual drive are for the most part unchanged following placement of a prosthesis. The patient needs to clearly understand that penile implants only restore the ability to penetrate. They do not restore any special sensitivity or sexual drive that may have been present in earlier years. If the cylinders are removed at a later date, the capsule remains, and the empty space will partially fill with proliferating scar tissue. This may make it difficult for the patient to respond adequately to other treatments, such as medication or a VCD.

It is important that the patient have realistic expectations for his penile prosthesis. Along this line of reasoning, the patient should be informed of the following possible complications related to the prosthesis prior to implantation: infection and its consequences, pain, mechanical failure, penile shortening, and autoinflation. Numerous studies have shown high satisfaction rates for both patients and partners.
2.4. Clinical correlates between erectile dysfunction and coronary artery disease

When dealing with the ED patient, the following considerations should be always discussed in detail: (1) ED and coronary artery disease (CAD) share the same risk factors, (2) sexual activity for couples in a stable relationship does not increase cardiac events, (3) sex is not an undue stress to the heart, (4) men with ED should have their CAD risks assessed and treated, (5) sexual activity safety can be assessed using noninvasive stress testing, and (6) exercise stress testing and computed coronary angiography can be used to detect occult CAD.

The correlation between ED and the metabolic syndrome should also be considered with attention and discussed with the ED patient taking the following points into account: ED is closely linked to the metabolic syndrome, and the metabolic syndrome is associated with hypogonadism and reduces the effectiveness of PDE5-Is. Testosterone should be measured when the metabolic syndrome is present.

2.5. Clinical correlates between testosterone deficiency and erectile dysfunction

Testosterone deficiency (TD) is a clinical and biochemical syndrome frequently associated with age and comorbidities and is characterized by a deficiency in testosterone and relevant symptoms. It may affect the function of multiple organ systems and result in significant detriment to QoL, including alterations in sexual function. The clinical manifestations of TD are variable. Sexual dysfunction, particularly hypoactive sexual desire, ED, and delayed ejaculation, are prominent and often the presenting symptoms. Visceral obesity is often associated, and muscle mass and very likely bone mineral density are diminished. Diminished strength and alterations in spatial cognition and mood may be associated.

Physical examination is frequently unhelpful, but small testicular size, alterations in testicular consistency and hair distribution, gynecomastia, and small prostate size can be detected. It is important to recognize that cardiovascular disease is often associated with low testosterone. All men with TD as well as all men over 40 years of age or those younger with a strong family history should have their cardiovascular risk factors assessed and addressed.

Although a number of questionnaires have been proposed to support screening for or diagnosing TD, they typically show good sensitivity but low specificity. The diagnosis of TD must be based on both symptoms and serum testosterone values. Although there are no generally accepted lower limits of normal total testosterone (TT), there is general agreement that TT >12 nmol/l (3.5 ng/ml or 350 ng/dl) does not usually require substitution, whereas men with TT <8 nmol/l (2.3 ng/ml or 230 ng/dl) usually benefit from testosterone treatment. Between these levels, measuring free testosterone by equilibrium dialysis or calculating it from TT and sexual hormone-binding globulin levels may be helpful. A lower limit of 225 pmol/l (65 pg/ml) is accepted by many experts.

The indication to start testosterone therapy must be based on a clear clinical picture together with evidence of hypogonadism. Absence of an appropriate response after adequate testosterone treatment for 3–6 months calls for further investigation to rule out associated comorbidities.

Current commercially available preparations of testosterone (with the exception of the 17α-alkylated options) are safe and effective. The treating physician should have sufficient knowledge and adequate understanding of the advantages and drawbacks of each preparation. Finally, the patient should be given the opportunity to actively participate in the choice of testosterone formulation. The contraindications and cautions for the use of testosterone remain controversial. Testosterone therapy is contraindicated in men with clinical evidence of prostate cancer (PCa) until more evidence on safety is available; that said, there is no compelling evidence that testosterone treatment causes PCa or PCa progression in noncastrated men. Men with significant erythrosis (hematocrit >52%) or severe symptoms of bladder outlet obstruction should not start testosterone therapy without prior improvement in the comorbid condition.

2.6. Clinical correlates between erectile dysfunction and radical prostatectomy

It is becoming increasingly recognized that a number of sexual dysfunctions may occur after RP, the most commonly used treatment for clinically localized PCa. These dysfunctions include ED, libido reduction, changes in orgasm, anejaculation, penile size changes, and possibly Peyronie’s disease. These sexual dysfunctions should be extensively discussed with the patient prior to surgery.

It is recommended that physicians use a validated instrument with recognized cut-offs for normality and severity in their preoperative and postoperative evaluation of erectile function in their patients. Physicians should discuss the recognized predictors of erectile function recovery: patient age, baseline erectile function, and nerve-sparing status. It should also be pointed out to patients that other factors such
as comorbidity status and surgeon experience have been shown to be significant contributors to recovery. Physicians must provide patients with a realistic time frame for recovery of erectile function.

**Penile rehabilitation** is defined as the use of a medication, a combination of medications, or devices (alone or in combination with medication) in the early stages after RP. The goal of rehabilitation is to maximize preservation of all components of the local erectile mechanism and optimize recovery of erectile function. It is recommended that based on the strong animal and basic science evidence, understanding the strengths and weaknesses of the existing human studies and the negative consequences of long-term ED after RP, physicians should discuss with patients that penile rehabilitation has significant potential benefits for the patient or partner and should be considered after RP.

No specific recommendations regarding the structure of the optimal rehabilitation regimen can be given. Unfortunately, numerous variables remain undefined with regard to the ideal rehabilitative approach. These variables include defining the best time to start rehabilitation after RP; the frequency of medication use, specifically daily versus on-demand exposure, the best dosing schedule (low dose vs maximum dose), the duration of rehabilitation after its commencement, and the strategies used (PDE5-Is, ICI, transurethral prostaglandin suppository, vacuum therapy). Unfortunately, no definitive evidence exists favoring one rehabilitation strategy over another.

### 3. Orgasm and ejaculation disorders in men

#### 3.1. Premature ejaculation

##### 3.1.1. Definition of premature ejaculation

In August 2007, the International Society for Sexual Medicine convened a panel of experts to review criteria for premature ejaculation (PE; Table 2). This panel proposed the following evidence-based definition of lifelong PE: “ejaculation which always or nearly always occurs prior to or within about one minute of vaginal penetration, and the inability to delay ejaculation on all or nearly all vaginal penetrations, and negative personal consequences such as distress, bother, frustration and/or the avoidance of sexual intimacy.” The panel concluded that there was insufficient evidence to propose definitions for acquired PE, although it is recognized that men with acquired PE have acquired this disorder at some point after experiencing normal ejaculatory latencies and that onset may be either sudden or gradual. The appearance of PE may be the result of urologic dysfunctions, thyroid dysfunction, or psychological or relationship problems.

The possibility that other sexual problems coexist with PE should be investigated routinely. Although most men with lifelong PE do not suffer from concomitant ED, PE coexists in about one-third of patients complaining of ED. In some instances, PE and ED may form a vicious cycle in which a man trying to control his ejaculation instinctively reduces his level of excitation (which can lead to ED) or a man trying to achieve an erection basically attempts to do so by increasing his excitation and arousal (which can lead to PE). Although reduced time to ejaculation is only rarely an early manifestation of ED, it may occur when the man has an unstable erection because of a fluctuation in penile blood flow. In this case, the man may reach ejaculation quickly to compensate for the weak erection.

##### 3.1.2. Evaluation of premature ejaculation

Men with PE should be evaluated with a detailed medical and sexual history; a physical examination; and appropriate investigations to establish the true presenting complaint, identify obvious biologic causes such as medication or recent pelvic surgery, and uncover sufficient detail to establish the optimal

| Table 2 – The four premature ejaculation syndromes |
|-----------------|-----------------|-----------------|-----------------|
| Variable        | Lifelong PE     | Acquired PE     | Natural variable PE |
| IELT            | (<1–1.5 min)    | (Very) Short IELT (<1.5–2 min) | (3–8 min)          |
| Frequency       | Consistent      | (In)consistent  | Inconsistent     |
| Etiology        | Neurobiologic and genetic | Medical psychological and/or Normal variation of ejaculatory performance |
| Treatment       | Medication with or without counseling | Medication psychotherapy and/or Psycho-education, reassurance |
| Prevalence      | Low             | Low             | High             |

PE = premature ejaculation; IELT = intravaginal ejaculation latency time.
treatment plan (Fig. 3). The following relevant information should be obtained from the patient:

- A basic medical history, including the use of prescribed and recreational medications
- The cultural context and developmental history of the disorder, including whether the PE is global or situational, lifelong or recent in its development
- Quality measures of each of the three phases of the sexual response cycle (desire, arousal, and ejaculation); the desire and arousal phases may affect the ejaculatory response
- Details about the ejaculatory response, including the patient’s subjective assessment of his intravaginal ejaculatory latency time (IELT) and sense of ejaculatory control, the level of sexual dissatisfaction and distress, and the frequency of sexual activity
- The partner’s assessment of the situation, including whether the partner suffers from female sexual dysfunction
- Assessment of the sexual and overall relationship

3.1.3. Treatment of premature ejaculation
3.1.3.1. Psychological therapy

Present-day psychotherapy for PE is an integration of psychodynamic, systems, behavioral, and cognitive approaches within a short-term psychotherapy model. The guiding principles of treatment are to learn to control ejaculation while understanding the meaning of the symptom and the context in which it occurs. Besides teaching self-control techniques to delay ejaculation, modern psychosexual therapies try to achieve the following aims:

- Help the patient recover his self-confidence and confidence in his sexual performance.
- Reduce performance anxiety.
- Solve relational problems.
- Increase communication between the partners.
- Resolve interpersonal issues that precipitate and maintain the dysfunction.

In addition, psychotherapists seek to modify rigid sexual repertoires and help the couple remove

Figure 3 – Management algorithm for premature ejaculation.

*IELT = intravaginal ejaculatory latency time; PE = premature ejaculation; ED = erectile dysfunction.*
3.1.3.2. Medical treatment for premature ejaculation

The efficacy and safety of off-label daily dosing of selective serotonin reuptake inhibitors (SSRI; paroxetine, sertraline, citalopram, fluoxetine) and the serotonergic tricyclic, clomipramine, and off-label on-demand dosing of clomipramine for the treatment of PE is well established. Within this group of drugs, a meta-analysis of published data suggests that paroxetine (an SSRI) exerts the strongest ejaculatory delay. The use of SSRIs is limited by the lack of approval by the US Food and Drug Administration, the European Medicines Agency, or other regulatory agency and therefore must be prescribed off label. Recently, dapoxetine has been officially approved in Europe and other extra-European countries for the on-demand treatment of PE. The efficacy and safety of dapoxetine is well established. The decision to treat PE with either current off-label SSRI daily dosing or on-demand dosing of dapoxetine must be based on the treating physician’s assessment of individual patient requirements.

The efficacy and safety of off-label on-demand topical anesthetic agents in the treatment of PE has also been shown. The efficacy and safety of off-label on-demand or daily dosing of PDE5 is has been shown in the treatment of lifelong PE in men with normal erectile function, although the level of evidence is lower. There is no evidence to suggest that selective dorsal nerve neurotomy or hyaluronic acid gel glans penis augmentation are effective treatments for PE. Surgery may be associated with permanent loss of sexual function and is contraindicated in the management of PE.

3.2. Orgasmic dysfunction

3.2.1. Definition of orgasmic dysfunction

Orgasmic dysfunction is the inability to achieve an orgasm or markedly diminished intensity of orgasmic sensations; it can also be the marked delay of orgasm during any kind of sexual stimulation. There can be self-report of high sexual arousal or excitement in this disorder, and orgasmic dysfunction can occur together with ejaculatory function.

Delayed ejaculation (DE), retarded ejaculation, and inhibited ejaculation (IE) are probably the least common, least studied, and least understood male sexual dysfunctions. Yet, the impact of these conditions is significant in that they typically result in a lack of sexual fulfillment for both the man and his partner, an effect further compounded when procreation is among the couple’s goals for sexual intercourse. Problems with “difficulty” in ejaculating may include varying delays in the latency to ejaculation as well as the complete inability to ejaculate (anejaculation). Reductions in the volume, force, and sensation of ejaculation may occur. At the extremes are anejaculation (time) and retrograde ejaculation (direction) but IE and DE are more commonly encountered. Partially retarded ejaculation (PRE) is sometimes observed in men who attempt to control ejaculation by suppressing the muscular contractions associated with ejaculation. These men experience diminished pleasure and sensation as semen is released during emission, and the ejaculatory sensations are dulled through attempted suppression of striate muscle response. PRE is sometimes observed in men with PE as they first attempt to consciously delay their orgasm. A final disorder, anorgasmia, refers to a perceived absence of the orgasm experience, independent of whether any or all of the physiologic concomitants of ejaculation have taken place. In this paper, we briefly summarize the main principles in the management of DE (Fig. 4).

3.2.2. Evaluation of delayed ejaculation

Treatment should be etiology specific and should address the issue of infertility in men of a reproductive age. If a man has difficulty with ejaculation, a small volume of ejaculate, or absent ejaculation, it must first be established whether the problem is congenital or acquired and whether organic factors are implicated. Assessment begins by reviewing the conditions under which the man is able to ejaculate—for example, during sleep, with masturbation, with stimulation of the partner’s hand or mouth, or infrequently with varying coital positions. The course of the problem is documented, and variables that improve or worsen performance are noted. Questions concerning the man’s ability to relax, sustain, and heighten arousal and the degree to which he can concentrate on sensations are posed.

If orgasmic attainment had been possible previously, the life events and circumstances temporarily related to orgasmic cessation are reviewed. The events in question may be pharmaceutical or related to congenital problems, illness, trauma, or a variety of life stressors and other psychological factors (eg, following his wife’s mastectomy, the man is afraid of hurting her and therefore is only partially aroused). Societal and religious attitudes that may interfere with excitement are noted, such as the spilling of seed as a sin. Finally, questions
concerning the quality of the nonsexual relationship are posed and problems explored. This assessment, in conjunction with appropriate physical examination and laboratory results, will provide understanding and help determine an appropriate treatment path.

3.2.3. Treatment of delayed ejaculation

As indicated previously, before considering a psychological or behavioral approach toward the treatment of DE, physicians need to exclude probable iatrogenic and pathophysiologic causes. They should be alert for various medical conditions as well as medications that might delay ejaculation and, in the case of antidepressants, consider a reduction in dose or use of an antidote (Table 3). Vascular or neuropathic damage that causes DE is usually irreversible; therefore, the patient might be counseled to seek alternative methods to achieve mutual sexual satisfaction with his partner. Androgen deficiency—another potential cause for DE—requires appropriate testosterone replacement therapy.

Regardless of whether a clear pathophysiologic cause is present or absent, patients might be counseled to consider lifestyle changes, including enjoying more time together to achieve greater intimacy; minimizing alcohol consumption; making love when not tired; and practicing techniques that maximize penile stimulation, such as pelvic floor training. Patient education regarding existing factors that can exacerbate DE is an important first step and may represent a segue into either short-term or long-term counseling. Treatment of DE or IE with pharmaceuticals has met with limited success. No drugs have been approved by regulatory agencies for this purpose, and most drugs that have been identified for potential use have limited efficacy, impart significant side effects, or are considered experimental in nature.

4. Priapism

4.1. Definition of priapism

Priapism is an uncommon medical condition in men that is defined as an unwanted erection not associated with sexual desire or sexual stimulation and lasting for more than 4 hours. Three different types of priapism are recognized, although there may be some overlap among these categories. Ischemic
or veno-occlusive priapism is the most common form of priapism and is associated with a failure of detumescence, increasing anoxia, and ultimately necrosis of the cavernous muscle if untreated. It is an example of the compartment syndrome and requires urgent treatment. Nonischemic or high-low priapism is less common than the first type and often occurs following blunt straddle injury of the penis. It may also be congenital or idiopathic in origin. The third type, recurrent or stuttering priapism, commonly occurs in men with sickle cell disease but is not confined to them. Such priapism is usually starts with a high-flow state but may become typical ischemic priapism.

4.2. Diagnosis of priapism

Careful history and physical examination are sufficient in most cases to make the diagnosis and classification of priapism. The physical examination should focus on the rigidity of the penis, the severity of pain, and the presence of potential causative or comorbid factors, such as secondary tumors in the penis.

An initial corporal blood aspirate is essential to differentiating ischemic from nonischemic priapism. A corporal blood gas test (if this technology is available) on the initial aspirate is recommended in the emergency evaluation of priapism. Color Doppler ultrasonography (if this technology is available) of the penis and perineum is recommended in the evaluation of priapism when the history or examination suggests penile trauma.

4.3. Ischemic priapism (veno-occlusive)

4.3.1. Treatment of ischemic priapism

The recommended initial treatment for ischemic priapism is the decompression of the corpora cavernosa by aspiration. Aspiration immediately softens the erection and relieves pain, and it should be repeated until no more dark blood can be seen coming out of the corpora and fresh, red blood is obtained. This process of repeated aspiration leads to a marked decrease in the intracavernous pressure and resuscitates the corporal environment, removing anoxic, acidic, and hypercarbic blood.

Aspiration should be followed by the intracavernous injection of a sympathomimetic drug. Worldwide availability of adrenergic agents varies, and effective reversal of priapism has been documented with dilute injections of ephedrine, epinephrine, etilefrine, metaraminol, or phenylephrine. Regardless of the intracavernous sympathomimetic agent chosen for the management of ischemic priapism, physicians should consult their pharmacies and develop clear mixing and dosing protocols for safe administration. Some sympathomimetic drugs are activators of both α- and β-adrenergic receptors. Significant α-

1279
mediated effects on peripheral vasculature and β-mediated ionotropic and chronotropic effects on the heart may occur.

During ICI of sympathomimetic drugs, the physician should monitor the patient for subjective complaints and objective findings consistent with known undesirable effects of sympathomimetic agents: headache, chest discomfort, acute hypertension, reflex bradycardia, tachycardia, palpitations, and cardiac arrhythmia. Patients (and parents of child patients) should be informed about these potential complications. Blood pressure monitoring is recommended if repeated sympathomimetic dosing is given in an attempt to reverse ischemic priapism. In patients with significant cardiovascular risks, a medication history should be taken, and electrocardiogram monitoring is recommended.

Ischemic priapism associated with sickle cell disease requires intracavernous treatment. A hematologist may provide concurrent systemic therapies, but the best resolution rates are achieved with therapies directed at the penis. Oral therapy is not recommended for the treatment of acute ischemic priapism.

Shunt surgery should be considered for all cases of veno-occlusive priapism failing aspiration and ICI of sympathomimetics. Patients should be counseled that erectile function outcomes decline significantly when priapism has lasted longer than 24–36 hours and that complete ED is anticipated if priapism persists for longer than 36 hours. In men presenting with ischemic priapism longer than 48 hours in duration or failing interventions for up to 48 hours, severe ED is inevitable. Consideration may be given to implantation of a penile prosthesis after 48–72 hours of unresolved ischemic priapism.

4.3.2. Treatment of stuttering ischemic priapism

The goals of managing a patient with stuttering ischemic priapism are prevention of future episodes, preservation of erectile function, and balancing of risks versus benefits of various treatment options. A trial of either daily oral sympathomimetic therapy (α-adrenergic) or PDE5-I therapy may be used in the management of patients (adults and children) with stuttering ischemic priapism associated with hemoglobinopathies. Androgen ablation therapy is also an effective therapy. Dosing efficacy should be monitored and may need adjustment.

4.4. Nonischemic priapism (high-flow, arterial)

In the management of nonischemic priapism, corporal aspiration has only a diagnostic role. Aspiration with or without injection of sympathomimetic agents is not recommended as treatment. Color Doppler ultrasonography (if this technology is available) of the penis and perineum is recommended in the evaluation and management of high-flow priapism. The initial management of nonischemic priapism may be observation. Immediate invasive interventions (embolization or surgery) can be performed at the request of the patient but should be preceded by a thorough discussion of the chances for spontaneous resolution, the risks of treatment-related ED, and the lack of significant consequences expected from delaying (immediate) interventions. Penile arteriography should be reserved for the management of high-flow priapism when embolization is elected.

Selective arterial embolization is recommended for the management of nonischemic priapism in patients who request treatment. Autologous clot and absorbable gels, which are not permanent, are preferable to coils and ablative chemicals, which are permanent.

5. Peyronie’s disease

5.1. Definition of Peyronie’s disease

Peyronie’s disease is considered a wound-healing disorder that presents with a fibrous inelastic scar of the tunica albuginea; it is currently believed to occur in genetically susceptible individuals following some form of trauma to the penis. A palpable scar develops in the flaccid state and causes a variety of deformities in the erect state, including curvature, shortening, narrowing, and hinge effect. In the early phase, an inflammatory component often causes pain. This inflammatory pain tends to resolve with time, but because of the deformity, intercourse may be compromised or impossible. Peyronie’s disease is also frequently associated with ED and a variety of other comorbid disorders, including diabetes, hypertension, dyslipidemia, and low testosterone.

5.2. Evaluation of Peyronie’s disease

The diagnosis of Peyronie’s disease is usually apparent from the patient history and penile examination. A detailed history should be obtained focusing on onset, duration, pain, deformity, and presence of ED. This data collection can be facilitated by using a disease-specific questionnaire. Plaque measurement is inaccurate by any modality and is operator dependent; therefore, it is not a reliable assessment for treatment response. An assessment of the curvature on erection is best made by an ICI of a vasoactive agent. This test is more accurate than a home photograph or a vacuum-assisted erection
test. Dynamic duplex ultrasound—a useful but unnecessary test—provides assessment of plaque calcification, vascular flow parameters, and objective measures of deformity. It is imperative that the stretched penile length be measured preoperatively so that the patient realizes that the length loss postoperatively is mainly the result of the disease itself, not the surgery.

5.3. Treatment of Peyronie’s disease

5.3.1. Nonsurgical treatment

Men with early-phase disease (ie, longer than 12 months in duration) manifest by unstable or progressive deformity and painful erections as well as those men not psychologically ready or interested in surgery may be considered candidates for nonsurgical therapy. In general, nonsurgical treatment has limited evidence of benefit, but multiple reports of deformity stabilization or reduction make it reasonable to offer electromotive drug administration and/or intralesional injection of verapamil or interferon and/or traction therapy.

5.3.2. Surgical treatment

Surgery remains the gold standard for correcting erect penile deformity in the man with stable disease. Surgical reconstruction is indicated for the man who has had stable disease for more than 6 months, painless deformity, compromised ability or inability to engage in coitus secondary to deformity, and/or inadequate rigidity when there is extensive plaque calcification as well as for the man who desires the most rapid and reliable result. Preoperative consent is critical to setting proper outcome expectations for the patient. It is imperative to have a discussion about the risks of persistent or recurrent curvature, loss of erect length, diminished rigidity, and decreased sexual sensation. Several surgical algorithms have been published, with general agreement that for men with adequate preoperative rigidity, some form of tunica plication procedure is best for those with curvature of less than 60° and with no hourglass deformity resulting in a hinge effect. For those with more severe deformity (more than 60° and/or hourglass) and good preoperative rigidity, incision or partial excision and grafting is recommended. Penile prosthesis implantation with additional maneuvers to correct the deformity is recommended when there is preoperative ED that is not responsive to oral medication (PDE5-Is).

6. Penile trauma

6.1. Definition of penile fracture

Penile fracture is defined as the traumatic rupture of the tunica albuginea. It usually occurs during sexual intercourse when the erect penis is thrust against the partner’s symphysis pubis or perineum.

6.2. Evaluation of penile fracture

A careful history and physical examination are essential. The classical presentation includes a cracking sound at the moment of injury, a sharp pain, detumescence, swelling, and ecchymosis. The typical appearance has been described as eggplant deformity or aubergine sign by some authors. A palpable defect in the tunica albuginea can occasionally be felt, but usually the swelling conceals this sign. It is important to remember that a concomitant urethral injury—partial or complete—may occur in 2–20% of patients. Imaging (cavernosography, ultrasound, or magnetic resonance imaging) can be used for localization of the injury, whereas retrograde urethrogram (preoperative or perioperative) can be performed if a urethral injury is suspected. The ultimate decision for surgery is based on clinical findings; once diagnosed, there is no indication for conservative management.

6.3. Treatment of penile fracture

Conservative management of a penile fracture with catheterization, compression dressings, analgesia, antibiotics, and erection-inhibiting agents should be avoided. Once penile fracture is diagnosed, surgical exploration is widely accepted as the gold standard therapeutic option, even in the event of a delayed presentation (48 hours after injury).

7. Penile augmentation and lengthening surgery

This area of research and practice is controversial because an increasing number of patients now present with an anatomically normal penis that the patient perceives to be inadequate in size. The risk of performing unjustified surgery in these cases is obvious.

Both penile lengthening and augmentation techniques have been described with variable success rates. A critical analysis of the pertinent literature, however, does not reveal proven efficacy outcome data. On the contrary, findings clearly demonstrate that the complications related to these procedures may be significant. Stretching devices may be viable alternative treatment options, whereas liquid silicone injection should be discouraged. It is mandatory to recommend that the patient to undergo a thorough psychological assessment prior to considering any surgical approach.

A penis with stretched length of <7 cm should be
considered a micropenis. These patients should undergo a thorough multidisciplinary assessment. Many surgical techniques are recommended for these rare cases.

### 8. Sexually transmitted infections

There is a paucity of state-of-the-art information about sexually transmitted infections (STIs) affecting sexual function. The problem is underscored by high prevalence rates: It is estimated that 35% of adult men suffer from sexual dysfunctions and that 340 million people live with STIs.

Patients with HIV frequently suffer from sexual dysfunctions due to both pathology (ie, HIV lipodystrophy and HIV neuropathy/encephalopathy) and HIV therapies (ie, highly active antiretroviral therapy). HIV-associated sexual dysfunction is ideally addressed by a multidisciplinary team, and the importance of education as a protective factor against HIV must be emphasized.

PDE5-Is prescribed for ED, as well as recreational drugs and unprotected sexual behavior, may play a role in HIV transmission among HIV-infected and HIV-negative men having sex with men. Disclosure of HIV status among partners should be encouraged (especially with newly regained erectile function following PDE5-I or sexual-aid use), and stigmatizing attitudes should be discouraged to promote voluntary counseling and testing. Male circumcision will reduce the risk of acquisition of HIV in heterosexual men and is not associated with high-risk sexual behavior (disinhibition).

Patients with frequent recurrences of genital herpes should be evaluated on a regular basis for coexisting psychological and psychosexual illness and given appropriate treatment including possible continuous antiviral medications. *Chlamydia trachomatis*, gonorrhea, and human papillomavirus may also be associated with sexual dysfunction, but more information is needed before causality can be established.

Prostatitis and chronic pelvic pain syndrome (CPPS) are associated with sexual dysfunction. The severity of the pain and illness in acute bacterial prostatitis interferes with sexual function. Chronic bacterial prostatitis (CBP) and CPPS are frequently associated with ejaculatory pain or premature ejaculation (77%) as well as with ED in 15–72% of cases. The efficacy of PDE5-Is for amelioration of the symptoms of prostatitis in patients with CBP or CPPS and disturbed sexuality remains unclear.

### 7. Conclusion

The 2009 International Consultation on Sexual Dysfunctions in men convened all the recognized experts in the field and produced evidence-based guidelines and an evaluation-treatment algorithm. It is recognized that most patients with any of the known sexual dysfunctions should be approached in a multidisciplinary fashion. The contemporary sexual medicine expert must be knowledgeable in many scientific areas, including urology, andrology, endocrinology, and internal medicine. The patient's psychological perspective remains a key parameter to be considered for successful management of these conditions.

**Keywords:** Female sexual dysfunction, diagnosis and treatment of women's sexual dysfunction, desire disorder, arousal disorder, orgasm disorder, sexual pain disorder

**ABSTRACT**

**Introduction:** Women's sexual dysfunction includes reduced interest/incentives for sexual engagement, difficulties with becoming subjectively and/ or genitaly aroused, difficulties in triggering desire during sexual engagement, orgasm disorder and sexual pain.

**Aim:** To update the recommendations published in 2004, from the 2nd International Consultation on Sexual Medicine pertaining to the diagnosis and treatment of women's sexual dysfunctions.

**Methods:** A 3rd International Consultation in collaboration with the major sexual medicine associations assembled over 186 multidisciplinary experts from 33 countries into 25 committees. Twenty one experts from 6 countries contributed to the Recommendations on Sexual Dysfunctions in Women.

**Main Outcome Measure:** Expert opinion was based on grading of evidence-based medical literature, widespread internal committee discussion, public presentation and debate.

**Results:** A comprehensive assessment of medical, sexual and psychosocial history is recommended for diagnosis and management. Indications for general and focused pelvic genital examination are identified. Evidence based recommendations for further revisions of definitions for sexual disorders are given. An evidence based approach to management is provided.

**Conclusions:** There remains a need for more research and scientific reporting on the optimal management of women’s sexual dysfunctions including multidisciplinary approaches.

**Keywords:** Female sexual dysfunction, definition, diagnosis and treatment of women’s sexual dysfunction, desire disorder, arousal disorder, orgasm disorder, sexual pain disorder

**Running Title:** Recommendations for Women’s Sexual Dysfunction
Recommendations for Women’s Sexual Dysfunction

I. INTRODUCTION

The current conceptualization of women’s sexual function emphasizes the responsive component of women’s desire. The circular model depicted in Figure 1 explains our current understanding of how desire is triggered during the sexual engagement thereby adding to any initial desire. Research confirms that women provide a variety of reasons and incentives for engaging in sexual activity. Sexually competent stimuli are integral to a sexual response and must always be assessed when considering a diagnosis and formulation of dysfunction. Women’s sexual dysfunction includes reduced interest/incentives for sexual engagement, difficulties with becoming subjectively aroused and/or genetically aroused and difficulties in triggering desire during sexual engagement. Frequently, all of these aspects are involved. Orgasmic disorder denotes sexual experiences consistently associated with high arousal but absence of orgasm. Other dysfunctions include pain and difficulty with attempted or completed intercourse or any attempts at vaginal penetration.

II. DEFINITIONS OF SEXUAL DISORDER IN WOMEN

The available evidence suggests that there are problems with existing definitions of sexual desire, arousal, and orgasmic disorders in women. The proposed definitions that were sponsored by the AUAF in 2003 present alternative criteria for these disorders: currently these are recommended for the clinical setting. Given the upcoming publication of the DSM-V in 2012, it is likely that the current diagnostic criteria for these disorders will change. GRADE B

1. SEXUAL DESIRE/INTEREST DISORDER
   (OR HYPOACTIVE SEXUAL DESIRE DISORDER; HSDD IN THE DSM-IV-TR)

There are absent or diminished feelings of sexual interest or desire, absent sexual thoughts or fantasies and a lack of responsive desire. Motivations (here defined as reasons/incentives) for attempting to

FIGURE 1: Circular sexual response cycle of overlapping phases may be experienced many times during any one sexual encounter. Desire may or may not be present initially: it is triggered by the arousal to sexual stimuli. The sexual and nonsexual outcomes influence future sexual motivation.

Copied with permission from Lippincott Williams & Wilkins from Figure 2: R. Basson. Female Sexual Response: The role of drugs in the management of sexual dysfunction. The American College of Obstetricians and Gynecologists 2001;98(2):350-352.
become sexually aroused are scarce or absent. The lack of interest is considered to be beyond the normative lessening with lifecycle and relationship duration.

Apparently innate desire (or experienced desire where the stimuli are not evident to the woman) present before sexual engagement begins is sometimes present for women, especially early in relationships and sometimes associated with menstrual periods. However, this definition of sexual desire disorder argues that its absence does not equate to dysfunction.

**a) Arousal disorder (or Female Sexual Arousal Disorder; FSAD in the DSM-IV-TR)**

Somatically-healthy women diagnosed with sexual arousal disorder usually show a normal vasocongestive response in the genitalia in response to erotic sexual stimulation, when tested in a controlled laboratory environment. Thus, it is these women’s lack of subjective arousal that is key to their distress, rather than failure of genital congestion.

It is recommended that subtypes of sexual arousal disorder are recognized: subjective sexual arousal disorder, genital sexual arousal disorder, combined genital and subjective arousal disorder and persistent genital arousal disorder. Of note, it is the woman’s self-report of absent or impaired genital congestion and lubrication that is the basis of these definitions and psychophysiological testing would be necessary to identify any actual reduction of congestion.

**b) Subjective arousal disorder**

There is absence of or markedly diminished feelings of sexual arousal (sexual excitement and sexual pleasure) from any type of sexual stimulation. Vaginal lubrication or other signs of physical response still occur.

**c) Genital sexual arousal disorder**

There are complaints of impaired genital sexual arousal. Self-report may include minimal vulvar swelling or vaginal lubrication from any type of sexual stimulation and reduced sexual sensations from caressing genitalia. Subjective sexual excitement still occurs from non-genital sexual stimuli.

A woman diagnosed with the genital subtype of arousal disorder indicates that she can still be subjectively aroused by, for instance, viewing an erotic film, or pleasuring her partner, being kissed or receiving breast stimulation. She complains of the marked loss of intensity of any genital response including orgasm. Awareness of throbbing/swelling/lubrication is absent or markedly diminished. Moreover, loss of sexual quality of sensations despite apparently adequate engorgement can occur and is poorly understood.

**d) Combined genital and subjective arousal disorder**

There is absence of or markedly diminished feelings of sexual arousal (sexual excitement and sexual pleasure), from any type of sexual stimulation as well as complaints of absent or impaired genital sexual arousal (vulval swelling, lubrication). It is the lack of the subjective excitement from any type of sexual stimulation that distinguishes these women from those with genital arousal disorder.

**e) Persistent genital arousal disorder**

There is spontaneous, intrusive and unwanted genital arousal, e.g. tingling, throbbing, and pulsating, in the absence of sexual interest and desire. Any awareness of subjective arousal is typically but not invariably unpleasant. The arousal is unrelieved by one or more orgasms and the feelings of arousal persist for hours or days.

The disorder is poorly understood but becoming a more frequently recognized syndrome. More research is needed on its prevalence, etiology, and effective treatments.  

2. **WOMEN’S ORGASMIC DISORDER (OR FEMALE ORGASMIC DISORDER; FOD IN THE DSM-IV-TR)**

Despite the self-report of high sexual arousal/excitement, there is either lack of orgasm, markedly diminished intensity of orgasmic sensations or marked delay of orgasm from any kind of stimulation.

3. **DYSPAREUNIA (DYSPAREUNIA IN THE DSM-IV-TR)**

There is persistent or recurrent pain with attempted or complete vaginal entry and/or penile vaginal intercourse.

It is recommended the experience of women who cannot tolerate full penile entry and the movements of intercourse because of the pain, be included in the definition of dyspareunia. Clearly, it depends on the woman’s pain tolerance and her partner’s hesitancy or insistence.

4. **VAGINISMUS (VAGINISMUS IN THE DSM-IV-TR)**

There are persistent or recurrent difficulties for the woman to allow vaginal entry of a penis, a finger, and/or any object, despite the woman’s expressed wish to do so. There is often (phobic) avoidance, involuntary pelvic muscle contraction and anticipation/fear/experience of pain. Structural or other physical abnormalities must be ruled out/addressed.
III. RECOMMENDATIONS REGARDING FURTHER CHANGE TO DEFINITIONS

Recommendation for HSDD:
The currently accepted definition of HSDD in women is highly problematic and the emphasis on sexual fantasies and desire for sexual activity is not applicable to all sexually healthy women. We recommend that desire be regarded as the result of an incentive (sexually competent stimulus) which activates the sexual system where subjectively perceived desire is one of many components. GRADE C

Recommendation for FSAD:
The focus on “lubrication/swelling response” in the DSM-IV-TR definition of FSAD is highly problematic given that this is rarely the complaint motivating treatment seeking. Moreover, there is minimal, if any, correlation between subjective and genital sexual arousal. Given the importance of “adequate sexual stimuli” for sexual arousal and desire, this should be assessed clinically when evaluating whether or not an arousal or orgasm disorder is present. GRADE C

IV. ASSESSMENT OF WOMEN’S SEXUAL DYSFUNCTION

The framework for assessment of sexual dysfunction is to assess predisposing, precipitating and maintaining factors. When there is a current sexual relationship (and if appropriate), both partners need to be evaluated to understand the aforementioned factors. A biopsychosocial approach is recommended. Current contextual factors are commonly etiologically important. For lifelong sexual dysfunctions, developmental history and past relationships are also commonly etiologically relevant.

1. MEDICAL AND PSYCHOSOCIAL HISTORY

A comprehensive medical and psychosocial history is highly recommended for all sexual dysfunctions (Table 1) GRADE C. Further assessment of the woman is recommended if she discloses a history sexual abuse. This includes assessment of the woman’s recovery from the abuse (with or without past therapy): identify any history of major depression, substance use disorders, significant anxiety, self-harm or promiscuity, any inability to trust people, especially those of the same gender as the perpetrator or an exaggerated need for control or need to please (and inability to say no). When there are concerns about residual abuse-related symptoms, assessment of the sexual dysfunctions per se are deferred temporarily.

When assessing arousal disorders, it is recommended to clarify which component(s) of arousal is absent/problematic. This will allow sub-typing of the arousal disorder so as to guide choice of therapy. For assessment of women’s arousal and orgasmic concerns it is recommended to assess the following: Is there adequate and acceptable stimulation with her partner and/or with masturbation? Is the degree of trust and safety she feels she needs present? Are orgasms wanted but absent and/or very delayed and/or markedly reduced in intensity?

In the case of dyspareunia and vaginismus, clarification of the aspects of the woman’s pain, her fear of pain, and avoidance responses are recommended. (Table 2)

A detailed medical enquiry with review of systems is highly recommended for all sexual dysfunctions (Table 1). This would include screening for depression as regardless of antidepressant use depression is consistently related to sexual dysfunction, particularly to low sexual desire. GRADE C

2. ASSESSMENT OF DYSFUNCTION IN THE CONTEXT OF CHRONIC ILLNESS

The multiple factors contributing directly or indirectly to sexual dysfunction require assessment. Included are alterations in response from the disease itself, its treatment, associated pain, immobility, fatigue as well as impairment of self image, loss of independence, of continence and of fertility and difficulties with partnerships imposed by the disease.

3. PHYSICAL EXAMINATION

The genital exam is often highly informative, can be very therapeutic, but its intimate nature demands there must be a reason for its inclusion. A focused pelvic genital exam is highly recommended in the following circumstances:

• For women with dyspareunia, especially those with lifelong pain and difficulty with penile entry, an educational exam is recommended.

• For women with vaginismus diagnosed from the history, confirmation is obtained by an exam done in progressive stages once fear of vaginal entry has lessened with therapy: an educational exam is advocated.

• For women with genital arousal disorder, information will be limited because the genitalia are in a non-aroused state, but estrogen deficiency, or more rarely, disease such as connective tissue disorder, can be identified.
### Table 1: Components of a Comprehensive Sexual, Medical, Psychosocial History

• For women with combined arousal disorders likely there will be no abnormality. Nothing arouses these women mentally/subjectively be it written, visual, non-genital physical stimulation and the evidence to date is that their genital response is healthy. Nevertheless, a “normal” exam is highly informative to the woman. It is also possible that a woman with combined arousal disorder goes on to become estrogen deficient – adding physical vulvar atrophy to her longstanding problems of disconnection from genital events.

2 Pelvic floor muscle tension
Do you recognise the feeling of pelvic floor muscle tension during sexual contact?
Do you recognise the feeling of pelvic floor muscle tension in other (non-sexual) situations?

3 Arousal
Do you feel subjectively excited when you attempt intercourse? Does your vagina become sufficiently moist? Do you recognise the feeling of drying-up?

4 Consequences of the complaint
What do you do when you experience pain during sexual contact? Do you still continue to include intercourse or attempts at intercourse, or do you use other ways to make love instead? If so, are you both clear intercourse will not be attempted?
What consequences does the pain have on the rest of your sexual relationship?

5 Biomedical antecedents
When and how did the pain start? What tests have been done? What treatment have you received?

* Substitute dildo/fingers for “penis” when necessary.

Table 2: Assessment of Sexual Pain

| 1 Pain | Where does it hurt? How would you describe the pain? Is the pain with penile* contact to the opening of your vagina, once the penis is partially in, with full entry, after some thrusting, after deep thrusting, with the partner’s ejaculation, after withdrawal and for how long, with subsequent micturition? Do you find your body is tensing when your partner is attempting, or you are attempting to insert his penis? What are your thoughts and feelings at this time? How long does the pain last? Does touching cause pain? Does it hurt when you ride your bicycle or when you wear tight clothes? Do other forms of penetration hurt (tampons, fingers)?
| 2 Pelvic floor muscle tension | Do you recognise the feeling of pelvic floor muscle tension during sexual contact? Do you recognise the feeling of pelvic floor muscle tension in other (non-sexual) situations?
| 3 Arousal | Do you feel subjectively excited when you attempt intercourse? Does your vagina become sufficiently moist? Do you recognise the feeling of drying-up?
| 4 Consequences of the complaint | What do you do when you experience pain during sexual contact? Do you still continue to include intercourse or attempts at intercourse, or do you use other ways to make love instead? If so, are you both clear intercourse will not be attempted? What consequences does the pain have on the rest of your sexual relationship?
| 5 Biomedical antecedents | When and how did the pain start? What tests have been done? What treatment have you received?

* Substitute dildo/fingers for “penis” when necessary.

• For women with combined arousal disorders likely there will be no abnormality. Nothing arouses these women mentally/subjectively be it written, visual, non-genital physical stimulation and the evidence to date is that their genital response is healthy. Nevertheless, a “normal” exam is highly informative to the woman. It is also possible that a woman with combined arousal disorder goes on to become estrogen deficient – adding physical vulvar atrophy to her longstanding problems of disconnection from genital events.

• For women with neurological disease affecting pelvic nerves where a detailed neurological genital exam is also necessary, clarify light touch, pressure, pain, temperature sensation, anal and vaginal tone, voluntary tightening of anus, and vaginal and bulbocavernosal reflexes.

• For women with a history of pelvic trauma.

• For women with any disease potentially affecting genital health.

• For women with acquired and lifelong orgasmic disorder even if otherwise healthy. A normal examination is of reassurance value.

• When the history indicates the opportunity for Pap smear/STI investigation should be taken.

GRADE C

A general physical exam is highly recommended as dictated by the general medical enquiry, for women with chronic illness and as part of good medical care, for example evaluation of blood pressure, breast exam etc. GRADE C

Although frequently no laboratory investigations are needed for assessment of the sexual dysfunction per se, certain situations may require laboratory testing and are guided by the general medical assessment, for example, fasting blood glucose or TSH. When an infective etiology for dyspareunia is possible, vaginal, cervical and vulval discharge microscopy/cultures should be performed. When investigational testosterone therapy is contemplated, accurate assay of baseline serum testosterone via mass spectrometry methods is recommended (see subsequent discussion).

4. PSYCHOPHYSIOLOGICAL ASSESSMENT OF AROUSAL

Psychophysiological tools are available but typically reserved for the research setting. Observation of the genital arousal response to adequate stimulation by means of audiovisual, cognitive (fantasy) and/or vibrotactile stimuli may be useful. However, it is important to note that this often does not correlate with the woman’s subjective report of (impaired) sexual arousal. Although psychophysiological testing to date is not a routine assessment, such a test may be crucial in establishing the etiology of arousal disorder. Recent study has demonstrated how difficult it is to rule out that sexual arousal problems are not caused by a lack of adequate sexual stimulation. Moreover, women with sexual arousal disorder may be less aware of their own genital changes; thus, they lack...
adequate proprioceptive feedback that may further increase their arousal. A normal genital response demonstrated in the laboratory would clarify the lesser importance of any identified organic factors potentially contributing to the arousal problem of the individual. The evidence is that sexual arousal problems in medically healthy women are more often related to inadequate sexual stimulation due to personal, contextual, and/or relational variables than to somatic causes. (Of note, nonresponse in the psychophysiological assessment does not automatically imply organicity. The woman may have been too nervous or distracted for the stimuli to be effective, or the stimuli offered may not have matched her sexual preferences.)

5. SELF REPORT MEASURES

The Female Sexual Function Index is currently the most often used measure. Diagnostic cut off scores were developed by means of sophisticated statistical procedures. Together with a Female Sexual Distress Scale score of 11 or higher, indicating distress, there is some evidence to suspect a diagnosis of sexual dysfunction. Use of self-report measures alone is not recommended for clinical purposes because they lack sensitivity and specificity with regard to etiology. Unfortunately, and contrary to evidence from epidemiological and qualitative research, current validated questionnaires are based on the assumption that (distressing) absence of sexual desire ahead of and at the outset of sexual engagement represents dysfunction in all women.

V. FORMULATION OF WOMEN’S SEXUAL DYSFUNCTIONS

Predisposing, precipitating and maintaining factors should be assessed and often the etiology is multifactorial (Table 1). Common psychosocial issues include a fear of letting go control, fear of negative outcome, inability to stay present, and lack of or inaccurate information regarding women’s sexual response. Graham and Bancroft describe a “three windows” approach helpful for contextualizing factors influencing the sexual complaint (Figure 2). These three ‘windows’ echo the descriptors recommended by the AUA committee in 2003. The first window describes aspects of the woman’s current situation (e.g., poor communication, relationship difficulties, fatigue, or lack of useful stimuli). The woman plagued with fatigue might benefit from a course of sleep hygiene therapy prior to (or instead of) sex therapy. The second window is to individual vulnerability factors influencing the presentation of complaints. These include the woman’s persistently negative

---

attitudes about herself and her body, a high need to maintain control in all life and sexual situations, a past history of sexual abuse or trauma such that flashbacks to the prior abuse are frequent and intrusive when she is attempting to be sexual. If such individual vulnerability factors are present, she may benefit from cognitive behavioral (CBT) treatment focused on that vulnerability factor (e.g., it is focused on the sexual assault, perfectionism, etc.) The third window views health-related factors influencing the sexual response, importantly, depression or anxiety. Included also are problems in the neural control of desire, arousal, and pain perception, problems in vascular supply to the genitals, endocrine dysfunction, and metabolic problems as well as both over-the-counter and prescription medications. The role of deficiency in estrogens and androgens continues to be debated. There is minimal evidence that serum levels of estradiol or testosterone are linked to desire or subjective arousal but assays other than mass spectrometry have been used and these are unreliable at the low testosterone levels found in women. Future studies should measure serum testosterone by mass spectrometry methods in women with and without diagnosed sexual dysfunction GRADE C. Moreover serum levels do not reflect intracrine sex hormone production – the major source of androgen and only source of estrogen in post menopausal women. Future studies should also measure total testosterone activity by means of androgen metabolites in women with and without definite dysfunction GRADE C.

A formulation of the diagnoses is recommended. The formulation integrates all information obtained from (sometimes a series of) in-person assessments of the woman with and without a partner, and any relevant physical examinations, blood assays, psychophysiological testing, and self-report questionnaires GRADE C. On the basis of the formulation, a diagnosis is applied, preferably using both the DSM-IV-TR as well as the AUAF systems. The clinician also continues to modify the formulation as information emerges during treatment. The "three windows" approach can be very helpful for considering the many biopsychosocial factors that influence the woman's sexual complaints. An effort should be made to determine the duration and severity of symptoms and to speculate on level of insight and prognosis.

VI. MANAGEMENT OF WOMEN'S SEXUAL DYSFUNCTION

General recommendations; GRADE C

Some investigational pharmacological agents are being used to treat specific sexual disorders. The lack of long-term safety data should always be openly discussed. It is recommended that the clinician has an interdisciplinary approach. Research is needed to identify efficacious combined/integrated treatments for sexual dysfunction. Even when sexual function has been healthy prior to medical insult, there are psychological and interpersonal repercussions plus sexual adaptations that may or may not be useful: medical management alone may be insufficient.

General issues related to improved emotional and physical well-being such as addressing depression or anxiety symptoms, possible alcohol or chemical substance use, insuring adequate sleep, exercise and healthy diet should first be addressed. Advise also on prescription and non-prescription medications and supplements. Referral to appropriate medical or specialty providers may be necessary especially in the context of chronic disease or significant psychological symptoms. The early stage of treatment might also include providing education on sexual response, basic genital anatomy and physiology, and a discussion of sexual stimulation and sexual activities other than intercourse. Patients should be encouraged to use techniques that enhance arousal including enhancing the sexual context and stimuli.

VII. MANAGEMENT OF DESIRE AND COMORBID COMBINED AROUSAL DISORDERS

Discussion of the normality of age and relationship duration-associated declines in sexual drive is a logical first step in treating the woman with distressing low desire. The clinician can provide a current understanding of how desire is triggered and that women have a variety of reasons and incentives for sexual engagement, encouraging the woman to consider her own reasons for sexual activity and challenging her belief that “sex should only happen when I’m in the mood”. For women with a DSM-IV-TR diagnosis of HSDD but who retain the ability to become sexually excited during the encounter thereby triggering desire, this process of discussing incentives for sexual activity is especially important and often sufficient. For women with sexual interest/desire disorder (with associated arousal disorder) discussion of the components of women’s sexual response depicted in Figure 1, and identifying problematic areas may be sufficient to allow women and their partners to make the needed changes (Level 4). For other women, however, more intensive strategy will be required.

1. PSYCHOSEXUAL TREATMENT FOR DESIRE AND AROUSAL DISORDERS

There are few outcome studies but our general recommendation is that when the low desire is better
accounted for by depression, poor body image, sexual abuse sequelae or other more general personality, individual, or relationship factors, then those factors must be addressed initially. **GRADE C**

Psychological management of desire and arousal disorder might include cognitive behaviour techniques (CBT) and traditional sex therapy.

CBT is based on the theory that thoughts, feelings, and behaviors interact and mutually influence one another. By targeting negative or maladaptive thoughts, both behaviors and affect can improve and disrupt the dysfunctional cycle. The behavioral component includes attending to a problematic sexual context or behaviours in either partner which reduce attractiveness or trust and ability to focus on the sexual stimuli and feelings. The cognitive component of CBT targets maladaptive thoughts that foster negative emotions and maintain problematic behavior such as avoidance. This may include identifying and challenging beliefs that she is unattractive, idealizing an unrealistic mode of sexual response portrayed by media, or challenging beliefs that unless she feels a high level of desire all the time, then she is dysfunctional. Group CBT improves sexual desire disorder in 74% of couples and this effect was maintained in 64% at one year (Level 2).

A modified Masters and Johnson sex therapy was also found to improve sexual function in 57% of women with sexual desire disorder (Level 3).

Other psychological modalities have also been investigated and may target more distant factors in the woman’s history such as unresolved themes from childhood including abuse or neglect, control issues, low sexual self image. There has been only one published study using such an approach, however, there was a benefit to sexual desire in women (Level 3).

More traditional sex therapy stems from the work of Masters and Johnson and Kaplan and includes sensate focus exercises consisting of exchanging physical touch, moving from non sexual to sexual areas of the body, with partners taking turns and giving verbal and tactile feedback. Among the very limited available empirical literature, one study showed that 65% of 365 married couples improved by clinical judgment at the end of therapy (Level 3).

Most recently, a mindfulness-based CBT administered to women in group format with desire and arousal disorder has also been explored in an uncontrolled trial. Mindfulness is an eastern practice with roots in Buddhist meditation which focuses on present moment, non-judgmental awareness. Women were taught in-session mindfulness exercises and encouraged to practice for approximately 5 hours during the 2 weeks between each of the four sessions. This resulted in significant improvements in sexual desire, arousal and other domains of sexual response and mood (Level 3). One non-controlled trial of mindfulness-based CBT for women with genital arousal disorder secondary to gynecologic cancer found significant improvements in sexual response, distress, and mood (Level 3).

**2. RECOMMENDATION RE MANAGEMENT OF LOW DESIRE:**

Psychological approaches to low desire have a long history and have been found to be effective immediately after treatment with sustained improvements over time. Moreover, they are without adverse side effects. Newer cognitive-behavioural treatments which integrate mindfulness meditation have shown excellent promise for sexual desire problems but await randomized controlled testing. There is also evidence that brief cognitive behavioural interventions are helpful for improving desire. Overall there is an urgent need for more randomized controlled investigations of psychological therapy for women’s low desire/ interest disorders. **GRADE C**

**3. RECOMMENDATION RE MANAGEMENT OF LOW AROUSAL:**

Despite our support for evidence-based practice, careful management of women with sexual problems according to the rules of “good clinical practice” must continue without solid proof of efficacy. There is one noncontrolled trial showing benefit of mindfulness-based CBT for genital arousal disorder in women secondary to gynecologic cancer. There is clearly great need for controlled efficacy studies in this area. From our review we conclude that the majority of sexual arousal problems in healthy women are not related to impaired genital responsiveness: it follows that we recommend psychological treatment for arousal disorder. **GRADE C**

**VIII. HORMONAL TREATMENT OF LOW DESIRE AND LOW AROUSAL**

**1. TESTOSTERONE**

Randomized trials of transdermal testosterone have mostly targeted surgically and naturally menopausal women. Both sudden loss of ovarian androgens and the inevitable decline in adrenal sex hormone precursors might predispose to desire and arousal disorders. However the evidence is inconclusive. Prospective studies have not confirmed sexual dysfunction subsequent to surgical menopause for benign disease. Distress about low desire is more prevalent in relatively recently surgically menopausal women, but not low desire per se. The prevalence of low desire may increase with age, but low desire associated with distress changes little with age.

A review of testosterone trials among estrogen replete surgically and naturally menopausal women
found that those women receiving the 300µg/day patch reported an increase in sexually satisfying events of 1.9 per month vs. 0.9 events per month from placebo and statistically significant increase in desire for sex.

Notably, in all of the recent testosterone trials, a strict entry criterion was a certain baseline frequency of satisfactory sexual activity and most women experienced 2-3 sexually satisfying episodes per month. Compared to the majority of women seeking treatment for sexual difficulties, where sexual frequency may take place on a once every several month basis, women recruited for research trials have a much higher level of sexual response and frequency. It is unknown if testosterone therapy would be of benefit to the large majority of women seeking treatment for sexual desire concerns. Moreover, what also remains unknown is whether testosterone treatment would significantly benefit women meeting the AUAF definitions of Sexual Desire/Interest Disorder, where there is lack of interest for sexual activity but also a failure to become sexually excited during the sexual interaction to trigger same desire.

Despite its lack of approval in the USA, many women seek out testosterone therapy for problematic low desire. Formulations for men are adapted or compounded preparations are prescribed whose safety and/or efficacy have not been evaluated. Testosterone patches are approved for use in compounded preparations are prescribed whose safety and/or efficacy have not been evaluated. Testosterone patches are approved for use in surgically menopausal women in Europe. We recommend that the clinician and patient should engage in a careful discussion of the benefits and hazards of such treatment GRADE C. Whether breast cancer and cardiovascular disease would be increased is unclear GRADE C.

**Summary of recommendations on testosterone therapy**

The decision to use must be individualized and patients informed about risks and benefits Grade C. The testosterone patch appears to be effective in the short term in postmenopausal women with HSDD Grade B. Patients must be informed about lack of long term safety data Grade C. Additional studies are needed before long term use is recommended Grade C. Use of testosterone in pre- and perimenopausal women is not supported by current data Grade A. Achieving physiological testosterone levels by transdermal delivery minimizes adverse effects Grade C-D. Relative contraindications include androgenic alopecia, acne, hirsutism hyperlipidemia and liver dysfunction Grade C. Absolute contraindications include presence or high risk of breast cancer, endometrial cancer, venothrombotic episodes, cardiovascular disease Grade C.

Monitoring should include annual breast and pelvic examinations, annual mammography, evaluation of abnormal bleeding, evaluation for acne, hirsutism and androgenic alopecia. Monitor testosterone by mass spec, (SHBG, calculated free T) with goal of not exceeding normal values. Consider lipid profile, liver function tests, complete blood count. Use for more than 6 months is contingent on clear improvement and absence of adverse effects GRADE C.

2. **ESTROGEN**

There is evidence that treatment with local and systemic estrogen benefits vulvo-vaginal atrophy and relieves vaginal dryness and dyspareunia (Level 1).

3. **LOCAL DHEA**

A recent RCT of vaginal DHEA benefited vaginal atrophy and other aspects of sexual function. No increases in serum DHEA, testosterone, estradiol or androgen metabolites were detected. No recommendation can be made until this is validated by others.

4. **SELECTIVE ESTROGEN RECEPTOR MODULATORS (SERMS).**

A Selective Estrogen Receptor Modulator was originally defined as a compound that binds with high affinity to the estrogen receptor (ER), without significant binding activity to any other nuclear receptor; which induces “estrogen agonistic” activities in some tissues, and “estrogen antagonistic” activities in others. Emerging data show that the interaction between a particular SERM and the ER results in a response in a given tissue which cannot necessarily be characterized simply as either “agonistic” or “antagonistic”. Each SERM may have a unique set of clinical responses, which are not always predictable from those seen with another SERM. Ospemifene is a novel SERM under trial for the treatment of vaginal atrophy in postmenopausal women.

5. **TIBOLONE**

Tibolone is a 19-nor testosterone derivative which is metabolized into three main metabolites: the 3α-hydroxy and the 3β-hydroxy, which are estrogenic, and the δ-4 isomer, which has progestagenic and androgenic properties. Tibolone is a selective tissue estrogen activity regulator (STEAR). In postmenopausal women, it acts as an estrogen on brain, vagina, and bone, but not on endometrium and breast. Sexual benefit has mostly been recorded in women recruited for reasons other than sexual dysfunction. Tibolone is available in Europe but has been declined approval in the USA.
IX. NON HORMONAL PHARMACOLOGICAL TREATMENT OF LOW DESIRE AND LOW AROUSAL

1. CENTRALLY ACTING AGENTS

In non-depressed women with HSDD, the antidepressant bupropion, which blocks norepinephrine and dopamine reuptake, was found to significantly improve sexual arousal and orgasm, but not sexual desire (Level 2). In women with SSRI-associated mixed sexual symptoms, 4 weeks of treatment with the addition of bupropion led to a significant increase in self-reported feelings of desire and sexual activity, but no significant effect on sexual thoughts (Level 1). Fibanserin is a 5-HT1A agonist/5-HT2A antagonist and was originally tested as an antidepressant. In an unpublished trial of 333 women with generalized, acquired HSDD, fibanserin showed a significant improvement over placebo on all FSFI domains, sexually satisfying events, and daily diary measures of desire (Level 1).

Centrally acting agents show some promise for targeting low desire in women but published RCTs are required and an evaluation of their safety remains to be studied. GRADE C

2. PHOSPHODIESTERASE INHIBITORS.

In a large study of diagnostically heterogeneous sexually dysfunctional women, 50-100mg sildenafil showed no benefit. In general, the literature has conflicting findings with one study showing benefit dependent upon psychophysiological-measured impairments in sexual arousal. In small studies of women with impaired genital arousal due to spinal cord injury or diabetes there was a significant beneficial effect of sildenafil.

A new approach to the study of efficacy of PDE5-inhibitors is combining this drug with testosterone. The rationale for such an approach is that activation of central sexual mechanisms is necessary for the interpretation of stimuli as sexually inviting. Then these stimuli can produce (behavioral) sexual responses (i.e., an increase in sexual desire and motivation, inducing sexual approach behavior). Activation of central “sexual” mechanisms is a necessary condition for activation of the nitric oxide pathway, which in turn is necessary for a PDE5-inhibitor to be effective. The authors argue that centrally working drugs will increase the sensitivity for sexual stimuli, and may induce a condition required for PDE5-inhibitors to be effective. Color naming latency times in a Stroop test was the measure of preconscious attentional bias for sexual cues. In an initially low-attention group, preconscious attentional bias increased with testosterone, in another initially high-attention group, attentional bias decreased with testosterone. Only in the former group did the combination of 0.5 mg sublingual testosterone (producing high supraphysiological levels) and 10 mg vardenafil cause an improvement in genital response (VPA) and subjective indices of sexual functioning, supporting the idea that testosterone sensitizes the brain, paving the way for vardenafil to be effective. The high dose of testosterone administered in this study limits the generalizability of the findings.

In summary, women with various medical conditions, but not medically healthy women, may have an impaired genital response and may therefore have more to gain from a genital arousal enhancing agent such as a PDE5-inhibitor. Similarly, other briefly studied drugs to augment genital congestion, e.g. l-arginine, prostaglandins, phentolamine are unlikely to benefit healthy women with arousal disorders. PDE5-inhibitors combined with high dose testosterone may have a beneficial effect over placebo in certain groups however, the high dose testosterone requires safety evaluation.

X. MANAGEMENT OF ORGASMIC DISORDER

In their 1997 review, Heiman and Meston concluded that only Directed Masturbation treatment for lifelong orgasmic disorder fulfills the criteria of “well-established” treatment. Directed Masturbation studies for acquired disorder fell within the “probably efficacious” group. This conclusion is still valid. Directed Masturbation in conjunction with sex education, anxiety reduction techniques and CBT remain the main therapeutic tools. No effective pharmacological treatments have been found to date for orgasmic disorder.

Ninety eight women with SSRI-induced FOD were recruited over four years across 7 American treatment centers to an RCT of 50 - 100mg sildenafil. Orgasmic function significantly improved in the treatment group. However, the highly specific inclusion criteria call into question the generalizability of the findings.

In conclusion, there are no significant new data on orgasmic disorder since the 2003 International Consultation except the one published RCT of sildenafil showing positive effects on orgasmic disorder in a highly selective sample of women with SSRI-induced orgasmic disorder. GRADE C

XI. MANAGEMENT OF SEXUAL DYSFUNCTION IN WOMEN WITH ENDOCRINE DISEASE

Recommendations on the management of sexual dysfunction in the context of neurological, renal and psychiatric illness and cancer are addressed in other manuscripts.
Endocrine disorders that alter estrogens and testosterone and precursors variably impact female sexual function. The consequences of hormone therapies in these states, including, hypothalamic amenorrhea, premature ovarian failure, surgical and natural menopause is variable but is indicative of benefits of low dose HT in individual patients. Hormonal therapy for chemically induced estrogen deficiency from selective estrogen receptor modulators (SERMs) and aromatase inhibitors has not been studied.

Hypopituitarism, hyperprolactinemia, thyroid disorders and adrenal insufficiency alter a variety of hormones, each to a variable extent. Data are limited on the effects of therapies with estrogens, testosterone and DHEA in each of these disorders, but they may provide additional model systems for future interventional trials. Studies on the effects of hormonal excess observed in PCOS, hormonally active ovarian or adrenal tumors, congenital adrenal hyperplasia and obesity induced hyperandrogenism do not suggest that excess androgens and/or estrogens per se promote normal or hypersexuality, suggesting an optimal balance of hormonal milieu is critical to normal sexual functioning. Information on the effects of diabetes and metabolic syndrome on female sexual dysfunction suggest that this is a common problem, but no data are available as to interventions to improve metabolic control and subsequent effects on female sexual function. Most importantly, the available literature emphasizes that hormones are only one component of the many factors that contribute to normal sexual function in women.

Conclusions and Recommendations

For hypopituitarism associated with E, T and DHEA deficiency consider ET and T until age of natural menopause, unless medically contraindicated **Grade B**

For hyperprolactinemia, data are lacking on any effect of prolactin on sexual function independent of effects on estrogens. We recommend further studies on effects of hyperprolactinemia and female sexual function **Grade C**

Data are lacking on thyroid dysfunction and sexual function in women and studies are recommended.

The majority of the albeit small clinical trials of DHEA in women with primary or secondary adrenal insufficiency do not show benefits on sexual function so that DHEA is not recommended for women with adrenal insufficiency **Grade A**

Interestingly, case series of women with Androgen Insensitivity Syndrome (genetic XY) show normal sexual function. This represents a model of high estrogen state without any androgen action.

Overweight but not lean women with PCOS have increased incidence of sexual dysfunction. Further research in women with PCOS needed.

Studies on women with sex hormone producing tumors are inconsistent.

Data are limited on sexual function in women with congenital adrenal hyperplasia. We recommend individualized management of signs and symptoms of androgen excess along with psychosexual counseling. **Grade C**

There is an increased incidence of sexual dysfunction in diabetes Type 1 and Type 2 which is strongly linked to comorbid depression. Glycemic control does not correlate with sexual function **Grade B. We recommend screening women with diabetes for sexual dysfunction Grade C**

There is an increased incidence of sexual dysfunction in women with metabolic syndrome. (Level3). This may be due to metabolic, vascular, neurogenic, hormonal and psychological etiologies. We recommend screening women with metabolic syndrome for sexual dysfunction. We also recommend studies of treatment interventions.

**XII. MANAGEMENT OF SEXUAL PAIN DISORDERS**

Sexual pain disorders are heterogeneous, multisystemic and multifactorial disorders. Other pain syndromes may be present. In general treatment should be multimodal taking into account etiological factors, risk profile and context.

Research of psychological function in women with Provoked Vestibulodynia (PVD) – the most prevalent type of sexual pain, has shown an increased prevalence of comorbid psychopathology, specifically depression and anxiety disorders. However, both more problematic and non-affected psychological functioning has been reported. Although this could reflect differences in study samples and instrumentation, it could also indicate true heterogeneity of women with PVD. However, increased trait anxiety, pain catastrophizing, reward dependency and harm avoidance have consistently been found in multiple studies. This may represent a complex of stable characteristics of avoidant, dependent, and obsessive-compulsive personality features which may be etiologically important. Single study findings of women with PVD included elevated rates of shyness, perfectionism, low self-esteem, and negative feelings towards sexual interaction, erotophobia, and problems with subjective sexual arousal and lubrication during sexual interaction with partner, but not during masturbation.

Women with PVD have been found to be more sensitive to thermal, painful and tactile stimulation, reflected in lowered thresholds for sensitivity. An etiological element may be a deficit in information processing, i.e. hypervigilance for pain-related stimuli. These latter findings require replication in future studies.

Women with vaginismus have been found to
have significantly increased comorbid anxiety, but not depressive disorders. The role of childhood sexual trauma is unclear since different frequency rates were found, and the presence of increased rates of posttraumatic stress disorder has not yet been investigated. Psychological characteristics, measured with self-report instruments, only partially lend support to the role of anxiety in the etiology of vaginismus. Personality features found to be more often present in this group include the presence of pain catastrophizing cognitions, disgust propensity, and a specific fear of penile-vaginal penetration.

1. TREATMENT MODALITIES FOR SUBTYPES OF CHRONIC DYS Pareunia

In table 3 the various treatment modalities for subtypes of chronic dyspareunia are outlined. They include chronic pain medications along with sexual and psychological methods.

a) Provoked Vestibulodynia (PVD)

In terms of medical interventions for PVD, there are only three level 2 RCTs. Neither fluconazole nor cromolyn 4% proved to be more effective than placebo. Botulinum toxin injections did not result in significantly greater improvements in pain, sexual function, or sexual distress as compared to a placebo (saline injections); in fact, the placebo group fared better than the botulinum toxin group in terms of sexual distress scores. Other medical interventions with some reported success include capsaicin, ketoconazole, lidocaine/xylocaine, tricyclic antidepressants, duloxetine, venlafaxine, and anticonvulsants - carbamazepine and gabapentin. Grade C/D

b) Vaginal EMG Biofeedback, Pelvic Floor Physical Therapy, (Group) Cognitive Behavioral Therapy, TENS and Vestibulectomy Grade B

Although receiving limited study, pelvic floor EMG biofeedback and physical therapy, Kegel and relaxation exercises, TENS, (group) CBT are clinically useful interventions with long term benefit. Similar benefit is also seen from multilevel local anesthetic nerve blockade and from vestibulectomy in certain (more localized and not lifelong) cases. (Level 2/3)

2. VAGINISMUS

Although ‘vaginismus’ (strictly defined as fear and difficulty with penetration with associated muscle tightening and no physical changes such as allodynia), and PVD often overlap in terms of clinical presentation and may respond to some similar treatment options (e.g., pelvic floor physical therapy, sex therapy), treatment options for vaginismus typically tend to target the muscle tightening over and above the symptom of (feared) pain. As such, the major focus of treatment tends to be vaginal accommodation/dilatation combined with progressive desensitization and a variety of relaxation techniques. Additional components may also be part of the treatment regimen, ranging from sex education to decreasing penetration fear and anxiety.

Some literature on less commonly used adjunct components also exists, and includes educational gynecological examinations, the application of topical anesthetics, pelvic floor biofeedback, botulinum toxin injections, anxiolytic medication and surgical intervention.

Many treatment studies are methodologically unsound. Recently, an RCT (N=117) was conducted comparing group CBT and bibliotherapy for women with lifelong vaginismus, and waiting list. At post-treatment, 14% of treated women were able to experience vaginal penetration as compared to none in the control group. At 12-month follow-up, 21% of the women in the CBT group and 15% of the women in the bibliotherapy group reported successful intercourse. Outcome was predicted by reduced fear of intercourse and avoidance. A recent prospective trial investigated the effectiveness of therapist-aided exposure for lifelong vaginismus. 10 women were evaluated during 24 weeks. During exposure, patients performed vaginal penetration exercises on themselves, in the presence of a female therapist. Nine of 10 participants reported having intercourse after treatment, and in 5 of 9, intercourse was possible within the 1st week of treatment. The results were sustained at 1-year follow-up.

2. MANAGEMENT OF SEXUAL DYSFUNCTION FOR THE WOMAN WITH PREVIOUS CHILD SEXUAL ABUSE

If considered necessary (see previous section), treatment for the sexual trauma should predate any treatment for sexual dysfunction. Therapy should help women understand any possible connections between past and current sexual functioning, particularly in regard to trust and being sexually vulnerable. Important aspects of therapy include:

• Encouragement that women can be in control of their sexual encounters.

• Women learning to be able to mentally and physically relax prior to and while receiving sexual stimulation.

• Women’s recognition that they need only engage in encounters with which they are fully comfortable.

• Helping women to develop verbal and non-verbal communication with their partners to limit further sexual stimulation when they feel overwhelmed, “numb” or fearful.

• Assisting women’s development of relationships where there is a healthy balance of power to minimize feelings of victimization and maximize feelings of control.
**Table 3: Management of Subtypes of Chronic Dyspareunia (continued)**

<table>
<thead>
<tr>
<th>Medical Disorder</th>
<th>Type of dyspareunia</th>
<th>Findings on physical examination</th>
<th>Therapeutic options and general comments</th>
</tr>

<tbody>
<tr>
<td>Vulvovaginal atrophy: associated with menopause, renal failure, hypothalamic or pituitary disease</td>
<td>Introital pain and with penile-vaginal movement. Possible post coital burning. Deeper dyspareunia when vaginal atrophy advanced.</td>
<td>Pallor, dryness, increased fragility and thinning of vulvovaginal epithelium, vaginal shortening, loss of rugae, narrowing, or urethral caruncle.</td>
<td>Local ET is highly recommended: vaginal ring or tablet. Although minimal systemic absorption is possible, there are no reports of adverse effects. Tibolone improves this disorder beyond placebo. Frequent sexual arousal and (if necessary), nonpenetrative activity may promote genital health. Recent trials of vaginal DHEA show promise.</td>
</tr>
<tr>
<td>Chronic (abdominal) pain; Endometriosis; Chronic PID; IBS; Crohn’s disease; Ulcerative colitis; Ovarian tumour; Abdominal wall pain.</td>
<td>Deep dyspareunia. IBS is also associated with introital pain from comorbid VVS.</td>
<td>General tenderness to deep bimanual examination.</td>
<td>Sexual dysfunction is highly prevalent in such patients. Organic disorders should be treated accordingly but sexual dysfunction may still need to be specifically managed. Irrespective of the organic or functional nature of the pain, a history of possible negative sexual experiences should be queried before any procedures or treatment.</td>
</tr>
<tr>
<td>Lower Urinary Tract Symptoms (LUTS) with urinary incontinence.</td>
<td>Introital and deep dyspareunia or vulvar burning after sexual intercourse.</td>
<td>Perineal and vulvar inflammation.</td>
<td>Voiding dysfunction, recurrent bacterial cystitis, hypoactive sexual desire, and sexual pain disorders are highly correlated. For recurrent cystitis give local ET, antibiotic self-treatment or preventative treatment, and recommend postcoital micturition (based on CE). In case of prolapse, surgical treatment can be curative but can also have undesired effects on sexual functioning.</td>
</tr>
<tr>
<td>Pelvic radiation.</td>
<td>Introital and deep dyspareunia.</td>
<td>Thinning and fragility of vaginal epithelium, loss of elasticity, stenosis, or foreshortening.</td>
<td>Preventive measures such as transposition of the ovaries to prevent ovarian failure. Therapeutic options based on CE include couple counselling about non-penetrative sexual activity, topical ET, lubricants, vaginal inserts, and vaginal reconstruction.</td>
</tr>
<tr>
<td>Chronic vulvovaginal candidiasis associated with diabetes and HIV.</td>
<td>Introital dyspareunia and with penile vaginal movement.</td>
<td>Erythema, swelling of vulva, and thick white or pale yellow vaginal discharge.</td>
<td>Oral anti-fungal agents recommended for recurrent symptomatic candidiasis.</td>
</tr>

<tbody>
<tr>
<td><strong>Provoked vestibulodynia (PVD)</strong></td>
<td>Superficial vulvovaginal pain on (attempted) penetration, pain on non-penetrative vulvovaginal touching, postcoital burning, or burning from partner’s ejaculation fluid.</td>
<td>Variable erythema of the vestibule. Allodynia typically located between 4 and 8 o’clock on the introitus, just exterior to the hymenal ring but can involve the skin around the openings of the Skene’s ducts or the whole introital rim. Hypertonic pelvic floor muscles. Pain with attempted digital or speculum entry.</td>
<td>Vaginal EMG biofeedback, pelvic floor physical therapy, (group) CBT, supportive psychotherapy, TENS and vestibulectomy have been shown to have clinical benefit. Based on CE is treatment with topical estrogen, cromolyn, xylcaine, capsacin. Based on CE, and the not yet proven assumption that neuropathic pain is at least in part responsible for the pain of provoked vestibulodynia, give TCAs or AEDs. For comorbid IC, DBPTs have shown benefit of oral or intravesical pentosan polysulfate, intravesical dimethyl sulfoxide or resiniferatoxin (vallinoid). Based on CE, there may also be benefit from antihistamines, quercetin, intravesical heparin, lidocaine, or a combination.</td>
</tr>
<tr>
<td><strong>Generalized vulvodynia.</strong></td>
<td>Introital dyspareunia and pain with penile-vaginal movement. The pain is always/always constant, covers the entire vulvar area, and may or may not be increased upon provocation.</td>
<td>None.</td>
<td>Vulvar burning and pain that causes sexual and psychological distress accompanied by the complete absence of any physical abnormality on examination, in biopsies or culture. Based on CE, TCAs or AEDs can be of partial benefit.</td>
</tr>
<tr>
<td><strong>Female genital mutilation (FGM).</strong></td>
<td>Introital pain and with penile-vaginal movement and deep dyspareunia.</td>
<td>Type I: all or part of the clitoris and its prepuce or skin excised. Type II: clitoris excised, labia minora partially or totally removed. Type III: all external genitalia excised, vaginal opening closed except for a matchtip-sized hole to allow urine and blood to escape.</td>
<td>Experienced by an estimated 130 million women, in particular from north Africa, the middle east, and southeast Asia. Most of the studies do not support the hypothesis that FGM destroys sexual function or precludes enjoyment of sexual relations. Based on CE, use a respectful approach and provide information about health consequences. Offer sexual counselling, psychotherapy, and support groups. Offer to repair the vulva, vagina, or both. Involve the partner, the family, or both in decisions. Clarify the legal and ethical responsibility of the physician, who must decline any request to re-infibulate after childbirth. Offer specific management of sexual dysfunction as needed.</td>
</tr>
</tbody>
</table>
**Table 3: Management of Subtypes of Chronic Dyspareunia (continued)**

<table>
<thead>
<tr>
<th>Medical Disorder</th>
<th>Type of dyspareunia</th>
<th>Findings on physical examination</th>
<th>Therapeutic options and general comments</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Dermatological diseases.</strong></td>
<td>Can be introital dyspareunia (eg. eczema) or deep (eg. lichen planus affecting vagina.)</td>
<td>Benign non-STI: can be atopic eczema, contact dermatitis (including iatrogenic), lichen simplex, lichen planus, psoriasis, hidradenoma, fox- fordycye, chronic vestibular gland infection, pediculosis pubis, pin worm infections, Behçet’s, aphthous ulcers, cicatrical pemphigoid, pyoderma gangrenosum, anorectal Crohn’s, burn, or trauma. STD can be HSV, syphilis, chancroid, lymphogranuloma venereum, granuloma inguinale, condylomata accuminata, or molluscum contagiosum. Neoplasia can be VIN, vulvar Paget’s, or melanoma.</td>
<td>For a benign non-STI, based on CE, give corticosteroids (oral, topical or injectable); immunosuppressive drugs (azathioprine, dapsone, tacrolimus, pimecrolimus, thalidomide, or infliximab); immune augmentation drugs (imiquimod); surgery; behavioural and physical therapy; and biofeedback. Also offer psychosexual support for sexual problems resulting from limited skin contact, visible symptoms, disrupted self-image, inability to meet a partner, shame, lack of confidence, or a combination of these. For treatment options for STI consult Guidelines from ISTI, WHO and CDC USA. Asymptomatic shedding and further infection necessitate strong encouragement of protective measures and safe sex. For neoplasia attempt surgery, laser therapy with radiation, or chemotherapy, as appropriate. Sexual activities do not stop for most couples. Based on CE, psychosexual counselling can be of benefit, in particular in the first year after treatment.</td>
</tr>
<tr>
<td><strong>Anatomical variations.</strong></td>
<td>Introital or deep dyspareunia depending on abnormality.</td>
<td>Labial fusions, rigid hymen, vaginal septum, vaginal agenesis, or hypoplastic vagina.</td>
<td>Based on CE, in case of vaginal agenesis nonsurgical options can be highly successful. Surgical intervention is recommended for imperforate hymen, labial fusions or a painful vaginal septum.</td>
